Scorpionism in South Africa

A report of 42 serious scorpion envenomations

G. J. MÜLLER

Abstract

Forty-two cases of serious scorpion envenomation, of which 4 had a fatal outcome, are presented. The clinical profile, differential diagnosis and management of scorpionism are discussed.

Most envenomations occurred in the summer months, peaking in January and February. An immediate local burning pain was the most prominent symptom. Systemic symptoms and signs developed within 4 hours of the sting in most instances, characterised by general paraesthesia, hyperaesthesia, muscle pain and cramps. Other striking features included dysphagia, dysarthria and sialorrhoea with varying degrees of loss of pharyngeal reflexes. The blood pressure and the temperature were often raised and the tendon reflexes increased, while motor power was often impaired. In a considerable number of patients the course was complicated by varying degrees of respiratory dysfunction, which tended to be more serious in children. The outstanding feature in children was an extreme form of restlessness characterised by excessive neuromuscular activity.

Victims of scorpion sting, particularly in high-risk localities, should be closely observed for 12-24 hours. Children and other high-risk patients should be hospitalised. All patients with symptoms and signs of systemic envenomation should receive antivenom.

Parabuthus granulatus (Hemprich & Ehrenberg, 1828) has been identified as the most important venomous species in the western Cape. The antivenom is produced from the venom of the medically less important P. transvaalicus Purcell, 1899. A strong case can therefore be made for the inclusion of P. granulatus venom in the production of a polyvalent antivenom.

Although serious scorpion envenomations are not as common in South Africa as in certain regions of North Africa, the Middle East, India and North and South America, scorpionism is an important clinical entity in southern Africa and the sting of several local species is potentially lethal. Forty-two cases of serious envenomation, 4 of which had a fatal outcome, are presented and the clinical profile and management of scorpionism is discussed.

Methods

Serious scorpion envenomations dealt with by the Tygerberg Pharmacology and Toxicology Consultation Centre from the summer of 1986/87 to the summer of 1991/92 were included in the series. In order to determine the venomous scorpion species most often responsible for serious envenomations in our region, particular attention was given to the collection of specimens implicated in incidents.

Scorpion sting causing systemic symptoms and signs is considered potentially serious, and the term scorpionism is used to describe this clinical syndrome.

Results

Of the total of 42 serious envenomations, 23 occurred in adults and 19 in children. Twenty-seven patients were treated at Tygerberg Hospital and the remainder in other localities in consultation with the author. The geographical distribution of the scorpion stings is shown in Fig. 1. All but 1 of the envenomations occurred in the spring and summer months from October to March, with a peak of 55% of cases in January and February. Seventy-five per cent of the stings took place in the evening, between sundown and midnight. Although most of the patients were stung outside the home and in the veld, 27% of the victims were stung inside the home. A sting mark was visible in only half of the 38 patients who were able to indicate the site of the sting and in these the surrounding inflammatory reaction was mild or insignificant. Of the 38 patients able to indicate the site of the sting, 28 were stung on the foot and lower leg, 7 on the hand and forearm and 3 on the back.
Prominent symptoms and signs of serious scorpion envenomations documented in this case series are summarised in Fig. 2. In the figure, the data on the children (< 13 years) is separated from that of the older age group because of marked differences in the clinical profiles. Although systemic symptoms and signs developed within 4 hours of the sting in most patients, onset in 4 adult patients was delayed from 4 to 12 hours.

Sixteen patients, 10 children and 6 adults, presented with difficulty in breathing or respiratory distress (Table I). Four of these, all of them children, died. Of the remaining 12 patients, 8 (5 children) required mechanical ventilation, and the mean assisted ventilation time was 2.4 days (range 10 hours - 6 days). One child was intubated to protect his airway but was not ventilated, and 3 adults were treated with mask oxygen only. The arterial blood gas values for 11 of the 12 patients are shown in Table II.

One patient presented with transitory ventricular extrasystoles and another with bradycardia. No abnormalities in cardiac rhythm could be demonstrated on ECG. Blood pressures in the 16 patients who presented with a hypertensive response ranged from 140/90 mmHg to 200/130 mmHg.

An interesting sign, elicited in 6 of the 11 adults with hyperactive tendon reflexes, was a marked prolongation of the relaxation phase of the ankle reflex.

Antivenom was given intramuscularly to 35 patients in an average dose of 10 ml; 22 patients received antivenom within 6 hours of the sting, 11 within 24 hours, 1 after 48 hours and 1 on day 5. None of the patients responded dramatically, as is seen when antivenom is used in the treatment of latrodectism. It was consequently difficult to distinguish between a sponta-
neous resolution and the effect of antivenom. The efficacy of the antivenom was especially questionable in 10 of the 12 survivors who presented with respiratory dysfunction (Table I). No instances of an allergic response to the antivenom or other adverse reactions were reported. Three patients did not receive antivenom owing to a mild form of systemic involvement. The 4 children who died were among the 7 patients who did not receive antivenom. One child died en route to hospital 1/2 hours after being stung; 1 other died suddenly in a small regional hospital 4 hours after envenomation, the 3rd died in hospital during a resuscitation attempt 3 - 4 hours after the incident, and the 4th aspirated stomach contents 1 - 2 hours after being stung, which led to the development of respiratory distress syndrome. She died in an intensive care unit, 2/6 days later, from complications of aspiration.

The results of various laboratory and radiographic investigations, performed on 22 patients who recovered completely, were as follows: 7 patients had a moderately elevated white cell count ranging from 11 to 24 x 10^9/l (the serum electrolyte values of these patients were normal), the blood glucose value was raised in 8 of 13 patients, 4 out of 6 had raised creatine kinase levels, and ECGs performed on 10 were normal. Four of 8 patients who were mechanically ventilated in Tygerberg Hospital showed signs of aspiration pneumonia on the chest radiographs.

Of the 15 scorpion specimens obtained which were responsible for stings, 14 were identified as Parabuthus granulatus and 1 as P. capensis (Hemprich & Ehrenberg, 1828) (Fig. 1). The 14 P. granulatus specimens have been deposited in the national collection of Arachnida (Plant Protection Research Institute, Pretoria) for reference purposes. The specimen identified as P. capensis has been lost and is thus not available for verification.

Discussion

Statistics on the incidence of scorpion sting in South Africa are not available. Although most scorpion stings induce local pain and a slight local inflammatory reaction only, serious envenomations do occur and can be life-threatening. The Tygerberg Pharmacology and Toxicology Consultation Centre is approached for advice on the management of scorpion stings on average 30 - 40 times in a season. Stings in a seasonal context are among small basic proteins (Mr < 8 000), which are the neurotoxins. The neurotoxins act on sodium channels of excitable cells, either by retarding inactivation (a neurotoxin) or enhancing activation (a β-toxin) leading to spontaneous depolarisation of excitable cells. The overall effect is a tendency of the neuron to fire spontaneously and repetitively.3,10 Noradrenaline and acetylcholine are released from adrenergic and cholinergic nerve endings, respectively, and adrenaline is released from the adrenal medulla.2,5,10 These agents may explain the sympathetic, parasympathetic and skeletal muscle effects of scorpion venom.7 Symptoms and signs of increased sympathetic activity include hypertension, tachycardia, cardiac dysrhythmias, increased perspiration, fever, hyperglycaemia and restlessness.2,10 An increase in catecholamine levels has been demonstrated in severe envenomations.7 Hypertension may also be induced by an increase in renin release.10 Reported parasympathetic effects include increased salivation, bradycardia, hypotension and gastric distension.10 Tremors and involuntary movements seen in scorpionism are due to excessive somatic neuromuscular activity.7 Although the muscular weakness, difficulty in breathing and bulbar paralysis could be explained by a phase of neurotransmitter depletion, some other unexplained central mechanisms may well be involved.

The spectrum and degree of symptoms and signs of systemic envenomation is determined by several factors, including the scorpion species involved, the body mass of the victim (children are more vulnerable than adults), the amount of venom injected, and the physical health of the patient.3 The clinical presentation of scorpionism in the under-13-year-old age group differs in many respects from that in the older patient (> 13 years). This could be due in part to a communication problem as well as difficulties in eliciting certain signs in a child presenting with extreme restlessness.

The clinical profile of southern African scorpionism can be described as follows:

The typical victim, barefoot or wearing sandals at the time of the incident, is stung on the foot, after sundown, outside the home. Immediate pain is the most prominent symptom, often described as burning and of an excruciating intensity. The pain lasts for a variable period, usually extending from hours to 1 day and sometimes even longer. It is usually accompanied by local paraesthesia and pronounced hyperaesthesia. In the normal course most adult patients become aware of paraesthesia in the hands and feet within 1 - 4 hours of being stung. Paraesthesia may also be experienced in the scalp, around the mouth or in other areas of the face. Generalised hyperaesthesia, muscle pain and cramps are

The medium-sized Buthus species (30 - 60 mm long) are restricted to Namaqualand and the northern Transvaal. Uroplectes, the smallest and the least toxic of the three genera, is widely distributed throughout South Africa.8

Scorpion venom is injected by means of a stinger located at the tip of the telson, the terminal segment of the 'tail'. The bulbous portion of the telson, also known as the vesicle, contains two venom glands, each with a duct opening on each side near the tip of the stinger.2 During the stinging process, muscles attached to the exoskeleton on each side of the gland contract, injecting the venom through the orifices. In addition, certain species of Parabuthus with large venom vesicles are able to squirt or spray their venom when alarmed suddenly.7

Although variations in the symptoms and signs of scorpion envenomation do occur, the clinical profile of scorpionism is essentially similar in different regions of the world.3 The syndrome primarily reflects a state of generalised neurological hyperexcitability and other excitable tissue, such as skeletal and heart muscle, may also be affected.2,3,9,11 Scorpion venoms are complex, aequous mixtures containing mucus, inorganic salts, low-molecular-weight organic molecules and many different small basic proteins (Mr < 8 000), which are the neurotoxins. The neurotoxins act on sodium channels of excitable cells, either by retarding inactivation (a neurotoxin) or enhancing activation (a β-toxin) leading to spontaneous depolarisation of excitable cells. The overall effect is a tendency of the neuron to fire spontaneously and repetitively.3,10 Noradrenaline and acetylcholine are released from adrenergic and cholinergic nerve endings, respectively, and adrenaline is released from the adrenal medulla.2,5,10 These agents may explain the sympathetic, parasympathetic and skeletal muscle effects of scorpion venom.7 Symptoms and signs of increased sympathetic activity include hypertension, tachycardia, cardiac dysrhythmias, increased perspiration, fever, hyperglycaemia and restlessness.2,10 An increase in catecholamine levels has been demonstrated in severe envenomations.7 Hypertension may also be induced by an increase in renin release.10 Reported parasympathetic effects include increased salivation, bradycardia, hypotension and gastric distension.10 Tremors and involuntary movements seen in scorpionism are due to excessive somatic neuromuscular activity.7 Although the muscular weakness, difficulty in breathing and bulbar paralysis could be explained by a phase of neurotransmitter depletion, some other unexplained central mechanisms may well be involved.

prominent. Every movement and surface contact, such as friction from sheets and bed clothes, causes pain. Some patients describe a sensation of vibration and experience a feeling akin to an electrical current moving through the body, and many complain of difficulty in swallowing and increased salivation. General weakness, reflected in difficulty in walking, is a common symptom. Some patients experience visual disturbances and a substantial number have difficulty breathing.

On examination, the adult patient is anxious and obviously in pain. Tremors and involuntary movements are pronounced. Striking features are dysphagia, dysarthria and drooling with varying degrees of loss of the pharyngeal reflexes. Increased salivation is probably due to bulbar paralysis rather than to parasympathetic stimulation. The mechanism responsible for the bulbar paralysis is difficult to explain. Whether or not the venom has a predilection for the IXth, Xth and XIIth
cranial nerves and their central connections, needs to be explored. The blood pressure and temperature are often raised and the tendon reflexes are hyper-reactive. The relaxation phase of the ankle reflex is occasionally delayed, and clonus may be present. The cause of these is not clear.

There is a general decrease in motor power and if the adult patient is able to walk at all he or she does so ataxically in a gait similar to that seen in alcohol intoxication. Some patients walk in a stiff-legged manner as if to avoid bending their knees. Posis, an increase in perspiration and retention of urine occur in a substantial number of patients.

Although children may present with symptoms and signs similar to those seen in adults, the most outstanding clinical feature is a unique form of restlessness.\(^2\)\(^,\)\(^3\) The restlessness should not simply be interpreted as a reaction to pain but should rather be recognised as a severe form of systemic envenomation. It is characterised by crying and screaming, uncontrolled jerking of the extremities, chaotic thrashing movements, flailing and writhing. The patient is unable to lie still and is difficult to restrain. He or she may assume an unnatural posture and contract the face in a simulated chewing motion, with grimaces and smacking of the lips. The behaviour is completely out of character and abnormal to the extent that those present gather to observe the spectacle. Excessive neuromuscular activity may sometimes be mistaken for convulsions or mimic the central effects of an overdose of neuroleptics, tricyclic antidepressants or anticholinergics. The restlessness caused by scorpionism in children has been described as ‘extraordinary and duplicated by little else in medicine’.\(^\)\(^6\)\(^,\)\(^7\) The smaller child or infant may, however, present with unexplained crying only. The mechanism responsible for the central effects of scorpion venom is difficult to explain. Some authors have suggested that the increase in the concentrations of circulating catecholamines may be responsible, but this is not convincing since these rather polar substances do not readily cross the blood-brain barrier.\(^8\)\(^,\)\(^9\)

Bulbar paralysis, accompanied by respiratory distress, is more frequent in children than in adults and tends to be more severe.

Respiratory failure is the most dangerous feature of severe scorpionism and was probably the primary cause of death in the 4 victims referred to above. In an analysis of blood gases performed in 11 of the 12 survivors with respiratory dysfunction, 3 showed alveolar hypoventilation. They either had muscular weakness or central depression. This impression is supported by a raised partial arterial carbon dioxide pressure (Paco\(_2\)) (range 5.7 - 8.1 kPa). All patients had either low ventilation/perfusion ratios or pulmonary shunts. This is supported by the fact that the alveolar-arterial oxygen tension difference was raised (mean ± SD 11.87 ± 4.42 kPa, \(N = 11\) (Table II). This could be due to aspiration of pharyngeal and oral secretions caused by bulbar paralysis, a decrease in lung volume secondary to a change in chest muscle tone with or without aspiration, or cardiogenic or non-cardiogenic lung oedema. Any of these factors could have contributed to respiratory distress. However, severe cardiovascular manifestations such as cardiac dysrhythmias, pulmonary oedema and cardiac failure, which are often associated with scorpionism in other regions of the world, did not feature prominently in this series.\(^10\)\(^,\)\(^11\)\(^,\)\(^12\) Although a high percentage of patients presented with raised blood pressure, it was not a consistent finding in those with marked respiratory dysfunction. Symptoms and signs of bulbar paralysis did, however, feature in 14 of the 16 patients with respiratory dysfunction (Table I). It would therefore be reasonable to assume that a central neurological mechanism played an important role in the pathogenesis of respiratory failure of these victims.

This series has identified \(P.\) granulatus as being the

most important venomous scorpion species in our region. Fig. 5 depicts the geographical distribution of *P. granulatus* in southern Africa. The importance of *P. granulatus* is further confirmed by 2 case reports unrelated to the present study. A 5-year-old child died 1 hour after being stung by a scorpion which was positively identified by a professional arachnologist as *P. granulatus*, and a preserved specimen involved in another serious incident of envenomation more than a decade ago has recently also been identified as *P. granulatus*.2,3 As already indicated, a single incident with a lethal outcome ascribed to *P. capensis* could not be satisfactorily verified.

The antivenom currently available is produced by the South African Institute for Medical Research from the venom of the medically less important *P. transvaalicus*.4 In view of the questionable efficacy of the existing antivenom experienced in many of our cases, a strong case could be advanced for the inclusion of the venom of *P. granulatus* in the production of a polyvalent antivenom.

The diagnosis of scorpionism can sometimes be difficult in the absence of a firm history of a sting and particularly in children. Conditions which should be considered in a differential diagnosis include the following:

**Spider bite.** Although different mechanisms of action are involved, both scorpion and widow spider venoms (genus: *Latrodectus*) cause an increase in the release of peripheral neurotransmitters, resulting in some similarities between latrodecticism and scorpionism.1 Classic symptoms and signs of scorpionism usually not found in latrodecticism include dysphagia with marked sialorrhoea, difficulty in breathing, visual disturbances and pronounced general hyperaesthesia. Profuse sweating and abdominal muscle rigidity, on the other hand, are much more prominent in latrodecticism. Cytotoxic spider bites are not associated with neurotoxic effects and are therefore not considered in the differential diagnosis.

**Snake bite.** In a substantial number of neurotoxic snake bites, as in scorpion sting, the bite site is either insignificant or cannot be located.5 Both Mamba and Cape Cobra bites can cause visual disturbances, ptosis and dysphagia as well as difficulty in breathing in the early stages of envenomation. Most of the patients will, however, rapidly progress to a state of complete flaccid paralysis within 1 - 4 hours. Although bong adder venom, which is partly neurotoxic, can induce marked ptosis and occasionally dysphagia, other prominent symptoms and signs include complete ophthalmoplegia, and disturbances of smell and taste. A local inflammatory reaction with marked tissue oedema is also typical of bong adder bite.5

**Organophosphate poisoning.** Both organophosphate poisoning and scorpion envenomation can cause a state of anxiety and restlessness, muscular twitching, increased salivation, decrease in motor power, raised blood pressure, tachycardia and respiratory distress. It is possible that an increase in the concentration of acetylcholine in the synaptic cleft, induced by both scorpion venom and organophosphate poisoning, is responsible for many of the similarities.

**Drug overdose.** Neuroleptic drug overdose in children typically presents with confusion, restlessness, slurred speech, dysarthria, difficulty in swallowing, painless spasms, hypertonicity and tremors; however, sialorrhoea, a prominent feature of scorpion sting, is not associated with an overdose of these agents. Other types of drug overdose to be considered in children with restlessness, hyperactivity and abnormal behaviour are the anti-cholinergics and tricyclic antidepressants.5

**Guillain-Barré syndrome.** This syndrome is characterised by a rapid onset of peripheral and cranial nerve dysfunction.6 Both scorpionism and the Guillain-Barré syndrome can present with paraesthesia, decreased motor power, dysphagia, dysarthria, autonomic nervous system dysfunction and respiratory distress. Scorpionism is usually more rapid in onset and resolves within 5 - 7 days.

**Tetanus.** Although tetanus is characterised by pronounced rigidity and reflex muscle spasm, excessive muscular activity of early or milder forms of tetanus could conceivably be confused with those seen in severe scorpionism.6 Both tetanus and scorpionism can present with dysphagia and excessive oropharyngeal secretions, respiratory distress and autonomic nervous system instability characterised by tachycardia, sweating and wide variations in blood pressure.

Other conditions that should be considered in the differential diagnosis include poliomyelitis, botulism, myasthenia gravis, encephalitis, meningitis, subdural haematoma and diphtheria.

**Treatment**

The approach to the management of scorpion sting will be influenced by the body mass and physical health of the victim and the scorpion species involved. Identification of a scorpion down to species level is difficult, however, and can only be accomplished by an expert; the traditional rule of thumb that scorpions with thick tails and slender pedipalps (pincers) are more venomous than those with slender tails and large pedipalps is therefore a more useful guide for the clinician (Fig. 3). Unfortunately the scorpion involved is recovered in only 20 - 30% of cases at best. Another useful guideline is that the more venomous scorpions occur west of a longitudinal line passing through Bloemfontein, and in areas of the northern and north-eastern Transvaal; the chances of a serious scorpion envenomation occurring in Pietermaritzburg or Umtata as opposed to Cape Town or Pletenberg are remote.

A victim of scorpion sting, especially in a high-risk area, should be closely observed for 12 - 24 hours and it is recommended that children and other high-risk patients be hospitalised. All patients with symptoms and signs of systemic envenomation should be given 10 ml of scorpion antivenin intramuscularly. The reduction or loss of upper respiratory protective reflexes and the development of respiratory distress is the most serious complication of scorpionism. Early intervention is necessary to secure and protect the airway and to provide appropriate ventilatory support.7 As scorpion venom induces autonomic nervous system instability, patients with serious envenomations should be closely monitored for the development of cardiac dysrhythmias, severe hypertension, hypotension and pulmonary oedema.8 The use of atropine to reduce secretions is not advisable as this may lead to unopposed adrenergic responses. Intravenous fluid therapy should also be closely supervised to prevent vascular overload.

Children presenting with restlessness should not be given any central nervous system depressants, e.g. opiates or benzodiazepines. These will not only aggravate the respiratory depression but increase the risk of emesis and aspiration. However, sedation may be indicated to allow intubation and ventilation.

The only effective treatment for the local pain is infiltration of the sting site with a local anaesthetic agent. Opiates are relatively ineffective and increase the risk of respiratory depression. Experience with non-steroidal anti-inflammatory agents is also disappointing. Although several authors recommend that crushed ice be applied to the sting site, most patients will not allow this due to the local hyperaesthesia. Intravenous administration of calcium gluconate is moderately effective for the
relief of generalised muscle pain and cramp, but its effect lasts for 20 - 30 minutes only and there is a limit to the amount that can be administered safely.

The routine use of antihistamines and glucocorticosteroids is not recommended unless they are administered to decrease the severity of a possible allergic reaction to the antivenom.

Scorpion antivenom is a refined equine serum globulin and the dose recommended in the package insert is 10 ml intramuscularly.\(^7\) Snake antivenom, on the other hand, which is prepared by a process identical to that used in the production of scorpion antivenom, is given intravenously. It seems, therefore, that there is no real contraindication to the administration of scorpion antivenom intravenously. In view of the disappointing therapeutic response to intramuscular scorpion antivenom and the absence of any valid objection to the administration of scorpion antivenom intravenously, we propose to evaluate the efficacy and safety of sufficiently diluted antivenom by this route in seriously envenomed patients.

This paper forms part of a Ph.D. project registered at the University of Stellenbosch by G. J. Müller.

The contribution by Professor A. R. Coetzee, head of the Department of Anaesthesiology, in the interpretation of blood gas values is gratefully acknowledged. The author is indebted to Dr G. Newlands for his permission to use the distribution maps in Figs 4 and 5, and thanks Dr J. G. L. Strauss, Chief Medical Superintendent of Tygerberg Hospital, for permission to publish.
