Abstract -- Certain types of PM electric machines are particularly susceptible to the proliferation of eddy currents flowing within the solid conducting regions in the rotor. These eddy currents can be induced by current winding harmonics, but also by the interaction of the static rotor magnetic field with the permeance variation of the slotted stator known as ‘slotting’. This work focuses on the analytical calculation of eddy current loss that occurs in the conducting regions within a rotor under no-load conditions. The results are compared with finite element analysis and measured results from a machine test. Good agreement is achieved between the three methods of comparison.

Index Terms-- permanent magnet, eddy current, losses, slotting, rotor yoke, analytical, finite element.

I. INTRODUCTION

Low speed permanent magnet synchronous machines are becoming an increasingly attractive option for many applications including use in direct drive wind generators. Depending on the machine topology and design, eddy-current induced solid loss in the conductive regions of the rotor can be a source of inefficiency in these machines. A high proportion of the literature in this field [1-10] has focused on the effect of asynchronous field harmonics caused by current in the stator windings. However, another not insignificant group of asynchronous field harmonics exist due to the interaction of the magnetic field due to the magnets, and the permeance variation due to the teeth of the stator, also known as ‘slotting’. This effect of slotting on eddy current rotor losses is often ignored in literature, which is an assumption which will not hold for all design types. An open slot, surface mounted magnet machine configuration can give rise to rotor losses as large as those caused by stator winding harmonics, and therefore, in many cases cannot be ignored.

II. ANALYTICAL MODEL

In order to calculate the no load eddy current spatial function, one must first calculate the magnetic fields due to slotting. For the machine model, a permanent magnet synchronous machine is linearised to create the machine model in the (x,y,z) plane shown in Fig. 1. The co-ordinate axes are fixed to the moving rotor reference frame. A current sheet lies on the stator surface and represents a collection of harmonics present due to the effect of slotting. The no-load magnetic fields consist of two major groups of harmonics. There are those harmonics caused by the rotor’s static magnetic field, which rotate synchronously with the rotor. The second group of harmonics arises due to the interaction of the static rotor fields and the magnetic permeance variation between the slots and teeth in the stator, which rotate asynchronously to the rotor.

The rotor magnetic flux function can be described as:

$$ B_r(x,y) = \sum_{k=1,3,5,...} B_{rem}(y) \cos \left( \frac{k \pi y}{L} \right) $$

(1)

where

$$ B_{rem}(y) = \frac{4r_{mc}B_{rem}}{\pi N_p k} \sin \left( kp \Phi_m \right) $$

(2)

where $r_{mc}$ represents the radius at the magnet centre.

In order for eddy currents to be induced in a conductor, there must be a relative speed between the conduction medium and the field harmonic. The group of harmonics in (1) rotates at a frequency of $2m_w$, which is synchronous with the rotor. However, when this static magnetic field harmonic interacts with the permeance variation in the stator, a new asynchronous set of harmonics is produced.

Fig. 1: The linear machine model shown in the x,y plane.
The permeance variation function is described in [11] in a 2-D model which uses a conformal transformation assuming a unit magnetic potential applied between the rotor and stator surfaces and assumes infinitely deep rectilinear slots. The permeance function is defined as

\[ \lambda(x, y) = \sum_{\mu=0}^{n} A_{\mu}(y) \cos(\mu N_s x) \]  

where

\[ A_{\mu}(y) = \frac{1}{K_c} \left(1 - 1.6 \beta \frac{b_0}{\tau}\right) \]  

\[ \beta(y) = \frac{4}{\pi \mu} \left[ 0.5 + \frac{\left(\frac{b_0}{\tau}\right)^2}{0.78125 - 2\left(\frac{b_0}{\tau}\right)^2} \right] \sin\left(1.6\pi \mu \frac{b_0}{\tau}\right) \]  

and

\[ A_{\mu}(y) = -\beta(y) \frac{4}{\pi \mu} \left[ \frac{1}{2} - \frac{1}{\sqrt{1 + \left(\frac{b_0}{2g}\right)^2}} \right] \]  

As this calculation is only interested in the permeance variation as seen by the rotor surface, the simplified version of the \( \beta(y) \) function is used, where \( \nu = 0 \). Note in (4), the Carter Factor has been used in the definition of the DC permeance variation Fourier coefficient to account for the overall reduction in flux due to slotting. The definition of the Carter factor is:

\[ K_c = \frac{\tau}{\tau - \gamma g} \]  

where

\[ \gamma = \frac{4}{\pi} \frac{b_0}{2g} \tan^{-1}\left(\frac{b_0}{2g}\right) \]  

and

\[ \tau = \frac{2\pi R_s}{N_s} \]  

One quantifies the effect of slotting, given various slotting dimensions, by multiplying the permeance variation function by the static field created by the rotor, as

\[ B_{\text{rotorsurface}}(x, y) = \sum_{\mu=0}^{n} A_{\mu}(y) \cos(\mu N_s x) \]  

\[ \times \sum_{k=1,3,5,...} B_{\text{rem}}(y) \cos\left(\frac{k N_p}{2} x\right) \]  

In order to simulate the machine’s movement, the rotor is defined as the stationary reference frame and the stator is moved at the negative of the rotor speed, i.e.

\[ x_s = x + \omega t, \]  

This gives:

\[ B_{\text{rotorsurface}}(x, y) = \sum_{\mu=0}^{n} \sum_{k=1,3,5,...} A_{\mu}(y) B_{\text{rem}}(y) \cos\left(\frac{\mu N_s}{2} x + \frac{k N_p}{2} x + \mu N_s \omega t\right) \]  

An important highlight from a rotor loss perspective is that each space harmonic is a function of the rotor field and the stator permeance harmonic numbers. These field harmonics operate at frequencies that are asynchronous to the rotor frequency causing them to induce eddy currents. In the sections where magnetic fields in the rotor are computed, the function described by (12) is required to be expressed in terms of magnetic vector potential:

\[ A(x, y) = -\int B_y dx \]  

\[ = -\sum_{\mu=0}^{n} \sum_{k=1,3,5,7,...} A_{\mu}(y) B_{\text{rem}}(y) \sin\left(\frac{\mu N_s}{2} x + \mu N_s \omega t\right) \]  

The expression for the electric field induced in a conductor is defined as the time rate of change of the magnetic vector potential, summed with a \( \text{grad} \) term which is constant in the \((x,y)\) plane, i.e.

\[ E(x, y) = -j\omega A(x, y) + \text{grad} \phi \]  

In this work, currents will be assumed to flow only in the positive and negative \( z \) direction. The current density is computed as

\[ J(x, y) = J_d(x, y) = -j\omega A(x, y) + C \]  

\[ = -j\omega (C_y e^{j \gamma y} + D_y e^{-j \gamma y}) e^{-ax} + C \]  

In a solid conductor, eddy current flow is limited only by the material conductivity. Using the magnetic vector potential, harmonic frequency and conductivity, the total ohmic loss due to heat produced by eddy currents can be calculated by:

\[ P_{\text{ave}} = \frac{l m}{2K} \cdot |J(x, y) \cdot J(x, y)^*| \]  

### III. Results

The 15kW PM synchronous test generator is shown in Fig. 2, with the dimensions listed in Table I. Measurements from this machine provide the magnet and rotor yoke loss...
data that is listed in Table II. The exact method for measuring the magnet and yoke loss is outlined in the Appendix.

The results of the eddy current density in the magnet for a specified machine are shown in Fig. 3. This machine is a permanent magnet machine with 40 solid magnets (poles) and 48 stator slots and a solid rotor yoke and run under no load. The two lines show the eddy current density function in the centre circumference of the solid magnets. The graph shows that an excellent agreement is achieved between the eddy current density values calculated analytically and those calculated using finite element analysis.

The next calculation uses (16) to determine the total losses in the magnets and solid rotor yoke of the machine. The results of this calculation are published in Table II. There is a good agreement between the overall results in the three machines.

### IV. Conclusion

This research proposes a new analytical method of calculating solid loss in conducting regions of a rotor due to the permeance effects of stator slotting. The overall results of the computation method can be regarded as being very accurate in the case of the magnet. It should be noted however, that due to variations in steel saturation, the assumption of constant permeability in steel as set in the analytical model is not ideal. This variation can cause some accuracy loss in the analytical solution of the solid rotor yoke affects the accuracy of the result. The finite element prediction does not suffer from this drawback. Despite this, however, the analytically calculated results are still very usable, and more importantly give very valuable insight into the cause of eddy currents and how it is affected by changing machine parameters.

### V. Appendix

The no load rotor loss measurement is done by comparing the losses in three different PM rotors, which was the subject of another study comparing different types of magnet segmentation. The rotors are identical in geometry, but differ in terms of magnet segmentation and rotor yoke core material as:
- **PM rotor 1**: solid magnets and solid mild steel rotor yoke;
- **PM rotor 2**: partially segmented magnets and solid mild
steel rotor yoke;
PM rotor 3: partially segmented magnets and a laminated rotor yoke.

For each of the three PM rotors the input shaft power, \( P_m \)
and the steady state outer rotor temperature, \( T_{ro} \),
are measured, with the PM machine each time at no load and
driven at a speed of 150 r/min. Assuming no hysteresis loss in
the PM rotor, the first equation for the total rotor eddy
current loss, \( P_{er} \), is given by
\[
P_{er} = P_m - P_{loss},
\]
where \( P_{loss} = P_{fr} + P_{ed} \), i.e. equal to the wind and friction
losses plus the core and winding eddy current losses in the
stator.

In a second equation for \( P_{er} \), Newton’s thermal law of
cooling is considered. In the thermal model two assumptions
are made. Firstly it is assumed that heat transfer takes place
only through convection, thus heat transfer through radiation
is ignored. Secondly, heat transfer to ambient via moving air
in the air gap is ignored. With these two assumptions \( P_{er} \)
can be expressed approximately as
\[
P_{er} = \frac{dQ}{dt} = h_r A_r (T_{ro} - T_a) + h_i A_i (T_{ro} - T_i),
\]
where \( Q \) is the heat energy, \( h_r \) and \( h_i \) are the outer and inner
rotor surface heat transfer coefficients, \( A_r \) and \( A_i \) are the outer
and inner rotor yoke surface areas, \( T_{ro} \) and \( T_i \) are the
measured outer and inner rotor surface temperatures and \( T_a \)
and \( T_i \) are the ambient and stator temperatures respectively.
It was found during measurements that \( T_i \approx T_a \) and that \( T_{ro} \approx T_{ro} \), so that (18) can be simplified as
\[
P_{er} = h_r A_r (T_{ro} - T_a) + h_i A_i (T_{ro} - T_a),
\]
From (17) and (19) three equations can be obtained for the
three PM rotor measurements assuming \( P_{loss} \) stays constant, namely as
\[
P_{m(1)} - P_{loss} = h_r A_r (T_{ro} - T_a) \quad \text{where subscript 1 is PM rotor 1},
P_{m(2)} - P_{loss} = h_r A_r (T_{ro} - T_a) \quad \text{where subscript 2 is PM rotor 2},
P_{m(3)} - P_{loss} = h_r A_r (T_{ro} - T_a) \quad \text{where subscript 3 is PM rotor 3},
\]
where subscripts 1, 2 and 3 refer to PM rotor 1, PM rotor 2 and
PM rotor 3 respectively as described above. From (20) on
average the constants \( P_{loss} \) and \( hA \) can be determined.
With these constants known \( P_{er} \) can be determined by (17)
or (19).
