Lessons from the hepatoblastoma-familial polyposis connection

S W Moore, N Tshifularo, J J Grobbelaar

Background. Approximately one-third of hepatoblastoma (HB) patients have associated congenital abnormalities, but familial recurrence is rare, except in association with familial adenomatous polyposis (FAP). This correlation may be missed if not actively sought, with implications for long-term outcome and management.

Methods. We retrospectively investigated 3 families with an HB-familial polyposis connection, from a cohort of 113 FAP families (1989 - 2010). Data were analysed to assess clinical problem, treatment, complications and management. Long-term morbidity and functional outcome were analysed to identify management difficulties.

Results. Three FAP families (2.65%) had an HB association. In one case, undiagnosed FAP at the time of HB diagnosis was only detected 5 years later, when the mother presented with advanced colorectal carcinoma. A chromosome 5 APC gene mutation (exon 15 codon 793 C>T) was then identified. In a second case, a non-related boy presented with a stage 4 multifocal HB with lung metastases. Genetic studies identified an APC gene mutation (exon 6 codon 232 C>T). Further family investigation showed >20 related FAP patients. A third HB-FAP association was identified in a known FAP family early in the study, prior to the availability of genetic testing.

Conclusion. Although a rare association, a family history of FAP in HB patients is an important ‘hidden connection’. Germline variation may be outside the usual FAP gene site. Identifying families with unknown HB/FAP is important due to long-term management implications and follow-up.

Hepatoblastoma (HB) is the most common primary liver cancer of childhood, accounting for up to 1% of all paediatric malignancies, particularly in the younger child. HB is associated with congenital abnormalities in approximately one-third of patients, suggesting complex genetic and/or epigenetic factors in its pathogenesis.

In addition to an association with low birth weight, there are several linked genetic diseases including overgrowth syndromes such as Beckwith-Wiedemann syndrome, chromosomally linked conditions (trisomies 2, 8 and 20) and X-linked Simpson-Golabi-Behmel syndrome, type 1 glycogen storage diseases, Li-Fraumeni syndrome, familial adenomatous polyposis (FAP) and type 1 neurofibromatosis.

Familial recurrence of HB is extremely rare outside of associated adenomatous polyposis coli (APC) families, and a causative relationship between HB and interstitial deletions of 5q21.3-q23.3 (the APC gene region) is well known. Consequently, offspring of FAP families have a 750 - 7500 times higher risk of developing HB.

Although 75 - 80% of FAP individuals have APC gene mutations, there is a group with non-typical de novo genetic variation. As a result, the screening of HB patients for APC gene variation in cases of childhood HB without a family HB history remains an open discussion. It appears to be important to identify these high-risk individuals and perform long-term screening to improve their management.

We aimed to investigate HB-FAP gene associations and clinical implications in a South African population.

Case 3
A male infant, born to a known FAP family, was diagnosed and successfully treated for HB early in the study, prior to the availability of genetic testing. The patient never developed further features of FAP and there was no familial recurrence.

Discussion
HB is a well-known embryonal tumour, with recognised genetic associations to several known cancer predisposition syndromes including FAP. Family histories are uncommon in these, with the exception of familial FAP, as shown in this study. The incidence of FAP in association with HB, identified in 3/113 FAP families (2.65%), was lower than a previous report of 8/93 (8.6%) HB families.12

There are several lessons from this study. Firstly, although the genetic links between HB and FAP are well established, it is a reminder to clinicians of this rare, possibly hidden link. Secondly, the clinical identification of associated FAP in our first case benefitted the patient to clinicians of this rare, possibly hidden link. The child, who developed an unsuspected metastatic carcinoma colun 6 years later on the basis of unsuspected FAP. Fourthly, predicting HB susceptibility on the basis of APC mutation has proven difficult, as no significant correlation between the site of mutation detected in those with or without HB has been demonstrated.13 The nature of the HB-associated APC mutations, however, appears variable, as shown in 2 families in this study where the APC mutation sites lay outside the loss-of-heterozygosity (LOH)-associated region for colorectal FAP (i.e. codons 1 251-1 378).14,15 in keeping with previous reports.1,15

From a molecular perspective, these genetic associations may be a more important link than previously thought in understanding the oncogenesis of liver tumours such as HB. Chromosomal variations occur frequently in HB, having been reported in up to 88% of cases in a genome profiling study.16 The most likely candidate genes identified thus far are CTNNB1 (catenin, beta-1-catenin)17 and insulin-like growth factor II (IGF2) tumour suppressor at locus 11p15.18,19 in addition, more than 85% of HBs show accumulation of β-catenin which is unknown, but it suggests that those associated with HB may relate to other sites on the gene.

Understanding the link between HB and FAP may, therefore, be of the utmost importance to patient evaluation and follow-up. Screening for APC gene mutations in infants with HB, although difficult, facilitates genetic counselling and an estimation of risk, owing to an autosomal dominant hereditary pattern.20 We agree that the presence of HB-risk APC mutations justifies HB screening in neonates born to gene carriers.21
