SUPPORTING CURRICULUM VITAE
DECLARATION

I, the undersigned, hereby confirm that work contained in this dissertation is my own contribution. It has not previously, in its entirety or in part, been submitted at any University for a degree.

DATE
DEDICATION

This thesis recognises the unfailing support of my wife and our two sons Sean Keiran and Wayne Clinton during three decades of still ongoing academic commitment.

It additionally honours the memory of our parents whose selfless sacrifices made possible a professional career.
ACKNOWLEDGEMENTS
Stellenbosch University for the honour bestowed by encouraging continued scientific, academic and intellectual commitment initially as the Honorary Professor of Haematology in 1995. Approximately a decade later to Foundation Professorial Headship of the newly established Division of Clinical Haematology within the Department of Internal Medicine - Faculty of Health Sciences and Tygerberg Academic Hospital.

To mentors, peers and role models is recorded, with the deepest possible respect, gratitude for instilling into me those principles of integrity, dedication, honour and humility that are inviolate in teaching students, training postgraduates and undertaking research. Without these ever-present unique examples no personal or other standards can be judged subjectively or measured objectively.

None of this would have been possible were it not for that first stimulus of basic scientific training that started during the student years. Early growth then nurtured as Clinical Tutorial Registrar at the University of the Witwatersrand in the Department of Internal Medicine by Professor Thomas H Bothwell. It was his uncompromising striving for perfection that has remained a beacon for half a century. Experience was accumulated through the opportunity as Eli Lilly Travelling Scholar and National Institutes of Health Senior Research Bursar to work with Professor Clement A Finch in his Division of Haematology at the University of Washington. There was kindled, at this time, an interest in stem cell physiology and the newly emerging application of these principles to bone marrow transplantation by contact with the legendary Nobel laureate Professor Edward Donnall Thomas and his Seattle team.

A seminal event was the privilege of appointment as Foundation Professor and Head of the new autonomous Department of Haematology at the University of Cape Town and Groote Schuur Hospital. With the recent and successful first human heart transplant by Professor Christiaan Neethling Barnard the environment in the medical school, strongly supported by staff at every level, was optimally conducive to the introduction - and subsequent development - of haematopoietic autologous and allogeneic grafting.
To many associates, and particularly the Haem Team that exists in the original unchanged format of a multidisciplinary group to this very day, belongs much credit for the pride of place that these procedures enjoy currently in this country. The example set by professional nurses, medical laboratory technologists and support staff - whether these were secretarial or janitorial - ensured that over decades one has been kept ever sensitive to the guiding principle – that of remaining a perpetual student.

Sister Lucille Wood as colleague and scientific collaborator over three decades: Mrs Christine Dölling and Miss Natasha Trueman as librarian and typist devoted long hours to cataloguing all the voluminous data and reliably typing the manuscript: sincere thanks to these three research co-workers.

Penultimately special collegial indebtedness to Patrick Bouic for being willing to promote this doctoral dissertation jointly with Stephen Hough. These two distinguished Professors have provided support and carefully considered advice during all phases from concept to submission. They have additionally guided the various stages through amendments required for approval by the protocol evaluation committee chaired by Professor Johann Schneider. This ethos reflects all that is good in a true university system and is unreservedly saluted.

Finally the raison d'être for each and every aspect of this all too short journey will forever remain the courage and fortitude of our patients and their families. These times were often difficult and carried with them great sadness but were balanced in others by modest success. This cumulative experience remains the powerful stimulus to keep alight that quest for new knowledge. It is a fervent hope that those who we serve will derive the benefit they expect from dedicated doctors and nurses in general, haematologists in particular and specifically the transplant community worldwide into whose midst we have the great honour of being accepted.

What greater reward or sense of fulfilment could any individual aspire to?
CHAPTER 1

EXPLANATORY INTRODUCTION
Orientation

An abortive attempt, that involved myself during the nineteen sixties in Johannesburg to allograft a medical student with refractory bone marrow aplasia, failed. This was primarily due to lack of understanding tissue-typing and the fundamental principles defining graft composition as well as recipient conditioning. Subsequently interest in the area was awakened during tenure of a Haematology Fellowship with Professor Clement A Finch at the University of Washington in Seattle as an Eli Lilly travelling scholar and National Institutes of Health senior research bursar. During this period one was privileged to benefit from stimulation and encouragement of the already legendary Professor Edward Donnall Thomas – subsequently Nobel laureate - and his team: an association that remains intact to this day. The opportunity to pursue a systematic study of stem cell immunobiology, as the basis for participation in the rapidly expanding field of transplantation, came about by the honour of appointment as Foundation Professor of Haematology at University of Cape Town and Groote Schuur Hospital. Reciprocally a commitment was given, as the first incumbent, to establish this area as the future direction for the new department. It is also appropriate, and a distinct honour, to acknowledge many distinguished friends and colleagues - both local and international – who to greater or lesser extent shared in this vision.

All those quiet and unobtrusive voices – now as much as then - unhesitatingly promoted this growth point as a realistic long term project. The basis was recognition of the fertile environment created by the first human heart transplant carried out by one of South Africa's greatest sons - Professor Christian Neethling Barnard.

Organisational philosophy

From inception one fundamental scientific principle, reinforced throughout postgraduate training, has been scrupulously adhered to. Thus each individual step logically consecutive, tested and consolidated before embarking on the next segment of the work. For example in vitro and animal studies were completed in the laboratory prior to evaluation in patients. This observation is made only to explain the way in which reports and presentations, peer reviewed en route to publication of outcome in first line journals, are organised in this thesis.
Furthermore it is noted that careful consideration has been given to all the Stellenbosch University policy and procedures for postgraduate students, including those referring to plagiarism, thereby facilitating a declaration that the concepts, experimental design and laboratory as well as human investigations being my own.

**Objective - Title and Scope**

This prospective work, approved by Stellenbosch University Protocol Evaluation Committee, can be somewhat artificially presented in two, but inseparable, components.

The first is participation in global or international transplantation programmes. This ongoing exercise explores the pathophysiology of bone marrow failure by collaborative studies such as those committed to understanding aplasia°. Using this autoimmune model to interactively work within European°-4 and American°6-8 groups constantly aiming to translate progress to our unit. To ensure that growth points actually included South Africa - to seek and have approved - registration of every outcome by sustained audit and accreditation°9. These mechanisms remain unbroken to the present time and underscore compliance with worldwide ethical and research principles.

Simultaneously to define a role for the interventions in haematologic malignancies such as leukaemia°7, lymphoma°8,°11 and myeloma°12,°13,°14 including amyloidosis°3 and wider afield to immunodeficiency and other disease categories including solid tumour oncology.

The second to cultivate a research environment supported, on merit and productivity, by University grants and investigator driven projects within the Medical Research Council as well as the National Cancer Association. The consistent theme remained documentation of haematopoietic recovery coupled with systematic exploration of cellular and humoral phenomena underlying graft failure and the various forms of injury to keratinocytes, enterocytes and biliary endothelium°15,°16,°17.
Methodology required careful selection of a suitable animal model in which to set-up automated blood counting. Thereafter to apply the standardised protocols to quantitative and qualitative characterisation of the mononuclear suspension from harvested marrow ensuring that these could be applied to our patients\textsuperscript{18}. To define, by introducing suitable immunophenotyping, the composition of this population and document long-term colony repopulation potential via clonogenic assay.

Blood and marrow reconstitution was standardised to use two inbred rabbit strains for creation of a model recapitulating the clinical graft-versus-host disease syndrome. Once secure to sequentially explore means for prevention and treatment with external quality control maintained by close interaction with the Basel team\textsuperscript{19}.

Based on preliminary experimental haematology there emerged further collaborative studies with the Swiss documenting benefit for administration of cyclosporin - A to the recipient. The end result was only partially successful. So to further improve outcome established with scientists from Oxford a joint programme to systematically investigate and subsequently describe exposure of the incoming graft \textit{ex vivo} or in-the-bag to the anti-CD 52 Campath series of monoclonal antibodies\textsuperscript{20}.

It is specifically reiterated that each and every step complied with local and international ethical and research guidelines including those from the Declaration of Helsinki. Also, that all patient studies were not only on approved protocols but individuals gave written fully informed consent: a practice still in force.

Experience accumulated over the three decades of consecutively completed, analysed and reported cases was systematically assembled. This imperative defined the success of developing a research group to actively participate in the utilisation of immunoohaematopoietic stem cell transplantation immunology and technology. From modest beginnings, for more than a decade in a solitary centre, there followed dissemination of these procedures throughout the country.
The second unit started with Professor Thomas H Bothwell at the University of Witwatersrand some 15 years after consolidation of the Cape Town programme. Further expansion necessitated establishment of a South African Bone Marrow Registry\textsuperscript{21} to accommodate the needs for location and recovery of grafts from matched-unrelated volunteers\textsuperscript{20,21,22}. Ongoing activity explores and extends the scope with a shift in emphasis from replacement to restorative medicine\textsuperscript{23}.

Concurrently to encourage endeavours in countrywide cooperation by activity reporting\textsuperscript{24}. This goal is envisaged as a first move to generating national collaborative clinical trials. These would have the importance of taking into account particular constraints existing in under resourced facilities with the compounding unique challenges of an escalating Acquired Immune Deficiency Syndrome epidemic\textsuperscript{25,26,27}.

\textit{South Africa in context of the first world – 1970 scenario}

Throughout this country eminent physicians practised haematology with the discipline located primarily in service pathology laboratories. One consequence was that local knowledge was not collected and published so that a reliable database could not exist. Understandably there resulted a general under-appreciation of the way in which more structured departments, that inseparably linked clinical and pathology components including immunology with blood transfusion technology\textsuperscript{28,29}, were evolving. Thus little uniformity existed about how well recognised and often lethal entities, with the prototype being bone marrow failure described as severe acute aplastic anaemia, were diagnosed and much less treated! There were areas of considerable expertise exemplified by nutritional anaemia studied by Professor Jack Brock and his associates at the University of Cape Town, iron metabolism and vitamin B\textsubscript{12} with Professor Thomas H Bothwell and Professor Jack Metz respectively in Johannesburg, platelet physiology and pathology in Bloemfontein. Additionally had been the very successful integration of all these aspects under the broad ambit of haematology by Professor Harry Greig in Durban. However, strikingly lacking from this landscape, was any cohesive effort to bring together those components needed for stem cell transplantation.
Additionally there was the unusual situation where many of the haematologic malignancies such as lymphoma and myeloma were treated primarily in radiotherapy without the benefit of strong multidisciplinary or combined clinics. The challenge was to harness these vibrant pockets of expertise\textsuperscript{30,31,32} having many quite different ideologies and forge a new dispensation focusing on stem cell biology. Many individuals shared in getting to this goal and these contributions recently paid tribute to\textsuperscript{33}.

**Professor Edward Donnall Thomas and the Seattle connection**

The above situation was highlighted during haematology fellowship with Professor Clement A Finch at the University of Washington that brought one into contact with the new and stimulating concept of bone marrow transplantation. The focal point was a team led by the already legendary Dr Edward Donnall Thomas — subsequently Nobel laureate — that had developed a sound understanding of how blood forming stem cells could be transferred between donor and recipient using a canine model\textsuperscript{34-36}. Concurrent technology was expanded through the use of continuous flow blood fraction separation, exploration of the cellular content and function of the harvested marrow\textsuperscript{37} with definition of the stem cell immuno-phenotypically using flow cytometry. The indications for these procedures emerged from two landmark publications in the New England Journal of Medicine so that clinical bone marrow transplantation started to attract ever-increasing worldwide recognition of its value\textsuperscript{34-38}. At the same time the unwanted consequences of the immunologic attack on a number of recipient organs and tissues, ranging from graft rejection to the dreaded entity of acute and chronic graft-versus-host disease, became recognised\textsuperscript{39,40}.

Early on complications of marrow harvesting from the donor became a focus of attention and comment on an all too frequently overlooked somewhat prophetic analysis\textsuperscript{41}. The enormity of the side-effects in the patient started to draw attention to the importance of quality of life and appreciation, it is interesting that survivorship was already an emerging consideration\textsuperscript{42-43}. It was into this worldwide transplantation community that one ventured recognising not only the value of a multidisciplinary approach but, specifically, how important and privileged it would be to have a chance of participating in existing registries with access to knowledge available from collaborative studies.
Many of these possibilities came to fruition with the great honour conferred by appointment as Foundation Professor of Haematology at the University of Cape Town. It was now possible to commit the new Department in the Faculty of Medicine to the experimental studies and project subsequent translational research calculated to responsibly move these procedures into clinical practice.

It is a matter of further privilege that, throughout these years, one has enjoyed the constant and personal encouragement of Professor Edward Donnall Thomas and the team at the Fred Hutchinson Cancer centre at the University of Washington. This is affectionately referred to as the Seattle connection and remains active at the present time.

*International collaboration over three decades*

From the earliest days of exploring the unique characteristics of the immunohaematopoietic stem cell two priorities were evident.

One was a need to capitalise on clues from cytomorphologic characteristics of tumour cells and, to this end, chance to participate in the lymphoma classification project in association with Professor James Armitage in the medical centre at Omaha Nebraska. This has had three important influences over the last 20 or more years. Thus there has been a constant and ready contact with one of the most distinguished and active transplantation groups in the world. Another to share in a series of collaborative investigations exploring geographical differences in the lymphomas and this is actively ongoing, including exchange and training programs for PhD students at that centre. A third to critically access to the particular expertise in the management and harvesting of these populations in general but with particular focus on the subsequent utilisation as an integral component of treating tumours of the lymphoreticular or immune system. This lively exchange of information is reflected in 25 years of collaborative existence of the South African Lymphoma Study Group.

The other was an acute awareness that accountability for every consecutive patient treated, including outcome analysis, mandatory in the maintenance of credibility and standards.
The privilege of participation in the lymphoma group of the European Organisation for Research and Treatment in Cancer has, to this day, maintained a critical reference point for protocol management. Recently these activities have been enhanced by interaction with the German Hodgkin Study Group culminating in the first joint meeting. To maintain the transplant focus there is active involvement with the European Group for Blood and Marrow Transplantation in both the chronic leukaemia and the acute leukaemia working parties. In this latter cooperation it is notable that this remains the only team listed as a transplant centre in this country.

As part of this broadly based and innovative landscape to maintain close relationships with other study groups in order that the perspective for all these procedures can be balanced against alternative treatment options. Thus association with the Myeloma Trialists Collaborative Group as well as the International Myeloma Working Group have proven valuable in this role.

*Local research and development in the corresponding period*

The historical and scientific perspectives spanning 35 years of prospective and structured research, where one project was the building block for the next stage, are a matter of record and the basis for this doctoral dissertation.

BONE MARROW FAILURE:
PATHOPHYSIOLOGY AND
MANAGEMENT

Peter Jacobs, MD, PhD
Department of Haematology
Wynberg Hospital
Cape Town, South Africa

Mosby
A Times Mirror Company
FOREWORD

The past 25 years has seen tremendous growth in our understanding of the way in which bone marrow performs. Hematologists have made great strides toward elucidating the cause of many bone marrow disorders, allowing the development of more appropriate therapy. And, of course, the last 25 years has seen the development and refinement of bone marrow transplantation, which for the first time has allowed us to cure some of these patients. Professor Peter Jacobs has long been on the cutting edge of this exciting specialty. In the current issue of Disease-A-Month, Dr. Jacobs provides us with a comprehensive view of the hematologic issues involved in bone marrow failure. His ability to translate the findings of experimental hematology into understandable concepts and to translate the relevancy of these concepts as well has gained Dr. Jacobs a worldwide reputation. I know that you will refer to the current issue again and again in your practice. We are fortunate to be the recipients of Professor Jacobs' expertise.

Roger C. Bone M.D.
Editor
BONE MARROW FAILURE:
PATHOPHYSIOLOGY AND MANAGEMENT

ABSTRACT.—Morphologically, bone marrow is made up of a relatively mature but heterogeneous population, fueled by a tiny pool of microscopically unrecognizable stem and progenitor cells. This complex tissue has the responsibility of maintaining our hematopoietic and, to a large extent, immunologic integrity, both of which are indispensable for health and, indeed, survival. Perhaps not surprisingly, bone marrow is the target of genetic, autoimmune, and environmental insults. Although robust, it has only a limited number of responses, one of which is reduction in cellular output, sometimes with superimposed qualitative abnormalities, and this is defined as bone marrow failure.

Bone marrow failure is a diverse entity but can be logically explained and classified on a pathophysiologic basis. Thus the major recognizable categories of bone marrow failure are congenital and acquired defects. Each of these is subdivided according to the number of cell lines involved, over and above which the severity of the damage will determine reversibility. In each case, the natural history dictates management, and this ranges from short-term growth factor support to biologic immune response modulation and finally to bone marrow transplantation.

In the past, many clinicopathologic variants of bone marrow failure were described, although their etiology was obscure and effective therapy was unavailable. This changed dramatically, however, when experimental hematologists, using radiobiology models, uncovered the dynamic nature of blood formation. Cardinal observations included the way in which spontaneous recovery followed irradiation, the central role played by pluripotent stem cells, and the integral participation of stroma in modulating this entire process. Understanding was refined once bone marrow cultures became available while, in parallel, the use of inbred mouse strains launched the era of allogeneic transplantation.

These approaches were combined, and the broad principles that govern basal or constitutive production emerged. Stem cells, with their characteristic commitment to self-renewal, exist at the apex of a hierarchy and generate a tier of proliferating progenitors that, in turn, give rise to a large postmitotic compartment of precursors that mature into distinctive myeloid and lymphoid lineages. The reserve potential is enormous, and output can be induced to meet even greatly increased demands. These events reflect the interaction of growth factors with a balancing set of negative regulators. The link between such diverse functions resides, to a large extent, in accessory cells and matrix geographically organized in what is now described as the hematopoietic inductive microenvironment.

Many details of these meticulously orchestrated processes are obscure. For example, how are adhesion proteins, expressed on vascular endothelium, subtly altered to facilitate release of mature cells into the circulation? Enigmatic also is the way in which membrane antigens change during recovery from chemotherapy or in response to growth factors, so that early progenitors flood the circulation and can be collected for subsequent autografting.

In spite of our newfound knowledge, patient management is often empiric. To illustrate this point, consider the inherited Josephs—Diamond—Blackfan anemia or global aplasia described by Fanconi, in which undoubted benefit—indeed cure—is possible with the nonselective transplantation of marrow. Our understanding of this process is rather crude and is a far cry from the exquisite specificity with which a solitary molecular defect, once defined, can be repaired using gene therapy.

Patients with acquired lesions are little better off. Some, such as those with idiopathic pure red cell aplasia, enjoy spontaneous remission, whereas others require varying degrees of pharmacologic immunosuppression. Perhaps more frustrating are the many cases of unexplained loss of hematopoietic tissue. It has been suggested that such individuals have a genetically fragile marrow that collapses when subjected to...
a relatively minor environmental insult and that possibly the collapse is acting through an immunologic mechanism. For want of a precise molecular diagnosis, the same relatively unsophisticated therapeutic approaches are used in these patients, albeit with substantial success. In this context, allogeneic transplantation is limited by rejection, whereas stable engraftment may be hampered by the not insignificant incidences of morbidity and mortality that result from graft-versus-host disease. Unfortunately, even this option is not always available, and alternatives such as antilymphocyte globulin, which do bring about quantitative responses, may be followed by the later development of myelodyplasia or acute leukemia. These obvious shortcomings prompted investigators to study closely the convoluted trail that leads back to faulty DNA to allow more exact intervention.

Against this background, there arises the question of how to structure a pragmatic and relatively uniform approach to the care of patients with bone marrow failure. Logically, treatment modalities should center on the currently understood model of hematopoiesis, in which lesions can arise in early stem cells, resulting in aplasia. This is in contrast to the damage of already committed progenitors in which, at least initially, single lineages are affected. Within each category, the defect may be inherited or acquired. Approached pathophysiologically, an algorithm for treatment evolves naturally and advocates simple support for those in whom spontaneous recovery is predicted, although this increasingly incorporates the use of recombinant human growth factors or interleukins, which are often given together. For irreversible damage, bone marrow transplantation is currently the treatment of choice. If this option is lacking, immunosuppressive regimens are effective, with the caveat that complications must be anticipated. The future is somewhat brighter, with the promise that more precise molecular diagnosis is, in many cases, well within our grasp. Armed with such vital information, gene therapy becomes a realistic possibility; precedent already exists in which adenosine deaminase deficiency, an otherwise lethal immunologic disorder, can be precisely corrected.

IN BRIEF

Like so many things in life, health is largely taken for granted, and this includes having normal blood, with its impressive range of functions. Consequently, bone marrow failure is a traumatic event, reflected in diverse clinical and hematologic syndromes. In some cases, bone marrow failure is inherited and is present in childhood, as opposed to acquired variants, which usually manifest in later years. In both situations, red and white cells, or platelets, may be reduced singly or in combination, often with superimposed qualitative abnormalities. Symptoms of one or the other cytopenia are common, so that relevant investigation and rational management require an appreciation of the etiology and natural history of cytopenia. A minority of patients recover spontaneously, although more typically, there is relentless progression, often extending to previously uninvolved lineages and leading to substantial morbidity and mortality.

The paradigm is severe acute aplastic anemia. This is a semantically incorrect synonym for global marrow failure but, nevertheless, is a suitable point from which to chronicle those many dynamic events concealed behind the bland histology of the trephine biopsy. Microscopically, we recognize only the mature precursors, whereas the hematopoietic stem and progenitor cells from which the mature precursors arise are nondescript. Furthermore, and for far too long, the complex microenvironment in which blood formation takes place was assigned a subsidiary role, being largely conceived of as providing mechanical support alone. All this has changed with the appreciation that these two populations are inextricably linked through an ever-widening range of growth-facilitating peptides that maintain physiologic or constitutive levels of production, which can, in times of need, be induced to expand dramatically. The balance necessary to meet homeostatic demand precisely for any one or all lineages is meticulously orchestrated by swift and highly selective responses to a series of stimulatory or inhibitory molecules. These ligands attach to cell-surface receptors that, once activated, transduce their signals rapidly through substrates in the cytoplasm to the nucleus, with the terminal one in the chain being described as a transcription factor. These, in turn, switch on or off genes that initiate responses as divergent as entering the cell cycle to proliferate to being diverted to programmed death, the other name for which is apoptosis.

In the last 25 years, such ‘new’ hematologic has spawned a whole new terminology and is, at first sight, daunting and appears remote from patient care. Nothing could be further from the truth. Understanding these principles has increased the basis for management. Unfortunately, current approaches are relatively crude, ranging from the administration of recombinant growth factors to bone
marrow transplantation. Nevertheless, it is from here that gene manipulation and insertional therapy, with their exquisite specificity, are likely to accelerate our understanding and improve patient outcome in the immediate future.

A historical perspective on bone marrow failure is provided by the observation that death in animals undergoing lethal radiotherapy was prevented either by seeding the animal with hematopoietic tissue or when autologous reconstitution took place from a shielded femur or spleen, thus establishing the existence and migratory nature of a multipotential stem cell. At the same time, tolerance by the recipient to donor marrow was systematically explored using total body irradiation and immunosuppressive drugs. This culminated in the monumental studies by Dr. Thomas and his associates at Cooperstown, who showed the feasibility of allografting and autologous transplantation with cryopreserved cells, but who provided the insightful caveat that graft-versus-host disease would emerge as a formidable problem. Predictably, early experience was discouraging because the significance of matching at the major histocompatibility complex was not yet appreciated. Nevertheless, the stage was set, and the first successful procedures were performed approximately 25 years ago in children with immunodeficiency, and immediately thereafter, the procedure was successful also in patients with acute leukemia. Currently, this procedure is the preferred form of management for many diseases and, notably, for bone marrow failure. It is the culmination of these experimental and clinical studies, supplemented by experience derived from clonogenic and long-term culture studies, coupled with the availability of recombinant growth factors, that has led to our present understanding of cellular output.

Blood production is achieved through a continuum of events, but it is convenient to consider those steps that transform unrecognized ancestors into a variety of mature progeny. On this basis, the pathogenesis, natural history, classification, and management of rather different disorders that are broadly grouped together as bone marrow failure are described.

Stem cells are heterogeneous, but they are functionally defined by an ability to sustain comprehensive lymphohematopoiesis. Their first division initiates the process of differentiation, contributing a daughter to maintain the integrity of this compartment and a progenitor that has lineage commitment and proliferative potential but with a reduced marrow repopulating capacity. Stem cells can be studied in a variety of culture systems, but none of these reliably reproduces the conditions that prevail in the intact bone marrow, and they are therefore inadequate to provide precise characterization. Morphologically, the stem cells bear a close resemblance to small lymphocytes, with typical expression of the CD34 antigen. An additional marker is the intensity of staining with dyes such as rhodamine B.

However, probably because of the low frequency with which they normally exist, the goal of isolating stem cells in large enough numbers for clinical use is, at present, tantalizingly just out of reach.

Growth factors initially attracted attention as stimulatory peptides. However, and predictably, molecules that exert the opposite effect on hematopoiesis, exemplified by the tumor necrosis factor, have since been identified and designated as negative regulators. Homeostasis is maintained by ligands in both categories attaching to their cognate transmembrane receptors, which, in turn, serially alter with the degree of differentiation. Such engagement is followed by a series of cytoplasmic events cascading down incompletely characterized pathways to transduce the external signal toward the nucleus. These events culminate in the generation of molecules or transcription factors that have a particular configuration or motif whereby they attach to specific genes whose function they then modify. As a result, cellular response appropriately ranges from entering the cycle to proliferate, mature, alter its function, or undergo cell death—all in accordance with basal requirements or as an adaptation to environmental stress.

The inductive microenvironment finally came into its own after cross-transplantation studies between inbred mouse strains that have a common phenotype of refractory anemia, absence of mast cells, and changes in skin color. These studies established that mutations involving quite different genes had the same result. In one, the product of the c-kit oncogene was not expressed, but the hematologic defect could be corrected by providing its normal counterpart. In the other, a mutation at the Steel locus prevented synthesis of the stem cell factor, resulting in a microenvironment that was incapable of supporting hematopoiesis. This type of complex interaction could not be unraveled in vivo, but with the availability of long-term cultures, it became clear that there exists a major network of accessory cells, ranging from adipocytes to vascular endothelium, and these synthesize a vast array of metabolically active products, many of which are stored or presented in an associated extracellular matrix. Conceptually, niches are present as highly specialized microgeographical areas, where adhesion molecules facilitate binding and correct alignment between stroma and progenitors. Although simplified, it is clear that these three major components constitute a single functional unit charged with the physiologic regulation of blood formation, and understanding this is helpful in our consideration of the syndrome of bone marrow failure.

Inherited defects may remain confined to a single lineage, as in Josephs-Diamond-Blackfan anemia and Kostmann's neutropenia. Alternatively, they may evolve, giving rise to global damage. White cells are affected initially in the Swachman-Diamond syndrome, and reticular dysgenesis occur or platelets are affected in those with
amegakaryocytic thrombocytopenia with absent radii. Conversely, all
the elements may be simultaneously lost in autosomal recessive aplas-
ia or its Esten–Dameshek variant. A similar sequence occurs in pa-
tients with dyskeratosis congenita. In the first example, as originally
described by Fanconi, there are distinctive clinical features and char-
acteristic chromosomal breakage, which is thought to reflect homozy-
gosity for genes giving rise to bone marrow failure. An interesting pos-
tulate is that the heterozygous state may predispose patients to he-
matopoietic failure after minimal superimposed environmental in-
sult.6

Acquired lesions are often reversible, resulting from exposure to a
variety of drugs and toxins and, although immune mechanisms have
been incriminated, most cases remain unexplained. Unfortunately,
and with surprising frequency, a previously healthy individual may
develop idiopathic pancytopenia as a result of irreversible loss of mar-
row precursors; we recognize this entity as severe acute aplastic ane-
mia. However, this is a misnomer because loss of red cells is but one
component of the much more widespread pathology.

A sensible algorithm when confronted by a patient with single or
multilineage cytopenia, particularly when it is severe and irrespec-
tive of symptoms, is to ensure that an accurate and, if possible, etio-
logic diagnosis is established immediately. This will depend on a me-
ticulously taken history to uncover both similar examples in the pa-
tient’s family and any exposure to drugs, toxins, or medications and
is followed by a careful physical assessment. Full blood count is fol-
lowed by bone marrow examination that should include cytogenetic
and, where appropriate, specialized culture studies. It is mandatory
to recognize and withdraw offending myelotoxic agents and treat as-
associated medical conditions.

The natural history of the disorder will determine outcome. How-
ever, because this cannot always be predicted, there is much to rec-
ommend early referral to an experienced multidisciplinary manage-
ment team so that the appropriate level of supportive care can be
provided until spontaneous remission takes place and the danger is
past. All too frequently, lack of judgment leads to well-intentioned
under or overtreatment, both of which have avoidable complica-
tions.

Irreversible aplasia is a particular problem that should be identi-
fied swiftly to avoid sensitization by transfusion of blood and related
products. Compatible sibling bone marrow transplantation is the
treatment of choice. Lack of a suitable donor is an indication for bi-
ologic immune response modulation or immunosuppressive regi-
ments, although both produce variable responses, and long-term out-
come remains uncertain. For this reason, recourse to family mem-
bers or matched unrelated marrow grafts, using the services of inter-
national registries, is an expanding option.

In the short term, refinements in allogeneic transplantation are
needed to reduce rejection and abolish graft-versus-host disease. To
this end, increasing the purity and yield of stem cells, exploring um-
bilical cord blood as an alternative source, and expanding stem cells
in suspension culture using ex vivo methods and stimulating them
with a variety of growth factors are clinical realities. In the longer run,
hope rests on the application of cellular and molecular biologic tech-
niques to identify individual defects that would then become ame-
nable to specific correction through gene transfer. Advances in these
areas have been impressive, and with the ever-increasing rate at
which DNA technology is being translated into the clinic, we hope
that the next decade will see definitive diagnosis and cure emerge
for many of our patients with bone marrow failure.
Peter Jacobs was educated at Prince Edward School in Salisbury, Southern Rhodesia. He then spent 6 years as a medical laboratory technologist before beginning to study medicine at the University of the Witwatersrand in Johannesburg, where he won a number of scholarships and graduated with class medals in medicine and surgery. From an early stage, Dr. Jacobs was attracted to research and studied iron metabolism as a Council for Scientific and Industrial Research bursar. He received both Eli Lilly and NIH Fellowships from the University of Washington, where he also served as Director of the Division of Hematology in the Department of Laboratory Medicine. During this period, Dr. Jacobs' area of interest shifted to the study of hematopoiesis under the influence of Dr. E. Donnell Thomas and his bone marrow transplantation group. Shortly after returning to South Africa, Dr. Jacobs was appointed Foundation Professor of Haematology at the University of Cape Town. During the last 25 years he has directed a team that continues to study systematically different aspects of hematologic malignancy and bone marrow failure, using clonogenic assays, long-term culture systems and, increasingly, cytogenetic, cellular, and molecular biologic techniques. From this laboratory base, multidisciplinary management strategies have been developed that encompass the use of hematopoietic growth factors, allogeneic transplantation, and autografting with stem cells derived from marrow or peripheral blood stem. Dr. Jacobs is a Fellow of the American College of Physicians, the College of Medicine of South Africa, the Royal College of Physicians, the Royal College of Pathologists, and the Royal Society of South Africa. He is a member of numerous other distinguished scientific groups as well and serves on the editorial boards of several international journals. He has traveled widely as a visiting professor.

BONE MARROW FAILURE: PATHOPHYSIOLOGY AND MANAGEMENT

THE PHYSIOLOGY OF HEMATOPOIESIS

INTRODUCTION

Students at all levels, including hematologists, have their first real contact with medicine in the time-honored courses of gross anatomy and physiology. Microscopy is then used to disclose the way in which cells are arranged into tissues, and minute detail is revealed ultrastructurally. These inert sections on slide preparations are brought to life by showing how their component enzymes and proteins function biochemically. In recent years, technological advances have unraveled many interactions, and the modern graduate is increasingly concerned with molecular regulating mechanisms, such as those for growth and apoptosis; the latter is known as programmed cell death.

These observations apply equally to the hematopoietic system, which, understandably and for many years, was described largely in terms of increases or decreases in recognizable mature elements in the blood or bone marrow. This began to change more than 20 years ago when the dynamic nature and output of this organ, which is approximately the size of the liver, was elegantly restated (Fig. 1). Tantalizing questions arose about its potential capacity to respond to bodily needs for each of the major cell types, a visionary role for the vasculature was postulated, and the existence of chemotactic signals was anticipated as the mechanism for cell release into the peripheral circulation. Once radioactive isotopes became available, it was possible both to image and to study kinetic events, making it possible to understand better the changes shown in the trephine biopsy and what they meant in functional terms.

Almost immediately, bone marrow failure, which was already recognized as an important topic in clinical medicine, came under intense scrutiny, with etiologic classification being linked to pathogenesis. Further insights into physiology and its disturbances were gained from carefully conducted experiments in animal models, including seminal studies of syngeneic and allogeneic transplantation. Subsequently, the availability of clonogenic assays brought new in-
FIG 1. In lymphohematopoiesis, a small population of stem cells divide. This pool is sustained while contributing a progenitor that has a lesser capacity for self-renewal but that increases lineage commitment. The major characteristic of this progenitor is proliferation.

sight into the response of early progenitors to growth factors, and long-term marrow cultures revealed the vital interdependence between these cells and the supporting microenvironment or stroma. Molecular biologic techniques are showing the way in which stimulatory or inhibitory molecules react with membrane receptors and initiate signals that are transduced to the nucleus and activate genes whose products bring about the specific homeostatic function required.

From this physiologic basis has grown an appreciation that hematopoietic failure can result from constitutional defects, whereas similar syndromes may be acquired through environmental injury acting in isolation or perhaps as a second insult in a genetically predisposed individual. Furthermore, there is greater awareness that in any situation, qualitative deficiencies may be superimposed on these quantitative changes, although the latter are generally easier to detect.

Perhaps predictably, a whole new terminology has evolved to describe modern-day understanding of blood formation. This lexicon can be confusing and at first sight so daunting that many clinicians shun away from the topic, believing that such minutiae can have little direct application to their practice. Nothing could be further from the truth. Indeed, there is an ever-increasing translation of experimental results into the more rational management of patients with marrow failure. The latter entity is surprisingly common, so that one or another variant is likely to be encountered, not infrequently, by the pediatrician, general practitioner, or primary care physician. Thus it is important that the mystique still surrounding this rapidly evolving area be dispelled by describing, in simple terms, a model that links these various phenomena. It will then be easier to appreciate etiologic mechanisms and anticipate the natural history as a basis for selecting appropriate therapy. Notwithstanding such an approach, treatment often remains empirical, ranging from the administration of recombinant human growth factors through immunosuppression to allogeneic grafting.

The challenge for this monograph is threefold. The first part of the challenge is to assemble what is currently known about the anatomy and physiology that regulate marrow output. The second challenge is to provide a practical approach to the classification of the syndromes that are of clinical importance. Finally, the last challenge is to consider the mechanisms that underlie the failure of the bone marrow to meet homeostatic requirements as a basis for contemporary management.

OVERVIEW OF THE HEMATOPOIETIC SYSTEM

Histogenetically, fusion of sperm and ovm result in a totipotential stem cell, from which, during development, different organs evolve through their own unique pluripotential counterparts. The untold steps en route to the recognizable embryo, although many continue to attract attention, remain shrouded in mystery. Some glimpses into the complexity of achieving a defined form are reflected in the examination of the Drosophila species, in which homeotic genes control the sequential assembly of body segments in a way that is probably analogous to what occurs in humans. Thus morphologically recognizable blood islands appear first in the yolk sac and move transiently to the liver and spleen, eventually localizing to the medullary cavities of the skeleton.

The details of how this migratory pattern is controlled are uncertain, but precedent from the fruit fly suggests a central role for homeobox genes that additionally encode transcription factors for many hematopoietic functions, including immunoglobulin synthesis and lineage commitment. These, like traditional oncogenes, are clearly crucial for normal organogenesis, but dysregulation through translocations has profound effects, including the development of tumors or leukemia. Precisely how these events result in neoplasia, with the characteristic uncoupling among differentiation, proliferation, and
maturation, is not clear because there are normally check points on intracellular events, such as cell cycling. For example, control exists at both the G1 to S transition and also at entry to mitosis, with the enzymatic activity of the regulatory protein kinases vested in cofactors, known as cyclins because of the way in which their concentrations rise and fall throughout this event. What does emerge, however, is that from fertilization to delivery, each step in the development of the blood-forming system is genetically determined, and many of the same mechanisms continue to operate throughout life. It follows that disruption or imbalance of these modulators may predispose or actually lead to syndromes at the opposite end of the spectrum—bone marrow failure or hematologic malignancy.

Anatomically, the marrow, when seen in histologic section, is deceptively simple, with its high level of activity difficult—even impossible—to appreciate. At this level, prominent features are the bony trabeculae with their associated osteoblasts and osteoclasts, blood vessels that vary in size, and accessory cells that include adipocytes and fibroblasts arranged on a delicate reticulin or collagenous network. This supporting stroma is not readily obvious until the hematopoietic tissue contracts in a centripetal manner with advancing age or is lost due to injury (Fig. 2).

Kinetically, the vast potential of this organ is revealed by its capacity for autologous reconstitution after severe but reversible damage. Subliminal whole-body radiation empties the marrow of its usual occupants, but after a variable period, they gradually return. Furthermore, segments of otherwise irreversible aplasia can be seeded from a shielded spleen or single limb, establishing the existence of a migratory pluripotential population. Such stem cells have the capacity to move from the circulation to a particular geographic area or niche, settle, and produce trilineage hematoopoiesis, suggesting that the apparently inert stroma has a rather more important role to play than previously anticipated.

Mature cells, such as reticulocytes, were shown to leave the marrow by amoeboid movement, whereas granulocytes became increasingly deformed so that they can enter the bloodstream through slits in the vascular endothelium. These phenomena were not initially appreciated, probably because of a preoccupation with the large numbers of relatively mature cells present under basal levels of hematoopoiesis or because of the dramatic expansion induced by stress. With technological advances, the previous concepts that blood forms in largely static terms needed to be modified to acknowledge the more dynamic nature of the process.

More attention has been focused on function since the demonstration, in short-term clonogenic assays, that mononuclear cells recovered from peripheral blood or marrow would form aggregates in response to a variety of stimulatory peptides. Elucidation of these regu-

![Image](image_url)

FIG 2. Organization of bone marrow. Left, bony trabeculae surrounded by easily recognizable megakaryocytes and other hematopoietic precursors. Right, the stroma can only be seen clearly after these megakaryocytes and other precursors are reduced. Lymphocytes, adipocytes, and plasma cells also can be identified. The function of the inductive microenvironment is to present stimulatory and inhibitory molecules to the stem or to the progenitors, either directly or through an associated matrix, thus regulating the entire sequence of blood formation, with the subsequent release of the mature elements into the circulation.

atory mechanisms centered on exposing the progenitors to growth factors, singly or in combination, and establishing correlations with the numbers of colonies formed and their composition.

Such a model was clearly rather simplistic, and experiments with two inbred mouse strains sharing a common phenotype of refractory macrophage anemia, an absence of mast cells, and changes in coat color showed that either a defective stem cell or a faulty stroma could be incriminated. These cellular facts established a central role for the latter, with its accessory cells that are in intimate contact with one another and are loosely grouped together to make up what is now described as the inductive microenvironment: the laboratory counterpart is the long-term marrow culture.

From a practical standpoint, much of this information can be brought together in a functional model. Here, a given level of homeostatic demand is selectively met by means of the appropriate ligand being presented by the stromal matrix and engaging its cognate receptor on a corresponding hematopoietic progenitor. Such a linkage initiates a signal that is transduced through a series of cytoplasmic substrates to the nucleus. The last molecule in this cascade is the
transcription factor, which has the capacity to activate genes that, in turn, generate their corresponding proteins or enzymes to determine a particular cellular activity. These range from entry into the cycle to the other extreme, known as apoptosis or programmed cell death.

Considered physiologically, it is possible to categorize the various forms of bone marrow failure. Initially, these forms can be divided into those having either a genetic or an acquired defect and, subsequently, they can be subgrouped according to whether one or more lineages are predominantly affected. This approach is attractive because it links the lessons learned from experimental hematologists directly to the clinic and establishes a rationale for current management strategies. To this end, it is illustrative to review, in a little more detail, what is known of some of these processes.

ANIMAL MODELS

The discovery of ionizing radiation dramatically influenced world events in the last half century. The potential for a nuclear holocaust has been offset, to some extent, by major benefits to the sick and suffering, including the application of ionizing radiation to the dissection of hematopoiesis.

Early work rested heavily on the use of this modality, leading to the development of new concepts such as the existence of renewal systems for many organs, including the bone marrow. The pattern whereby this physical force produced injury led to three cardinal observations. First, increasing cumulative doses eventually produced irreversible marrow damage, and recovery in those early studies masked simultaneous impairment of the stroma. Second, different target organs, exemplified by the central nervous system and the gut, had distinctive responses and, in the case of bone marrow, outcome could be modified by transplantation. Third, shielding of the spleen or a femur from lethal doses was followed by autologous reconstitution, establishing that stem cells could migrate, and this paved the way for modern sequential hemi-body radiotherapy regimens. These seminal observations from intact animals led to the introduction of clonogenic and long-term marrow-culture systems, with combinations of these techniques continuing to play a central role in unraveling hematopoiesis. Laboratory-based research has been linked with advances in medicine, spawning the industry of bone marrow transplantation—a major and often life-saving option when bone marrow function is irreversibly damaged.

THE HEMATOPOIETIC CELLS

The precursors of hematopoietic cells are morphologically well characterized, albeit heterogeneous, occupants of the marrow cavity. Of these, some retain the capacity to divide or proliferate. Most, however, undergo maturation in postmitotic pools; among these are reticulocytes, myelocytes, and later forms, as well as the distinctive megakaryocytes.

The progenitors are identifiable only by their ability to generate aggregates of progeny in culture systems. Such clonogenic assays require appropriate stimulating factors to be constantly released from feeder cells or to be present in the culture medium. Based on the growth factors provided, different cell types could be recognized. When these were a mixture of granulocytes and macrophages, they were designated GM-CFUc, an acronym for colony-forming units in culture.

The stem cells can similarly be defined only in functional terms. Totipotentiality resides exclusively in the zygote. Further growth leads to a series of tissue-specific families that are pluripotential, with one of these giving rise to the hematopoietic tissue. In irradiated rodent models, these cells form white masses in the spleen that contain all the normal lineages, and such colony-forming units are therefore designated CFUs. The same phenomenon can be repeated by homogenizing and retransplanting each of the aggregates, thereby demonstrating the repopulating potential of the earliest or ancestral cells.

It follows that, although they are few in number (accounting for only between 0.05% and 2% of the total nucleated marrow cells), CFUs have the intrinsic capacity to self renew and so give rise to the entire spectrum of the lymphomyeloid and probably even stromal lineage of each individual and to do so under basal as well as under stressed conditions. Such pluripotentiality is a vital resource that has naturally occurring protective mechanisms, exemplified by the majority of them resting in a quiescent phase of the cell cycle. Maintenance of arrest in this state can be achieved pharmacologically with agents like medroxyprogesterone acetate or macrophage inflammatory protein-1α, and these are used to provide myeloprotection during chemotherapy.

A second consideration is the intriguing conundrum of how these cells, which are predominantly sessile within the marrow extravascular compartment, migrate during fetal ontogeny from yolk sac to marrow and thereafter comprehensively maintain blood formation. Exploiting differences in physical properties, expression of cell-surface antigens, and cell-cycle status, it has become clear that there is considerable heterogeneity within this pool. Conceptually, there exist clones of varying maturity, with the most primitive constituting the reserve on which subsequent generations draw to replenish their numbers; the age-generation theory of stem cell descent. Such a continuum of immature hematopoietic ancestors ranges from pre-CFUs, with a capacity for long-term marrow repopulation, gradually merging into other bone committed compartments that have lost the abili...
ility to establish stable grafts. The marrow progenitors are migratory, and their low concentration in the circulation expands dramatically after aggressive therapy for malignant disease, at which time they can be readily collected and used for peripheral blood autografting.13

These stem cells have been designated long-term culture-initiating progenitors because of their in vitro behavior. However, it is not yet clear whether those stem cells derived from the peripheral blood, as a different anatomical site will prove identical in clinical practice when they are used for autologous transplantation.13

Another intriguing issue is how the earlier stem cells are enticed to leave their resting phases and contribute to renewal, differentiation, and, through lineage commitment, to proliferation, with consequent maturation. Is this a random or stochastic event, in contrast to its being determined by need? Available evidence suggests that the two processes for recruitment coexist in maintaining hematopoiesis, whether this is at the constitutive level or whether it occurs when the entire organ is induced to respond to stress. Furthermore, this applies throughout all phases of development.14 Uniform and modest overproduction of the marrow-repopulating cells constantly fill microenvironmental niches or undergo apoptosis because of lack of growth factor support.15 The homing of these cells to specific geographic sites probably reflects the expression of vascular cell adhesion molecules by the stroma, with subsequent growth and maturation by members of the macrophage lineage that produce the appropriate cytokines. Incremental engraftment into nonmyeloablated mice suggests that an exchange occurs between marrow and circulating cells.14

The transmembrane receptors that facilitate binding undergo constant change and, in this way, determine the localization of stem cells within the microenvironment. Thus downregulation of adhesion molecules assists the release of stem cells into the circulation. This type of interaction is believed to underlie the subtly different patterns of reconstitution that are based on competitive repopulation, in which the less mature marrow cells replace clones from the peripheral blood whose progeny have reached the end of their life span. In the context of chronic granulocytic leukemia, a not dissimilar hematopoietic competition may offer an explanation for graft-versus-leukemia effect.

One of the intriguing questions is “What do these cells look like?” Morphologically, they are relatively nondescript, resembling small lymphocytes. Immunophenotypically, the most distinctive antigen is CD34. Coexpressing this antigen with others, including CD33, human leukocyte antigen (HLA)-DR, or CD15, however, reveals that CD34 is already committed to the granulocytic–macrophage lineage. Similarly, irrespective of whether bone marrow, peripheral blood, or cord blood is studied, presence of the α3β1 transmembrane receptor with

tyrosine kinase activity is associated with erythropoiesis and granulopoiesis; its soluble form, released by normal human endothelium, may regulate the bioactivity of stem cell factor at the stromal level. This knowledge can be exploited by using immunologic techniques capable of harvesting the progenitors that can result in stable engraftment. At least in those derived from human umbilical blood, Thy–1 is expressed and derepresses inhibition of immature hematopoietic cells. Thus sources other than the marrow become attractive for autografting because they might, theoretically at least, have a lesser contamination with malignant cells. However, when those cells harvested from the peripheral circulation are considered for allogeneic transplantation, it becomes necessary to introduce some method for removal of the more abundant T lymphocytes, which, because of their larger numbers, regularly give rise to acute and chronic graft-versus-host disease (GVHD). A further word of caution is necessary. The use of peripheral blood mononuclear cells recovered after myelosuppressive chemotherapy for autografting, when peripheral blood mononuclear cells are defined only by the presence of the CD34 antigen, does not uniformly correlate with growth in clonogenic assays, and the latter may be a more reliable means for defining the repopulating potential.

Having arrived at this point, it is instructive to recall briefly those monumental studies in which the various cells, initially of marrow origin, were grown in culture and so focused attention on the whole growth factor field.

CLONOGENIC ASSAYS

Unraveling the organizational complexity of even a single tissue is a daunting challenge when isolated phenomena are considered, let alone when one is faced with understanding how blood formation is regulated in the intact organism. Without the capability to examine each sequential event in a culture system, it would not be possible to take the first step in identifying and characterizing growth factors. Only once this issue had been solved could attention be turned to the modulating influence of negative regulators. The logical extension of these studies was an exploration of the way in which receptors on stem and progenitor cells are brought into contact with their cognate ligands in the microenvironment.

The seminal observation was that growth could be induced in soft gel or agar using clones that contained mature leukocytes.15 16 The central requirement for growth was the presence of some factor in the medium, and because more than one clone of cells emerged, it appeared likely that there may exist a variety of peptides, each capable of stimulating the development of a different lineage. An important
Refinement was the use of serum-deprived conditions, in which exposure to pure growth factors showed that there was interplay among these, each sequentially activating specific genes that resulted in orderly differentiation. This technology continues to be applied to clarify the role of associated or permissive factors, including the interleukins (ILs). Once normal regulatory processes are understood, they become the basis for exploring the pathophysiology that underlies many hematopoietic disturbances. Furthermore, and of increasing importance, this knowledge has been extended to include the use of recombinant human molecules as potentially valuable therapeutic agents. However, there is already concern about the inappropriate use of recombinant human molecules; this is discussed later.

**CELL LINES**

At any one moment, marrow-culture systems yield populations at varying stages of differentiation, proliferation, and maturation. Such heterogeneity makes it difficult to study mechanisms operating at a particular point of development. This limitation can be overcome by using well-characterized cell lines in which specific phenomena can be defined under relatively homogenous conditions.

A good example is erythropoietin, in which the hormone is synthesized and secreted in human hepatoma systems that have proven helpful in unraveling molecular events. Comparable approaches have made it possible to understand the subcellular actions of stimulatory peptides in which, for example, it has been shown that IL-11 acts as an autocrine growth factor for megakaryocytopenesis.

Of note is the availability of long-lived stroma that provide tools to isolate those regulatory influences exerted by the microenvironment, including the extracellular matrix and cell-adhesion molecules. Similarly, albeit in a mouse model, a nonleukemic counterpart has been developed that is suitable for investigation of molecular changes early in hematopoiesis at a level at which genes are employed in self-renewal. The applicability of this technology to intact animals has been established by parallel studies in freshly harvested tissue. This has led to the recognition that progenitors have a multilineage phenotype, which provides a plausible explanation for the phenomenon of lineage infidelity ascribed to genetic misprogramming resulting from molecular aberrations that follow chromosomal translocations.

**REGULATORY GROWTH FACTORS**

Stimulatory peptides were the first molecules to attract attention. This came from the demonstration that colony formation in culture systems could be enhanced by substances secreted into the medium from a variety of leukocytes and the recognition that these exert important physiologic control of hematopoiesis. Stimulatory peptides were soon seen to act either directly through large glycoprotein receptors expressed on the surface of progenitors or as response modulators, in which case an accessory cell in the hematopoietic microenvironment was stimulated and this, in turn, produced a growth factor, as in the case of IL-1. As the number of stimulatory peptides has increased and individual actions have been clarified, the peptides have been shown to fall into two categories. Some act broadly, such as GM-CSF, IL-3, and the c-kit ligand, which expand the committed progenitor population but facilitate proliferation of more than one cell type. Others are lineage specific, exemplified by erythropoietin, G-CSF, M-CSF, and by IL-5, all of which control late-stage maturation changes. In most instances, the two classes act together, bringing about optimum marrow output.

This rather simplistic approach has already required modification because the concept of a mobile ligand linking to its stationary receptor is not strictly accurate. The mobile ligand, instead of necessarily being free, may be membrane associated, whereas the stationary receptor has soluble isoforms. Distinction between the older key-and-lock analogy thus becomes blurred, and the regulation of many cell functions is seen to be much more dynamic, with variations suggesting alternative mechanisms for intercellular communication. However, purely in the interests of clarity, the more traditional understanding has been retained in discussing some of the clinically important factors.

Erythropoietin levels in the plasma increase exponentially with lowered tissue oxygenation, irrespective of its cause. The origin of the hormone is uncertain, but restriction of the gene to subsets of cells within the kidney and liver is consistent with the oxygen-sensing mechanism residing in one of these organs. Support for this contention is found in experimental studies using hepatoma cell lines or appropriate animal models, in which messenger RNA is generated in response to hypoxia or exposure to cobalt. On release, the protein binds to its cognate receptor, which is a member of the hemopoietin superfamily, whose common feature is a lack of intrinsic tyrosine kinase domains. A soluble isoform is now known to exist, although its physiologic importance awaits clarification.

Ligand engagement initiates a series of events that culminate in the production of erythrocytes. The delivery of an adequate signal to this differentiation pathway also requires activation of globin genes regulated through the common transcription factor, designated GATA-1. Next, with the cooperation of early-acting cytokines, including IL-3 or the c-kit ligand, there emerge primitive progenitors, designated burst-forming unit, erythroid (BFU-E). These progress to the more ma-
ture CFU-E, which are extremely sensitive to low concentrations of erythropoietin. Maturation through recognizable normoblasts to erythrocytes is critically hormone dependent and usually occupies 10 to 20 divisions, with a prolonged S phase, but this stops at the level of orthochromatic cells that are arrested in G0.

Once erythropoietin was purified, it could be used to unravel interactions with other growth factors that affect this lineage. Predictably, erythropoietin was transferred to the therapeutic arena, in which its use has been beneficial in many diverse conditions, including anemia of chronic renal failure and myeloma.

Granulocyte-stimulating factor (GSF) is the prototype of late-acting molecules originally derived from the 5637 bladder cancer cell line, and its production is controlled by a gene located on the long arm of chromosome 17. The closely related macrophage and granulocytemacrophage peptides, the latter generated from a site on the long arm of chromosome 5 in close proximity to other glycoproteins that form part of a superfamly, share an ability to influence immunohematopoietic cell proliferation and function. 20

Cytokines, as with the interleukins, have highly conserved and overlapping amino acid sequences, which are essential for binding to their membrane-associated receptors. Such shared subunits help to explain both redundant and pleiotropic functions (Fig. 3). 20 In general terms, ligand attachment causes conformational changes in the transmembrane glycoprotein, with resultant modification of the intracytoplasmic domain. For example, there is induction in protein tyrosine phosphorylation or alteration in phosphatase activities. 23 Such steps initiate the transmission of signals to the nucleus that will, in turn, activate genes to bring about the desired alteration in cell function.

The availability of growth factors has contributed greatly to elucidating subcellular phenomena. In parallel, growth factors have been used for successfully treating many patients with bone marrow failure but, regrettably, commercial expediency has, in many cases, overtaken responsible use. 22 Certain oncogenes, exemplified by c-myc and c-fos, are activated as early events when stimulated by these products, and when taken in conjunction with their other observations, introduce a note of caution about potential adverse effects, particularly when these stimulatory peptides are used in high concentration. 23

The interleukins are a group of peptides that mediate communication, primarily among white cells, although their activities extend to nonhematopoietic tissues (Table 1). 24 The interleukins share many functions with the traditional growth factors, including common receptor binding and coagulation with them in the development of a variety of cell lines. In addition, the interleukins participate in the

*Many of these molecules act synergistically with growth factors and share with them redundancy, reflecting their production by many different cell types, and pleiotropy, acting on more than one target and doing so within the hematopoietic, lymphopoietic, inflammatory, and nervous systems.

---
acute-phase response to inflammation. In a like manner, they often act on early progenitors and cooperate with similar cytokines, such as the c-kit ligand, to facilitate production of both red and white cells as well as platelets.22 Conversely, the effects of interleukins may be exerted somewhat later, that is, after lineage commitment, as seen with monocytes and granulocytes or when ILs 6 and 11 affect, primarily, thrombopoiesis.19 As these molecules have been isolated, sequenced, and cloned, pure recombinant proteins have become available. This has been helpful in the exploration of both the complexities of hematopoiesis and the way in which this physiologic process overlaps with inflammation and immunologically mediated events. Predictably, these biologic products have been introduced into the clinic, and their therapeutic potential has already been recognized. Nevertheless, it is again essential to emphasize that prudence and scientific restraint are needed to prevent the irresponsible overuse of these pure recombinant proteins. Their use must be neither exploited commercially nor discredited through enthusiastic but inappropriate patient treatment.22

Transmembrane receptors that initiate signal transduction are made up of alpha, beta, and in some cases, gamma, subunits that, in various combinations, may be shared by the respective growth factors, and it is this phenomenon that contributes to both redundancy and pleiotropy.23,25 Additionally, these structures have similar free transmembrane and intracytoplasmic domains, with the latter participating in two major phosphorylation and dephosphorylation reactions as the first step in the onward passage of information to the nucleus.26

The enzymes catalyzing these processes in eukaryotes are protein kinases, with their complementary phosphatases. In the first of these processes, the phosphate is transferred to serine or threonine residues, in what is known as the G-protein-coupled pathway. Here, receptor binding leads to activation of protein kinase C by diacylglycerol in a calcium-dependent step.27 The intermediary stages in the process of cell-function modification are uncertain, but it is possible that the enzyme itself may directly bind to nuclear proteins or substrates that include the topoisomerases. The second is the tyrosine kinase pathway that involves many cytoplasmic proteins or enzymes, with at least some of these sequentially interacting with ras and raf protooncogenes and the MAP-kinases.3,27

In both examples, transcription factors bind to specific DNA segments, including oncogenes such as c-fos and c-myc, through a particular conformation or structure, exemplified by the zinc-finger motif. These may, in consequence, activate or repress programs for cell-cycle progression, replication, or apoptosis.28,29 Of relevance is the recent demonstration that short segments of nucleic acid can be synthesized to have subtly different structures from those of their naturally occurring counterpart. These antisense oligonucleotides can bind or hybridize to the normal cell product according to the rules of the genetic code and so may prevent its translation into the corresponding protein or enzyme. This technology may be applicable for use in switching off a critical intracellular event and may also prove useful to define regulatory mechanisms experimentally.

Permissive factors have little intrinsic activity but potentiate early hematopoietic events and thus generally affect multiple lineages. Examples of this include the c-kit ligand, basic fibroblast growth factor, and IL-6.28 Understanding these activities was facilitated by the use of a mouse model in which a common phenotype could arise in two different ways. Mutation at the white spotting (W) or Steel (S) loci affected, respectively, generation of the transmembrane protein kinase receptor c-kit or production of its cognate ligand.

An analogous situation occurs in humans. Here, the stem cells expressing the CD34 antigen are brought into contact with the Steel factor, which is synthesized by stromal cells, in part because of the stromal cells providing adhesion sites between the progenitor and environmental matrix. Once the c-kit protooncogene is activated, conformational changes take place in the ectodomain, and dimerization follows, after which autophosphorylation of the tyrosine kinase in the cytoplasmic segment leads to signal transduction and appropriate lineage expansion. These early events are well exemplified in the case of erythropoiesis, in which progenitors are amplified up to this stage of globin production, but then interaction with erythropoietin is necessary to complete their maturation (Fig. 4).

Similarly, basic fibroblast growth factor has limited intrinsic clonalogenic activity, but it acts synergistically with stem cell factor in narrow niches.40 Culture studies suggest that in its biologic form, a complex is generated with proteoglycans from the matrix, and only then does basic fibroblast growth factor modulate megakaryocyteopoiesis and other hematopoietic activities. For example, based on studies using a human erythroblastic leukemia cell line K562, basic fibroblast growth factor increases the pool of progenitor cells by antagonizing the effect of those cytokines that would otherwise induce their differentiation.

Other substances influencing blood production are the somatomedins, heme, hepatocyte growth factor, the leukotrienes, and perhaps not surprisingly, an influence on hematopoiesis for the sympathoadrenergic system. Although a number of these interactions remain controversial, preliminary results illustrate the extent to which our concepts must constantly be modified to keep abreast of new advances. Nowhere is this more true than in the need to develop a sound understanding of regulatory mechanisms so that these very powerful molecules can be responsibly used in therapy, such as in patients with bone marrow failure, albeit at a tangent to the issue.
Increasingly, attention is turning to the role that these molecules play in clinical practice. This is illustrated by the upregulation of gamma interferon-induced suppression of bone marrow progenitor cells in the pathogenesis of aplasia, although it is interesting that such effects may be overridden by growth factor combinations. These products are entering the therapeutic arena; they can be administered to protect stem cells from damage during treatment with alkylating or antimetabolite agents, including, as we have seen, medroxyprogesterone acetate or macrophage inflammatory protein 1-α.

THE HEMATOPOIETIC-INDUCTION MICROENVIRONMENT

The overall organization of the hematopoietic-inductive microenvironment is both anatomically and functionally geared to interact with pluripotent stem cells and provide geographic areas where these cells can reside and grow. The cellular components are heterogeneous and include adipocytes, members of the immune and lymphoreticular systems, fibroblasts, macrophages that lie free but may be found at the centers of erythroblastic or plasmacytic islands, and reticular and vascular endothelium. How these different populations contribute to hematopoiesis was impossible to determine until segments could be isolated in the laboratory using long-term marrow cultures. In spite of the availability of this technology, many questions remain unanswered. One such question is whether a corresponding role exists for the spleen in hematopoiesis. Another is the emerging concept that there may well be a common stem cell for both marrow and lymphomyeloid lineages. Additionally, there is an increasing appreciation of the need to distinguish between physiologic and pathologic responses in the hematopoietic microenvironment in hematologic disease and treatment. Lymphocytes are prominent, and those of T lineage, whether natural or lymphokine-activated killer cells, can experimentally exert both stimulatory and inhibitory effects on the stem cells. The mechanisms of action appear to be primarily through the release of soluble factors, some of which affect the early phases of differentiation and proliferation, with subsequent modification by more lineage-specific molecules that regulate maturation and cell release. To an extent, these interactions are bidirectional, with cells of the immune system also playing a role in the reconstitution that follows transplantation. Similarly, marrow failure appears, in certain circumstances, to result from enhanced expression of negative regulators, and a correlation exists between some of these clinical entities and quantitative or qualitative disturbances in the CD4+ population.

With this background, it was predictable that attempts would be made to exploit therapeutically the function of these accessory cells.
To date, examples include stimulation by bryostatin-1 that upgrades the in vivo production of IL-3 or GM-CSF by T cells. In a similar context, the impaired cytokine production that occurs with increasing age has been used as a model to gain insight into the regulation of genes that encode stimulatory molecules such as GM-CSF and then to develop strategies for modifying hematopoietic response in the elderly.

The vascular endothelium was for many years thought of as a simple mechanical barrier between blood and marrow. However, this is a dynamic population, with functions that include the synthesis of naturally occurring anticoagulants and regulation of cellular or molecular traffic by transendothelial or interendothelial routes. Furthermore, the vascular endothelium constitutively produces a range of stimulatory peptides that modulate myelopoiesis and can be induced by oncostatin M to generate G-CSF and GM-CSF. This information collectively underlines the important role that these intimal cells play in the physiologic regulation of granulopoiesis.

Insight into the anatomic relationships in the stroma comes from the study of long-term cultures, in which a blanket cell forms an epithelial layer that separates proliferating hematopoietic cells from the supernatant, with the former regarded as the in vitro equivalent of the extravascular compartment. These investigations have been aided by using cellulose acetate membranes, on which microvilli meet and trap migrating cells, thereby facilitating their perforation of the epithelial layer to gain entry into the cellular compartment. More recently, refinement has been added by introducing a microporous membrane between the hematopoietic progenitors and the stroma. These studies have demonstrated that direct contact between the two populations is not necessary for conservation of primitive hematopoietic cells, but it is essential for the regulated production of mature blood elements. This occurs through stroma-derived factors, which are probably different from those of the early-acting cytokines.

Adhesion molecules are centrally involved in guiding the movement of cells within the microenvironment, either by providing attachment to the stroma or by the facilitating release of maturing precursors. These are often grouped together in families. Examples are the cadherins, which bring about cell-to-cell binding through calcium-dependent mechanisms called the integrins, which are the prime mediators for attachment to the matrix, with protein being their major structural component; the selectins, in which this role is played primarily by carbohydrates; and the immunoglobulin superfamily, which is concerned with antigen recognition and adhesion, particularly in the T lymphocytes.

Many of the stromal regulatory events require reciprocal interaction between accessory cells in the bone marrow, including those of the vascular endothelium and hematopoietic stem cells. It is notable that such relationships appear to center on interdigitating microprocesses on the accessory cells in the bone marrow but are also found on a wide variety of other cells, including those that express the CD4 antigen and others of immunologic importance. Again, the parallels between such subcellular events and their clinical application can be enlisted to explain a number of phenomena. For example, this might underlie the retention of blasts in the marrow or may govern the localization of lymphoma cells in bone marrow through the linking of integrin to its ligand in the stroma, with upregulation of either molecule leading to increased adherence.

The extracellular matrix provides the final meeting ground for this wide range of cells, including their receptors and the corresponding ligands that are synthesized by the stroma. The extracellular matrix is a structurally complex tissue comprising a variety of collagens, laminin, fibronectin, and proteoglycans, all of which combine to provide physical support for the progenitors and dynamically orchestrate their orderly development. Of interest is basic fibroblast growth factor, which forms a complex with heparan sulfate, and in this specific environment brings together those cytokines that control, for example, human megakaryocyteopoiesis. The importance of these extracellular proteins was further demonstrated using a plastic immobilization model that linked thrombopoietin to the c-kit ligand and generated a signal leading to colony formation.

In a way, these experiments have come full circle, with niches that originally had largely morphologic connotation shown to be the dynamic interface between the progenitor and the inductive microenvironment. Direct applicability to bone marrow failure and its management is found in competitive repopulation experiments in which conventional wisdom is contraindicated by demonstrating that long-term engraftment can take place without prior conditioning, which was previously advocated as being necessary to make space for the incoming graft. Confirmation of this phenomenon in human studies would establish a precedent for infusion without first conditioning the recipient by chemoradiotherapy and would strengthen the argument for the use of stem cells as vehicles in gene therapy.

LONG-TERM BONE MARROW CULTURES

Clonogenic assays that were first used to provide information about stem cell response to positive and negative regulators were limited in that they reflected only a small segment of the hematopoietic process. Little insight could be obtained about the vastly more complex situation that governed homeostasis of blood formation in the intact animal, particularly the role of the inductive microenvironment, with its many accessory cells and molecular matrix. The seminal step in
overcoming this limitation was a demonstration by Dexter et al. of a method in which adherent stromal layers were established and then inoculated with bone marrow cells. The Dexter method was then refined and applied to humans, although some controversial issues persist. For example, there is debate about whether a single progenitor gives rise to stroma and stem cells or whether such commonality might be explained by differences in the technology used. Similarly, the importance of natural killer cells has also been examined, and it is noteworthy that these and possibly other lymphoid lineages are generated directly from progenitors before there being any phenotypic evidence of lymphoid or myeloid commitment. Nevertheless, this model deserves credit for the improved characterization of hematopoiesis, particularly the crucial regulatory interactions among stem cells, cytokines, and the inductive microenvironment.

Dexter's original method has been further modified to look at blast cell adherence. Here, the earliest phenotypes are presumed to express receptors for adhesion molecules whose ligands are generated by the stroma and so lead to their retention within the niches. Indeed, some of the early-acting molecules, exemplified by both Steel and basic fibroblast growth factor, appear to function in this way, either singly or very possibly in collaboration. Subtle alterations in this type of binding would allow the slightly more mature progenitors to pass through the agar into the supernatant, where they can be characterized in standard clonogenic assays based on their response to appropriate cytokines.

The capacity independently to manipulate these two major populations (stroma and hematopoietic stem or progenitor cells) has clear advantages and resulted in, among other things, characterization of the ancestors that can comprehensively regenerate lymphohematopoiesis and undergo in vitro expansion. In human studies, this is described as the high proliferative potential colony-forming cell and can be recovered from the peripheral blood in sufficient numbers for autografting. Although present in very low concentration, these are amenable to growth in suspension cultures, stimulated by a variety of early-acting cytokines such as IL-1 and Steel ligand, but this can also be achieved using molecules that are active when used on their own. It has emerged that primitive hematopoiesis can be initiated without stem cell factor.

The Dexter system and its blast colony modification paved the way for the better understanding of the physiologic mechanisms regulating hematopoiesis by accessory cells of the stroma and associated matrix. As the characteristics of the earliest progenitors were defined, including in particular their capacity to initiate and sustain long-term clonogenic engraftment, techniques have emerged to refine autografting by selectively enhancing the concentration of such recombining units and quantifying the units. Furthermore, corresponding fractions can be obtained from umbilical cord blood or from the peripheral circulation, the latter particularly after mobilization with recombinant human growth factors. Whether corresponding fractions are taken from umbilical cord blood or from peripheral circulation, it is possible to expand the very early committed lineages in vitro using a variety of growth factors. After their infusion, blood counts recover rapidly, facilitating early discharge of the patients from the hospital. It is notable that these maneuvers are swiftly being adapted to clinical practice, in which they have an established role in myeloprotection of individuals receiving escalating doses of chemotherapy. Their use can also shorten markedly the pancytopenic phase that follows bone marrow transplantation.

SUMMARY

It may appear that an inordinate amount of time has been devoted to describing the physiologic principles currently thought to underlie the regulation of hematopoiesis. This exercise is appropriate for three reasons. First, it bridges the gap from the early days of largely descriptive reports through an era in which experimental hematologists used radiation biology, cytogenetics, and marrow-culture systems to begin understanding the controlling mechanisms for blood formation. Second, the proposed model, which unifies many of these events, takes into account the surprising degree of heterogeneity in the stem and progenitor cell compartments, with their diverse response to stimulatory peptides or inhibitors, and emphasizes the cardinal regulatory role vested in the stroma. These various interactions can be used to classify rationally the syndromes of bone marrow failure. Third, with the more ready availability of recombinant human cytokines and an ever-widening choice of techniques for transplantation, some of the previously empiric approaches are being placed on a better footing. Examples include attempts to modulate hematopoiesis immunologically at the microenvironmental level through the use of antilymphocyte globulin, bryostatin-1, and immunosuppressive agents, ranging from corticosteroids to cyclosporins. In the therapeutic context, however, it would be less than responsible if concerns about inappropriate use of these valuable products were not emphasized.

OUTLINES OF PATHOPHYSIOLOGY

An inherited as opposed to acquired defect is a distinction all too frequently forgotten. There exist a number of genetically determined lesions that are experiments of nature. These are golden opportunities to understand pathogenesis, and the use of modern technol

The great diversity of these syndromes can be simplified by first dividing them into inherited or acquired categories. Inherited syndromes are generally irreversible, whereas those with acquired syndromes may recover spontaneously. Within each of these two broad groups, single-lineage defects may occur and remain unchanged. In contrast, other patients may have anaemia, neutropenia, or thrombocytopenia that evokes relentlessly to global failure or aplasia.

can then provide new information about the way in which lymphohematopoiesis is regulated (Table 2).

Spontaneous recovery is a major consideration that should be contrasted with irreversibility. Thus in many clinical situations, as well as infections or drug-related damage, the pancytopenia or hypoplasia will turn out to be self-limiting. Of more ominous significance are those cases in which relentless loss of hematopoietic tissue occurs. This is seen typically in congenital disorders or when the extent of the damage is so great that spontaneous recovery is precluded. In the last category are the effects of industrial toxins such as benzene or irradiation, in which cumulative effects erode the stem cell compartment beyond its capacity for regeneration.

The natural history of bone marrow failure is variable. Many cases start by involving a single lineage, for example, anaemia, leucopenia, and thrombocytopenia, and these may remain life-long. Isolated phenomena. In other patients, there is the same initial peripheral blood finding, but it evolves to pancytopenia with aplasia. Here there is a much greater management problem and, although recombinant growth factors are useful, autologous bone marrow transplantation currently offers the only realistic chance for cure. This procedure is relatively crude so that there is an overwhelming need to identify those individuals in whom there is a single gene at fault and in whom selective replacement is an ever-increasing reality.

CONCLUSIONS

These syndromes are all too commonly encountered in clinical practice, with outcome being determined by early recognition, accurate diagnosis, and appropriate therapy. These patients are seen by hematologists, specialists in internal medicine, and generalists alike, so that it can reasonably be argued that an understanding of hematopoiesis is necessary for all medical practitioners if optimal care is to be provided. To this end, recent advances in cellular and molecular hematology can be brought together in a progenitor cell model, and this should now be regarded as part of our general knowledge.

Moves are already afoot to refocus the effective approach of hematopoietic stem cell transplantation along much more sharply defined avenues in which defective genes, once identified, can be selectively replaced. Finally, if that is the bright side of our future direction, there is also a sobering perspective. Sadly, this is to be found in the epidemic of acquired immunodeficiency disease, which continues to sweep across the globe. Infection with this retrovirus has forever changed the face of lymphoproliferative disorders and is in the process of creating a whole new category of defects in hematopoiesis— including bone marrow failure.

CONGENITAL SYNDROMES: PERSISTENT SINGLE LINEAGE INTRODUCTION

In early life, anaemia, neutropenia, or thrombocytopenia can occur in isolation and fail to remit spontaneously. In some instances, these inherited defects remain restricted to a single cell line, as in the Josephs–Diamond–Blackfan anaemia and amegakaryocytic thrombocytopenia with absent radii. Conversely, the Shwachman–Diamond syndrome and reticulocytopenia may progress to pancytopenia as a consequence of trilineage marrow aplasia.

These are all examples, to a greater or lesser extent, of bone marrow failure, in which the causative lesion is seldom elucidated. There is, however, some evidence to support the existence of genes that, by their expression or repression, predispose to the different entities. In this context, it is reasonable to postulate that homozygosity would favor global hematopoietic involvement, as described by Fanconi. In contrast, heterozygosity may underlie fractures, in which solitary cytopenia can evolve into more widespread damage. Furthermore, it is conceivable that such a genetic deficiency creates an unstable chromosomal complement and, thus, predisposed to relatively minor environmental insult may precipitate the overt hematologic lesion—a point astutely predicted more than a half century ago. It follows that the various syndromes could be considered to be part of...
a common spectrum on the basis of the proposed progenitor cell model for hematopoiesis. The separate description of each syndrome is somewhat artificial but is a pragmatic solution; accordingly, for each syndrome, the clinical and hematologic defects are described, and the underlying pathophysiological mechanisms are used as a basis for summarizing an approach to therapy.

ERYTHROCYTES

Josephs–Diamond–Blackfan Anemia

This congenital erythroid hypoplasia occurs in families and is associated with a variety of extramedullary abnormalities. This disorder was initially reported to be normochromic and normocytic; however, in most cases, the mean cell volume is raised, but vitamin B₁₂ and folate levels remain normal.⁴⁶ Leukocyte and platelet counts are typically unaffected but may be reduced in some patients.

Historically, constitutional anemias were recognized as early as 1911, but it remained for Josephs, in 1936, to describe two infants who had an isolated failure of erythropoiesis. In a larger review of 175 cases, the congenital nature of constitutional anemia was confirmed, with 12% of the diagnoses being made within 2 months of birth and 72% of the diagnoses made by the age of 4 months, with abnormal thumbs, webbed neck, and growth retardation often occurring in these infants.⁴⁶ In 1951, the landmark observation that this disorder was responsive to therapy with steroids was reported. Currently, however, the use of recombinant human growth factors or bone marrow transplantation is preferred.

Clinically, the diagnosis becomes evident when progressive anemia with skeletal abnormalities is found in the newborn. Although not all the defects are necessarily present in one individual, the infant may have high-arched palate, inguinal hernia, absent ribs, growth retardation, horseshoe kidney, and cardiac septal defects, with radiologic changes usually limited to the thumb or cervical vertebrae.

The natural history of Josephs–Diamond–Blackfan anemia has changed little from the first description, with spontaneous remissions being infrequent. Treatment by splenectomy was not effective, and although red cell transfusions helped to prolong life, these transfusions led to siderosis. Outcome was significantly improved by the use of corticosteroids, which not only arrested growth retardation but also resulted in remission in some cases. Although it is unusual, the diagnosis of Josephs–Diamond–Blackfan anemia may first be made in adulthood. Long survival may be associated with neoplasia, such as hepatocellular carcinoma.

Hematologically, mean red cell volumes are generally above 100 fl. In addition, serum erythropoietin is present in the face of raised erythropoietin levels, and persistence of fetal hemoglobin or expression of the f antigen is frequently found. Leukocytes and platelets are typically unaffected, although neutropenia, thrombocytopenia, and thrombocytopenia can occur. Bone marrow examination shows isolated erythroid hypoplasia, which is confirmed by ferrokinetic studies.

Immunologically, a number of lesions are found, with blood lymphocytes inhibiting red cell production by marrow progenitors from normal controls⁴⁷ and autologous reconstitution after immunosuppression or the use of prednisone. One interpretation of this is that the operation of an immune mechanism renders erythroid precursors insensitive to erythropoietin, particularly when a crude hormone is used.⁴⁸ Other growth factors, however, may also be involved, whereas occasional extension to leucocyte and platelet lineages raises the question about whether an earlier or less committed progenitor might be the target for this genetic lesion.

Biochemically, red cell enzyme assays can be coupled with the hematologic findings to separate congenital hyperplastic anemia from related conditions, particularly transient erythroblastopenia of childhood.⁴⁹ In congenital hyperplastic anemia, the immune dysfunction, with its propensity to evolve into leukemia, has elevated levels of erythrocyte adenosine deaminase activity. This disturbance in purine metabolism has been advocated as a marker for identifying these patients, although similar levels may occur in Fanconi, hemolytic, and acquired aplastic anemia.⁵⁰ Changes in orotidine decarboxylase are less clearly understood with regard to the pathogenesis of congenital hyperplastic anemia.

In patients with Josephs–Diamond–Blackfan anemia, chromosomal analysis shows an increased number of random breaks, with abnormalities on chromosome number one, whereas pentasomy 21 has been reported to predict the subsequent development of acute leukemia.⁵¹

Clonogenic assays of these patients show that the T lymphocytes are normal, whereas in coculture studies, peripheral blood erythroid progenitors are deficient in either number or function.⁵² These observations contrast with a study that demonstrated persistence of lymphocyte-mediated suppression of BFU generation in two adults. Hematologic remission was then explained by postulating the development of a serum factor that blocked the suppressive effect on the red cell precursors by a population of autologous T cells. Additional support for immunologic mechanisms is found in lymphocyte dysfunction, reported in five patients. However, in only one of these was there a suppressive effect on erythropoiesis.

Cell lines have been studied relatively infrequently in these patients, although clinical similarities have been described with the W and S1 mutant mice. Tests on the proliferation of M-07 show evidence
that stem cell factor is produced constitutively by the microenvironment of patients with this congenital hypoplastic anemia, but the low number of receptors reported requires confirmation because, at least in two patients, both c-kit and its ligand were intact.53 The pathogenesis of this congenital hypoplastic anemia remains controversial. In early erythroid progenitors, aberrant colony formation is corrected after the addition of IL-354; this correction is most striking when stem cell growth factor and erythropoietin are added. It appears that this lesion worsens with time and, notably, is not restricted to the red cell line, which may explain the hematopoietic alterations associated with the increasing age of these children.50 The observation that three patterns of response are seen for the cytokine combinations supports the postulate that there may be more than one underlying molecular defect.56 There is speculation that this disorder arises from the genes coding for c-kit or its ligand, but failure to demonstrate abnormalities in either suggests that the primary pathology in most or all cases lies elsewhere57; indeed, erythroid failure has recently been characterized by accelerated apoptosis.58 Possibilities include impaired signal transduction or interference with transforming factors for gene activation. However, there is no support for a postulated defect in the stroma or for inactivation of antibody-mediated mechanisms, in spite of some tantalizing evidence of an underlying immunologic disturbance. Some researchers believe that these lesions arise independent of aberrant immunoglobulin production.

Diagnosis may be difficult in the first few weeks of life, when an infant has only anemia, for which alternative causes include blood loss, infection, immunohematology, aplasia, myeloma, and transient erythroblastemia of childhood.59 Notwithstanding this, a high index of clinical suspicion will generally lead to the examination of peripheral blood and marrow, with confirmation derived from clonogenic assays and cytogenetic studies.

Complications occur when multiple blood transfusions are given, leading to immunomodulation and compromising subsequent marrow grafting. Additionally, iron overload, culminating in hemochromatosis, is a potential hazard, and the use of high-dose deferoxamine, albeit costly, is a sensible option until definitive treatment is initiated.

Management with standard or high-dose corticosteroids is not without risk of endocrine and musculoskeletal damage or infections, whereas the addition of cyclosporin is largely anecdotal. The current therapy is based on the results of laboratory data and clinical trials and consists of recombinant human cytokines, particularly IL-3,58 in combination with stem cell growth factor.50 A significant number of patients respond to this therapy, whereas the role of other stimulatory peptides, such as GM-CSF and the addition of erythropoietin, awaits clarification. Ultimately, however, bone marrow transplantation seems to be the best option for these patients because of its curative potential.60 Here, the exposure of the graft to Campath 1G ex vivo, with its low rejection rate and abrogation of acute and chronic GVHD, is particularly attractive.60 It is not clear whether these results can be extrapolated to minimally histoincompatible family members or even to matched unrelated donors, in which much higher complication rates remain a problem.

**Congenital Dyserythropoiesis**

Congenital dyserythropoiesis embraces a group of hereditary refractory anemias unified by the presence of ineffective hematopoiesis. Distorted erythroblast morphology is typical; however, it is not specific, and white cell and platelet counts are unaffected. Usually, there is an increase in indirect bilirubin levels in the serum and an absence of haptoglobins, but the reticulocyte count is low for the hemoglobin level, in spite of marrow hypercellularity.

There are four subtypes of congenital dyserythropoiesis, which are separated by the degree of megakaryoblastic maturation, giant erythroblasts, dyserythropoietic morphology, serologic aberrations in red cell response to acidified serum or expression, and lysis by anti-I or anti-i (Table 3).60 The basic genetic defect of erythroid membranes occurs only in type II congenital dyserythropoiesis. In type II, these membranes lack the enzyme N-acetyl glucosaminyl transferase, which is concerned with glycosylation.63 This gives rise to increased susceptibility to lysis in an acidified normal serum, which may be related to a unique antigen that reacts with immunoglobulin M (IgM) antibodies that are found in a proportion of unaffected subjects. It is notable that this disorder may coexist with other genetic abnormalities, necessitating patients to more severe hemolytic. Further.

*In addition to the four established subtypes, new variants are described regularly.
more, individuals who have received multiple blood transfusions acquire isoantibodies, causing the direct antiglobulin test to become positive and confusing the diagnosis.

The classification of congenital dyserythropoietic anemia is constantly being revised with the description of new variants, including the occurrence of primary shunt hyperbilirubinemia. Historically, these are relatively rare disorders, with the bizarre nucleated red cells sometimes referred to as giantstoblasts. The first descriptions appear to have been made in 1943, with the literature collated and reviewed by Berman in 1947. The familial nature of these disorders was recognized in 1951 by Heimjel and Wendt. Impetus was given to developing the currently favored classification more than 20 years ago. Details of the classification system were provided by ultrastructural studies, with further information provided by a number of investigators.

Clinically, most patients have this form of congenital bone marrow failure early in life, having refractory anemia, ineffective erythropoiesis, and gross distortion of erythroblast morphology. Recognition of the disorder may be delayed into adulthood, however. The presence of hemosiderosis and hepatic cirrhosis sets the stage for evolution to hemochromatosis, and bone marrow expansion gives rise to extramedullary hematopoiesis, including paravertebral masses. On occasions there may be associated hydrops fetalis in which, paradoxically, the mother has mild disease, but the more serious variant occurs in the fetus, with a lethal outcome.

The natural history of congenital dyserythropoiesis is determined by the severity of the defect and the rate at which iron accumulates and hepatic dysfunction evolves. Most typically, the disease is relentlessly progressive, with only a small percentage of the patients reaching adulthood.

Hematologically, the red cells are macrocytic, although this may change after splenectomy, when normoblasts appear in the circulation and, unusually, stomatocytosis may be present, reflecting abnormalities in the membrane proteins. The bone marrow shows the most striking changes, with erythroblast multinucularity, which is often evident in the spleen.

Ultrastructurally, there is profound distortion of normal cytopathy. These findings are not pathognomonic and, furthermore, the anticipation that they would contribute to understanding the pathophysiology of this disorder has not been fulfilled, although modifications using immunogold electron microscopy may be of more diagnostic value.

Ferrokinetic studies confirm that hematopoiesis is ineffective. When ferrokinetic studies are combined with organ imaging, blood formation is shown to be widely distributed throughout the skeleton.

Use of this combined technique can sometimes identify blood formation in extramedullary hematopoiesis.

Immunologically, information about congenital dyserythropoiesis is largely limited to serologic changes in the acidified serum and sucrose lysis tests, although the pattern varies somewhat with disease subtype. The lesion appears to be due to abnormal complement regulation, at least in type II, and affects constituents other than decay-accelerating factor, known as CD55, or membrane inhibitor of reactive lysis, or CD59. The glycosylation defect that characterizes these cells involves glycoprotein A, which is the major erythrocyte sialoglycoprotein, a known complement regulator. Cold antibody hemoly-
sis may increase, resulting in variable expression of anti-I agglutinins, depending on the subtype being reported.

Biochemically, there is precipitation of beta-globin chains, supporting the concept that an unbalanced assembly of polypeptides makes up the hemoglobin molecule, although the effect of this lesion on the pathogenesis of the disorder is not established. A number of enzymes have been examined, but their diagnostic value has not been confirmed. In contrast, the fatty acid composition of erythrocyte glycosphingolipids is disturbed, particularly in type II patients. Consistent with this finding is an abnormality of both membrane and cytosolic proteins, with the primary defect being failure in glycosylation of substrate by a defective transferase that brings about the membrane lesion.

Clonogenic assays have suggested that erythropoiesis is normal, although ultrastructural studies of the erythroid BFUs showed changes consistent with a defect at the stem cell level. Furthermore, the distribution of erythroblasts within the cell cycle was disrupted, with reduced numbers undergoing DNA synthesis and corresponding increases in the G2 and G1 phases.

Pathogenesis is that of a genetically transmitted defect at the level of the hematopoietic stem cell that results in the biochemical lesions coupled with expression of membrane antigens, one of which has now been designated HEMAP.

Diagnosis is based on morphologic, ultrastructural, and serologic criteria in the peripheral blood and the marrow.

Complications arise from ineffective hematopoiesis, with red cell transfusions accelerating iron overload. In the presence of the erythroid hyperplasia, there is an increased risk of parvovirus infections and, unusually, osteomyelitis may develop.

Management centers on folate supplementation and giving the patient as few red cell transfusions as possible, keeping in mind that the objective of therapy is to keep the patient symptom free. This should be combined with iron chelation to diminish the risks of siderosis. Occasionally, splenectomy has been used, although the results
have been questionable. In rare instances, allogeneic bone marrow transplantation may be considered because it has curative potential, whereas the most realistic future option is replacement of the defective clone by gene transfer.

**WHITE CELLS**

Severe chronic neutropenia encompasses a heterogeneous group of disorders in which there is a selective decrease in circulating cells to levels often associated with recurrent fever, chronic oropharyngeal inflammation, and severe infections. The three major subtypes of severe chronic neutropenia are idiopathic, cyclic, and congenital. Although, traditionally, reduction in numbers has been the criterion for defining this form of bone marrow failure, it may be too narrow a view because qualitative lesions can be lethal, as in severe chemotaxis-induced dysfunction, in which granulocytopenia in the marrow appears normal.

**Chronic Idiopathic Neutropenia**

These disorders are poorly understood, but the obvious defect is chronic hypoplasia in the myeloid lineage that does not affect erythropoiesis or platelet production. No consistent genetic pattern has been reported, but autosomal dominant inheritance has led to familial occurrence among Yemenite Jews.

Historically, information is scanty and mostly anecdotal, with little added after the disorder was first described in 1931.\(^{75}\)

Clinically, the patient is first seen with infection, which is roughly in proportion to the degree of neutropenia, although there are a few serious sequelae.

The natural history is one of low counts, but spontaneous remissions can occur up to the age of 4 years, occurring less frequently thereafter.

Hematologically, the circulating neutrophils are not dysplastic, and the bone marrow shows arrest at the promyelocyte stage, with more mature forms of bone marrow being strikingly absent.

The pathogenesis of chronic idiopathic neutropenia remains unknown, and the defective maturation has not been explained either by demonstrating biochemical abnormalities or through the use of clonogenic assays. Evidence to support ineffective myelopoiesis is scanty.

Diagnosis is made on the basis of persistently very low neutrophil counts that seldom give rise to infections. Except in these circumstances, intervention with corticosteroids, androgens, splenectomy, and cytotoxic drugs would appear to be inappropriate.\(^{74}\) When infection does arise, the use of recombinant human G-CSF is rational.

**Cyclic Neutropenia**

This entity is better described to encompass other lineages because the periodic oscillations, usually occurring every 21 days, also affect erythropoiesis, megakaryopoiesis, and other white cells.\(^{26}\)

Historically, the recognition centered on a report by Leale in 1910 of an infant with recurrent furunculosis. Subsequently, the variants have been classified as being of childhood onset, with or without a family history, and emphasis has been given to distinguishing these from an apparently similar but acquired lesion that has an immunologic basis associated with large granular lymphocytosis.

Clinically, the entity is rather benign, although when counts are low, aphthous ulcers, stomatitis, fever, malaise, and cutaneous or subcutaneous infections may develop.\(^{76}\)

The natural history of the disorder was elucidated after the analysis of hundreds of reports and led to the recognition of three phases.\(^{77}\) The first phase usually lasts 1 to 3 days, with listlessness and irritability occurring. During a second equivalent period, aphthous ulcers appear on the oropharyngeal mucosa, with tender cervical lymphadenopathy. The third phase is a short recovery time.\(^{76}\) Infrequently, there may be associated abdominal pain and diarrhea.

Hematologically, neutropenia fluctuates from normal to very low levels, whereas other cell counts are unaffected or may be slightly raised. Episodes of thrombocytopenia have been reported.\(^{76,77}\) The bone marrow is mildly hypercellular, depending on the stage at which it is examined. When this phenomenon is characterized kineretically, the percentage of cells in the S phase corresponds roughly with circulating numbers.\(^{76}\) Such cyclic variations are also seen in red cell and platelet precursors as well as among lymphoid cells.\(^{77}\)

Clonogenic assays have shown fewer colonies at the time when absolute values are present, although it is not clear how this finding should be interpreted.

Pathogenesis has failed to incriminate an immunologic mechanism. Rather, when human and canine data are combined, a primary defect is seen to lie in early pluripotential cells, thus explaining changes that extend beyond the involvement of the granulocyte series, but the question of genetically determined periodicity remains unanswered. In addition, it is not known whether abnormalities in purine and pyrimidine metabolism documented in the grey collie dog or its clinical counterpart represent an epiphenomenon or may, in some way, point to the basic lesion.\(^{77}\)

Diagnosis of cyclic neutropenia depends on the distinctive sequence of events in hematopoiesis. The first of these is a typical superficial infection that occurs during a neutropenic episode. When this is in the skin, staphylococci and streptococci are responsible, whereas in the mouth, unusual aerobic and anaerobic organisms can
be isolated. There is little evidence that these individuals are particularly prone to viral, fungal, or parasitic infections. Management requires that the patient fully understand the nature of the illness. Although there has been some enthusiasm for the use of recombinant growth factors, these probably have limited value in treatment.

Kostmann's Syndrome

Also known as dysgranulopoietic neutropenia, the syndrome features recurrent infection, absence of neutrophils in the peripheral blood, and bone marrow that shows maturation arrest at the promyelocyte–myelocyte level. Inheritance may be as an autosomal recessive, dominant, or X-linked entity.

Historically, this lethal disease was described in 1956 as agranulocytosis infantalis hereditaria and encompassed multiple abscesses of the skin, as well as otitis, mastoiditis, and high fever resulting from agranulocytosis in a child who lived for 4 months without demonstrable neutrophils. The familial transmission was evident, with half of the eight siblings having died as infants. A similar syndrome had been reported on the father's side, in which all the children except the father died. Once the genetic basis had been recognized, a systematic survey was undertaken in the county of Norrbotten, Sweden, and particularly in the parish of Överkalix, leading to the seminal description of the disease in 1958. Interestingly, the unaffected individuals were normal, and most were typically Nordic, with little evidence to account for Finnish or Lappish ancestry.

Clinically, multiple abscesses develop in spite of the absence of granulocytes, and the distinctive feature is the family distribution; most patients die within 2 months of the onset of their disease, with few surviving beyond half a year.

Hematologically, neutrophils are absent, with the other two lines not directly involved. However, mild degrees of anemia may reflect associated hemolysis and blunted response to erythropoietin, as found in the presence of chronic infection. Reactive thrombocytosis has been recorded. The bone marrow shows striking arrest of maturation at the promyelocyte stage. Ultrastructural and cytochemical studies of neutrophils are consistent with defective formation or degeneration of primary granules, whereas their secondary counterparts are either markedly decreased or cannot be demonstrated at all; autophagia may be striking.

Clonogenic assays, in spite of the presence of neutrophils, show the anticipated numbers of colony-forming cells in both blood and marrow, with an intact maturation sequence.

Pathogenesis of this syndrome, with its dysmorphic neutrophilic granulocytes, ineffective granulopoiesis, negative serology, and absence of antineutrophil antibodies, is in many ways reminiscent of the findings in congenital dyserythropoietic anemia. GM-CSF was unaffected, whereas G-CSF could not be detected, suggesting a defect in the production of the latter stimulatory peptide. This contrasts with reports of supernormal levels, which may be evidence of a blunted response to endogenous levels of the latter ligand. One explanation is a mutation in the gene for the receptor, although this seems to be a relatively uncommon occurrence. Alternatively, because the number of binding sites and affinity are normal, the defect may lie more distally in the signal-transduction pathway, where there is interference with the mobilization of cytosolic free calcium, affecting chemotaxis, superoxide anion generation, and F-actin content.

In individuals with sepsis who have absent or poor wound healing, the diagnosis rests on the presence of severe neutropenia and a family history.

Management consists of local measures and the use of recombinant human G-CSF to restore neutrophil counts, at which point the lesions rapidly reverse. Escalating doses have been advocated, but caution is necessary because empirical use of neutrophils by megakaryocytes, has been observed in some patients, overlapping with the development of thrombocytopenia. Innovative treatment options include combinations with IL-3 or stem cell factor.

Myelokathexis

The association of moderate neutropenia with bizarre morphologic disturbances of granulocyte nuclei, although uncommon, results in intramedullary granulocyte death and can be confused with myelodysplasia. Management centers on the use of growth factors; however, in one case, bone marrow transplantation was successful.

PLATELETS

Thrombocytopenia andAbsent Radii

These patients are seen rarely and have low platelet counts, with bony abnormalities being fairly constant, although cardiac anomalies may occur in one third of these individuals, particularly tetralogy of Fallot and atrial septal defects.

Historically, the syndrome was defined in three families containing nine affected individuals, four unrelated patients, and a survey of 27 previously reported cases. Since then, an increasing number of confirmed reports have appeared.

Clinically, the syndrome occurs typically in children, although it may also develop in later life. Currently, more than 100 examples have been reviewed, resulting in a consolidation of the original features of the disorder and the addition of high-arched palate and abnormalities of the eustachian tract to the list.
The natural history is determined by the severity and duration of the thrombocytopenia, although there is often spontaneous improvement after 1 year of age, and therefore data on patients after puberty are scarce. Hematologically, thrombocytopenia is most severe at diagnosis, and counts fluctuate but tend to rise with age. Bone marrow is hypercellular, with eosinophils prominent and megakaryocytes typically small, immature, and apparently not producing platelets. Iron stores are decreased, reflecting blood loss. Usual associations are abnormalities of chromosome 3 and, possibly, superimposed immune thrombocytopenia. Chromosomal analyses show extreme sensitivity to x-rays, but fragmentation or breaks that typify Fanconi's anemia, which have led to confusion of this diagnosis, are unusual. Clonogenic assays reveal virtual failure of megakaryocytic growth, even in optimally stimulated cultures. Pathogenesis remains uncertain with the defect being absent or with arrested development of committed megakaryocytic progenitor cells in the face of high levels of the appropriate colony-stimulating activity. Diagnosis of the disorder is not difficult in the typical phenotype but may initially be missed when less gross defects are present either in the patient or in family members. Management has been unsatisfactory, with intravenous immunoglobulins recommended and splenectomy sometimes effective. The best results, however, have been obtained with recombinant growth factors or bone marrow transplantation. More recently, the use of IL-3, IL-6, and IL-11 has been advocated to stimulate megakaryopoiesis, but their role is uncertain because benefit is likely to be seen only as long as the stimulator peptide is administered.

CONGENITAL SYNDROMES: EVOLVING TO MARROW APLASIA

INTRODUCTION

Some cytopenias that also have a genetic basis differ from the previously described entities in that initial involvement of the single lineage progresses to global bone marrow failure. These are generally more ominous because of the life-threatening potential; therefore, they pose greater challenges for management.

ERYTHROCYTES

Fanconi's Anemia

Decreasing hemoglobin due to relentless erosion of hematopoietic tissue associated with multiple congenital defects as a typical occurrence in families was recognized more than 50 years ago and was subsequently confirmed. Age, natural history, and skeletal changes vary, and in the Estensen-Dameshek subtype, bone marrow failure may be the sole abnormality. Inheritance is an autosomal recessive with homozygosity producing the typical phenotype, whereas ploidy reduction may be accounted for by interaction with other genes. Contrasting, the heterozygotes have less striking physical and hematologic defects, which is consistent with partial expression of the Fanconi gene. This situation is thought to underlie all cases of acquired aplasia. With clinical expression precipitated by a superimposed environmental insult. This point has been contested, however, in spite of the biochemical lesion remaining obscure, classification is possible by complementation testing, which has identified four separate genes, with the defects localized to at least the long arms of chromosomes 20q and 9q.

Historically, aplasia was described by Erlich in 1888, and in a subsequent review of 64 cases, mental retardation, underdevelopment of the skeleton, and hypogastinalism were added. The syndrome was more precisely defined by Fanconi, after whom it was named. A number of reviews have crystallized the essential features, emphasizing the susceptibility of skin fibroblasts to transformation by oncogenic viruses, thereby raising the specter that chromosomal instability would predispose the patients and their relatives to a variety of malignancies. A consequence of the worldwide interest in this entity is the establishment of a registry at the Rockefeller University, with proposals that it may well be preleukemic and, if so, might provide an experiment of nature for the study of acute myeloblastic leukemia.

Clinically, failure to recognize subtle manifestations leads to underdiagnosis. Low birth weight with growth retardation, morphologic distortion involving mainly the head and face, skin pigmentation, and hypogastinalism, particularly when combined with skeletal abnormalities in the radial ray, should alert pediatricians to this possibility. Further frustration may make diagnosis difficult, and indeed, this entity may be recognized only as a result of hematologic deterioration occurring in pregnancy.

The natural history of Fanconi's anemia is dictated by changes in hematopoiesis, in which irreversible and worsening cytopenia culminates in early death, with survival rarely extending beyond puberty and frequent blood transfusions being complicated by siderosis. A seminal observation was that testosterone and corticosteroids could beneficially influence outcome, and this led to a clinical classification based on disease severity. Of note is the association with acute leukemia and myelodysplasia or solid tumors.

Hematologically, the blood count shows refractory normochromic normocytic anemia and pancytopenia that progresses slowly.
with age. The bone marrow findings differ with the stage of the disease, being normal early on, but gradually, hematopoietic reserve contracts. Erythroagocytosis is not unusual, and transfusional siderosis is striking and may result in secondary hemochromatosis. Radiolabel studies confirm loss of erythropoiesis and, in some cases, superimposed ineffective production. Serologic and immunologic abnormalities are not a feature. Biochemical defects are inconsistent but include the absence of terminal deoxynucleotidyl transferase.

Chromosomal analyses reveal endoreplication and breakage, with the latter more widespread than previously appreciated and associated with defective repair of DNA cross-links. These characteristic lesions can be demonstrated using micronucleus formation techniques, with response enhanced by the addition of mutagenic agents or flow cytometry, which gives information about cell-cycle status. Flow cytometry should be evaluated against the standard approach, in which hypersensitivity of these cells to cytotoxic and clastogenic effects of DNA cross-linking agents is demonstrated using the diethylnlobutane test. It is attractive to suggest that such profound chromosomal aberrations create a milieu that predisposes to rearrangement and subsequent transformation, especially when patients are exposed to low-level environmental mutagens and carcinogens. However, one caveat is that clonal abnormalities need not, in and of themselves, form the basis for high-risk intervention such as bone marrow transplantation, unless further data are provided that clonal abnormalities clearly predict the emergence of leukemia.

Clonogenic assays show reduced growth of erythroid and myeloid progenitors suggesting that there is a defect at the stem cell level. Long-term cultures provide an alternative explanation because hematopoietic progenitors are not only present, but they also have the capacity to proliferate and mature, thereby focusing attention on a potential role for the inductive microenvironment. Thus reduction in early-acting cytokines, specifically stem cell factor, GM-CSF, and IL-6, may have a more influential role than previously appreciated. When stromal cells from patients are examined, output of a variety of growth factors, both constitutively and in response to IL-1, is seen to range from blunting through augmentation in comparison to normal controls, and it is notable that these defects could not be directly attributed to the Fanconi mutations.

Pathogenesis remains controversial. Although not strictly applicable, it is instructive to draw an analogy from two distinct mouse models. Although the two models have a similar phenotype with refractory megaloblastic anemia, absence of mast cells, and changes in their coats, the causative lesion in each is quite different. Mutations in the dominant White Spotting (W) or Steel (S) loci, respectively, prevent expression of a receptor coded by the c-kit oncogene that has homology for a feline transforming retrovirus or its ligand required for clonal growth of early progenitors.

Given this precedent and the lack of a demonstrable biochemical lesion in these patients, it is not unreasonable to remain receptive to the concept that either hematopoietic stem or stromal cells could be primarily responsible for defective synthesis of the protein essential for the recognition, modification, and repair of the characteristic damage to DNA cross-linking. A start has been made in this direction, with complementarity studies that have demonstrated four genes, designated A through D, with one having been cloned and accounting for 15% to 20% of the cases that occur in the United States. However, as in its murine counterpart, it is not clear whether these variants necessarily bring about hypersensitivity to DNA-damaging agents with their predisposition to neoplastic transformation. Furthermore, as an alternative, or perhaps arising concurrently, cellular response to oxidative stress may fail because of a fault in one of the detoxification mechanisms that remove free radicals or their oxygen byproducts. Thus the challenge for experimental hematologists is to determine whether these molecular events are manifestations of a common mutation or whether they differ sufficiently to provide a means for subclassifying affected individuals.

Diagnosis is not difficult when the clinical and hematologic findings are supported by a positive diethylnlobutane test, abnormal micronuclear formation, or a flow cytometric equivalent. Complications are those of the pancytopenia, upon which are superimposed the development of myelodysplasia and acute leukemia.

Management is successful in roughly 50% of the patients given steroids and andabolic androgens as first-line therapy, in the course of which spontaneous remissions may occur. In contrast, experience with the use of lithium or infusion of recombinant human superoxide dismutase is limited. Similarly, administration of erythropoietin or recombinant growth factors has been advocated, but these agents do not have proven value. The preferred approach is allogeneic bone marrow transplantation, using matched siblings, although unrelated donors or umbilical cord vein blood, perhaps with ex vivo expansion, are options. A more definitive treatment awaits cloning of the FancnI gene, at which time direct replacement will have much to recommend it. A fascinating alternative, suggested by the experimental studies, is that intratertine grafting is not beyond our reach.

Dyskeratosis Congenita

This rare form of ectodermal dysplasia, also known as the Zinsser–Engman–Cate or the Cole–Bauschob–Toomey syndrome, is characterized by abnormalities in the skin, with dystrophy of the nails
arising in the first decade and extending to leukoplakia in the second, with age-related progression. The diagnostic triad is reticulated hyperpigmentation of the face, neck, and shoulders; leukoplakia of the mucous membranes; and nail changes. Bone marrow failure is found in half of the patients, usually during the second decade, with cancer developing in the third and fourth decades.

Inheritance is as an X-linked recessive, although other patterns have been reported that are consistent with autosomal transmission or X-inactivation, with this heterogeneity perhaps explicable by genes that are distributed over the X—as well as multiple—autosomes. Lymphocytes in these patients are hypersensitive to bleomycin treatment, which manifests as multiple chromosomal breaks. This phenomenon is a useful test for carrier definition.107

Historically, some 250 patients were originally reported to have poikiloderma atrophicans vasculare, with evidence for a familial occurrence and association with marrow aplasia or Fanconi’s anemia being poorly substantiated. Dyskeratosis congenita is currently considered to be a separate entity, and in the last 25 years, it has been accorded recognition in its own right. Extensive family studies106 have established the sequence in which clinical signs become manifest, beginning with skin pigmentation and nail dystrophy, and culminating in neoplastic changes and opportunistic infection, which lead to early death.

Clinically, the X-linked variant arises in men, although roughly equal gender distribution is found in what appears to be an autosomal-inherited subtype. The median age at presentation is generally 15 to 16 years but ranges from a few weeks to the mid-40s. Skin pigmentation is present in the majority of patients, and oral leukoplakia is found in two thirds. A number of these features simulate chronic GVHD, which has led to the suggestion that both have a similar pathogenesis. The mesodermal damage is genetically determined in dyskeratosis congenita, whereas with the acquired variant, morbidity and mortality typically occur after allogeneic transplantation.104 Other defects include epiphora, cataracts, dysphagia, nasopharyngeal atresia, early loss of teeth, and osteoporosis associated with fractures or aseptic necrosis characterizing the skeletal abnormalities, which are worse in patients being treated with prednisone.

The natural history shows that 10% to 20% of those affected will eventually develop cancer. The lingual hyperkeratosis has a potential for malignant change, which can be demonstrated immunocytochemically. Altered expression of the p53 suppressor gene appears to be a reliable marker for predicting neoplastic transformation in the lesions. The bone marrow fails in between half and three fourths of the cases, although this is generally less frequent in the autosomal variant. Confusion arises with Fanconi’s anemia, but these patients seldom have nail dystrophy, leukoplakia, hyperhidrosis, or hair loss, whereas those with dyskeratosis rarely have chromosomal breaks and appear to develop leukemia less frequently.

Hematologically, the blood count begins as normal, but thrombocytopenia may be the presenting event, and typically there is progressive pancytopenia. The bone marrow is usually hypocellular with radionuclide studies showing a variable distribution of hematopoiesis throughout the axial skeleton.

Immunologically, abnormalities exist in T-cell function, with striking lymphopenia and atrophy of lymphoid parenchyma, consistent with a defect in the cell-mediated immune system. These findings correlate with thymic aplasia and atrophy of the spleen and lymph nodes.108

Chromosomal studies, using appropriate restriction enzymes and probes, map the gene for dyskeratosis congenita to Xq28. Although this disorder is in the general category of chromosome-breakage syndromes, the data are conflicting. Some investigators have reported that findings in lymphocytes and fibroblasts occur spontaneously, with an increased level of sister chromatid exchanges. Other researchers have demonstrated normal values. Such variations can be reconciled if different complementation groups exist to this end. X-irradiation appears capable of revealing fragile sites that may be located for cellular oncogenes and therefore may have diagnostic value in both patients and possible heterozygotes. Skin fibroblasts are ideal for study in culture and have been used to show the marked increase in breaks, hypoploidy, and premature centromere disjunction. Furthermore, banding studies revealed nonrandom lesions that correspond to known breakpoints for cancer-specific rearrangements. Recalling high rearrangement rates occur; particularly in the elderly, an explanation is suggested for the dyskeratosis congenita defect predisposing to these chromosomal changes.

Clonogenic assays show abnormal growth patterns that may be immunologically mediated. However, this mechanism does not exclude the possibility that the stem cell is intrinsically defective. This is supported by data from long-term marrow-culture studies that reveal intact stromal function analogous to the situation in the W/WV mouse and focuses attention on the receptor encoded by the c-kit oncogene as a candidate for the lesion in these patients.110

Pathogenesis centers on the gene for dyskeratosis congenita having been mapped to the X-chromosome, but it is uncertain, from complementation studies, whether other defects may also exist within the genome. Expression results in the characteristic variety of ectodermal lesions. With regard to hematopoesis, the evolution of pancytopenia, based on clonogenic and long-term bone marrow culture assays, is most consistent with a normal microinductive envi-
enronment and a defective hematopoietic stem or progenitor cell. That the lesion is immunologically mediated remains, for the moment, anecdotal.

Diagnosis presents little difficulty when all the physical signs are present. However, this possibility is not always considered when patients are first seen with pancytopenia due to bone marrow failure, malignant change, lingual hyperkeratosis, other malignancies, or the complications arising from their immunocompromised status.

Management remains unsatisfactory, although treatment with recombinant human growth factors has proven beneficial in some instances and less so in others. Currently, bone marrow transplantation offers the best chance for cure. Here a word of caution is appropriate because there are similarities between these individuals and those with Fanconi's anemia, in which chromosome fragility, which is widely distributed throughout all the systems of the body, may be followed by an unusually high incidence of secondary malignancies. Although few innovative options are on the horizon, it is likely that once the genes have been more reliably identified and isolated, the way will be open for their specific replacement.

**WHITE CELLS**

**Shwachman's Syndrome**

Shwachman's syndrome is defined as the familial occurrence of bone marrow dysfunction and pancreatic insufficiency in childhood, with the latter not being due to cystic fibrosis. There are associated abnormalities at the metaphases of long bones, ichthyotic skin rash, hepatosplenomegaly, cardiomyopathy, frequent infections, and developmental retardation. Genetically, studies are relatively limited and show no consistent abnormality.

Historically, six children were described. The children had diarrhea, weight loss, and low levels of trypsin, lipase, and amylase. The distinctive feature, however, was normal electrolyte levels in the sweat. Four of the children had unexplained iron-resistant anemia, and all had intermittent or persistent neutropenia and thrombocytopenia. Another similarity was copper deficiency, and indeed, it was suggested that this was a contributing factor when associated with pregnancy. Over the years, very little new information has been added other than neurologic assessment, which has shown a reduced intelligence quotient, hypotonia, deafness, and retinitis pigmentosa, with sibship segregation ratios supporting an autosomal recessive mode of inheritance.

Clinical presentation is that of children who, in the first year of life, fail to thrive due to diarrhea, steatorrhea, weight loss, and eczema, with a differential diagnosis of cystic fibrosis. Aggregation among family members is evident soon after the index case is identified. Of note is just how many tissues and organs are involved, ranging from dental abnormalities, renal dysfunction, and endocrine disturbances, such as a delay in puberty or diabetes mellitus, to a variety of dysmorphic features. Unusually, there may arise central pontine myelinolysis, pancreatic lipomatosis, and respiratory dysfunction. Skeletal abnormalities are osteoporosis, in which copper deficiency could be incriminated. The outcome is typically determined by the severity of the marrow failure.

Hematologically, varying degrees of pancytopenia are present, with low neutrophil count generally detected in the first 5 years of life. Raised hemoglobin F levels may precede bone marrow function, and hypocellularity is usually found.

Ultrastructurally, cells reveal the Pelger–Huet anomaly, with dilated endoplasmic reticulum containing granules that look like intracellular inclusions. These could represent failure to secrete a normal product or may possibly reflect synthesis of an abnormal protein.

Immunologically, impaired function has been linked to aberrant phagocytosis and defective chemotaxis. Superimposed on this, however, is the suboptimal activity of natural killer cells, which may contribute to the recurrent infections. The latter report is somewhat at odds with previous descriptions, in which humoral and cell-mediated mechanisms were found to be intact.

Chromosomal analyses show increased spontaneous breakage that broadly links these children with those having Fanconi's anemia and dyskeratosis congenita.

Clonogenic assays have been carried out infrequently, but results are usually in the normal range.

Pathogenesis is uncertain but is consistent with a transient, albeit severe, copper deficiency in early childhood. Although multiple organs are involved, giving rise to protean manifestations, some insight into the causation derives from studies on isolated chondrocytes, in which large glycogen and small lipid deposits suggest that the basic defect resides in the function of microfilamentous elements. These findings become more prominent when the cultures are exposed to colchicine, which favors an intrinsic inability to repair the microtubules; this would be particularly damaging in active tissues such as the marrow.

Diagnosis is not difficult when a malnourished child is seen with hypoplastic pancytopenia and is found to have metaphyseal chondroplasia and a history of recurrent infection; confirmation is derived from a defect in neutrophil locomotion and natural killer cell activity.

Complications are numerous and involve the respiratory, gastrointestinal, hepatic, renal, and neurologic systems. A word of caution is
appropriate because many of these young children have features reminiscent of cystic fibrosis, although this possibility can generally be excluded.

Management is largely symptomatic, with the infections responding promptly to antibiotics. The morphologic abnormalities in the gastrointestinal tract are reversible with simple enteral nutrition. Lithium has been reported to benefit neutrophil function and does this without side effects, perhaps by improving the cytoskeletal defects. However, the current vogue favors the use of cyclosporin A. Probably the most efficient way to deal with the infection problem is by parenteral administration of recombinant human G-CSF. Bone marrow transplantation is clearly effective, although the data are largely anecdotal.

Reticular Dyogenesis

The coexistence of congenital agranulocytosis, lymphopenia, and the absence of cellular or humoral immunity is also known as thymic lymphopenia or aleukocytosis. No genetic defects have been demonstrated and, in spite of an excess number of males affected, this is not accepted as an X-linked disorder.

Historically, the first cases were reported in 1959, but few, typically aggregated in families, appear to have been described thereafter.

Clinically, infection dominates early infancy and the striking feature is failure of lymphoid tissue to develop in nodes or tonsils, with the thymus not demonstrable on chest radiograph or computed tomography (CT) scan. The severe granulocytopenia combines with immunologic paralysis to render the outlook extremely grave.

Hematologically, the counts are low and granulocytes are absent, resulting in a relative lymphocytosis; anemia is frequent, but thrombocytopenia is unusual. The marrow is hypocellular, with myeloid and lymphoid precursors being scanty. Normoblasts, although reduced, may be dysplastic.

Immunologically, there is an absence of T and B lymphocytes associated with a low immunoglobulin level and profoundly suppressed response to mitogens; biochemistry is normal.

Clonogenic assays have not been helpful, with colonies and clusters being reduced in size and number when compared to controls.

The pathogenesis is unknown and currently is speculated to reflect a defect in stem cells that are incapable of undergoing lympho-myeloid differentiation.

Diagnosis, if this syndrome is considered, is confirmed without difficulty, but the rapid progression of the disease leads to early death from overwhelming infection.

Management depends on early recognition of this possibility, and a successful outcome may follow allogeneic bone marrow transplantation.

PLATELETS

A megakaryocytic thrombocytopenia

A low platelet count in the infant, extending to the other two lineages, is an infrequent but well-recognized entity, although fewer than 50 cases appear to have been reported. Conceivably, many synonyms have diluted the distribution of reports in the literature, including congenital essential thrombocytopenia, familial thrombocytopenic purpura, isolated megakaryocytopenia, congenital hypoplastic thrombocytopenia with malformations, type III constitutional aplastic anemia, and megakaryocytic thrombocytopenia. A genetic basis has not been established, but at least some cases appear to be X-linked, and others have autosomal recessive transmission.

Historically, the infrequency with which cases have been described over many years may explain the lack of uniform diagnostic criteria. However, this does appear to run in families, with reports from Australia, suggesting the existence of male and female subgroups, designated type III and type IV. Such gender distribution is questionable, however. A preferable approach is to emphasize the presence or absence of physical anomalies.

Clinically, the dominant feature is bleeding into the skin, mucous membranes, or gut, with the majority of individuals progressing to marrow aplasia. Thereafter, children fall into two broad categories, with the common finding being bone marrow megakaryocytes that are either reduced or cannot be demonstrated at all. Specifically, all patients have a normal radial ray. Separation is based on those who have no associated organ abnormalities, in contrast to the remainder, who do have associated organ abnormalities. When these abnormalities are present, they are not characteristic of any other recognizable syndrome. Examples include defects of the central nervous system, the presence of cardiac disease, distorted facies, and retarded development.

The natural history is a median survival of 6 years in patients with no associated organ abnormalities, but only 2 years in those with associated abnormalities. Mean ages at death from thrombocytopenia were 1.9 and 0.5 years, respectively, and from aplasia, 8 and 2.7 years, respectively. In spite of the poor outlook, an extensive review of all reported cases has shown that a few patients may survive beyond childhood.

Hematologically, thrombocytopenia with macrocytosis is initially present, whereas bone marrow cellularity is unaffected except for a decrease in or absence of megakaryocytes, which, nevertheless, appear morphologically normal. Interestingly, there are increased levels of hemoglobin F and expression of the i antigen, which are two indices of significant bone marrow damage. Radionuclide investigations show unimpaired survival of homologous platelets, so that the low
counts are due to underproduction, which is consistent with loss of the corresponding marrow precursors. Accelerated peripheral sequestration is not usually found, although there is anecdotal reference to the presence of immune complexes in the serum, hinting at an underlying immunologic abnormality.

Chromosomal analyses demonstrate increased numbers of breaks and gaps, but contrary findings have also been reported. Clonogenic assays have not shown a decrease in megakaryocyte progenitors, but few cultures appear to have been carried out during the thrombocytopenic stage. Once aplasia has developed, overall hematopoiesis is profoundly reduced.

Pathogenesis remains unknown, but because congenital aplasia may first involve this lineage, these patients could conceivably reflect the initial events in the latter syndrome, which then extends to the other two lines. The diagnosis is suggested by thrombocytopenic bleeding at an early age, in the absence of bone marrow megakaryocytes.

Management requires the control of hemorrhage and infection, which remain the most common causes of death. Steroids are effective in about one third of patients and, when combined with androgens, can lead to partial response, whereas splenectomy is without value, and there are no long-term survivors. Given this poor outlook, attempts to base therapy with stimulatory peptides on the in vitro responses that occur with IL-3 and GM-CSF were reasonable, but the assays turned out not to have any predictive value. More recently, stem cell factor has become available, but inadequate data are available to comment on its usefulness in these rare individuals. Perhaps the most reasonable option, where indicated, is still autologous.

FAMILIAL MARROW DYSFUNCTION

A surprisingly large number of patients, having the common finding of aplasia that apparently occurs in families, do not fit comfortably into any of the recognized syndromes. An interesting approach is to group these patients on the basis of transmission, with the caveat that substantial overlap occurs with spontaneous mutations.

Autosomal Dominant

Examples of autosomal dominant familial marrow dysfunction include the oculo-oto-radial syndrome, with mild thrombocytopenia, leukocytosis, radial hypoplasia, and deafness. Closely allied is the entity described as WT that occurred in two families, who had abnormalities of the hand and subsequently developed leukemia. In others, there has been coexistent pigmentation, immunodeficiency, and vascular disease in the presence of neurologic dysfunction, culminating in ataxia. All of these have superficial similarity to the aplasia described by Fanconi but fail to meet the minimum diagnostic criteria of chromosomal breaks and gaps. Modern techniques should, however, make it easier to identify and classify correctly individuals with chromosomal gaps because peripheral blood and lymphocyte responses to diphenylbutane stress testing is now a standard procedure.

Autosomal Recessive

In a number of these patients, immunodeficiency occurs together with hematopoietic failure. A relatively wide range of possibilities has been described, and at least some have distinctive chromosomal abnormalities, including monosomy 7.

X-linked Recessive

Families have been identified in whom infectious mononucleosis or another viral related hemophagocytic syndrome gives rise to distinctive morphologic findings in the marrow. In one example, males over a number of generations apparently developed acute myeloblastic leukemia and light chain disease. As with any large pediatric experience, disturbed hematopoiesis occurring without stigmata in any other organ system, particularly when this is aggregated in families (even though it is sometimes limited to a single generation), raises a question about exposure to a common environmental mutagen.

Miscellaneous, with Associated Skeletal Abnormalities

There are odd examples of aplasia developing in children with physical defects that are not acceptable as variants of the syndrome described by Fanconi. These include Friedrich's ataxia, in which patients have short stature and hypogonadism and children who have webbed neck and abnormalities of the thumbs, but even these appear to vary widely within the individual family.

RARE HEMATOLOGIC SYNDROMES

Differing degrees of bone marrow failure have been associated with trisomy 21, or Down syndrome, in which there is transient neonatal myeloproliferation and a risk of leukemia in later life, although only a few of these individuals ever develop aplasia. Similar eponymous descriptions are those of Dubowitz and Seckel, with their individual distinctive growth defects, hematopoietic disorders, and malignancy.
ACQUIRED DEFECTS: PERSISTENT SINGLE LINEAGE

INTRODUCTION

Isolated anemia, leukopenia, or thrombocytopenia, which, by definition, are variants of bone marrow failure and therefore justify brief comment, may be late presentations of congenital syndromes, which in adults are more often immunologically mediated. The marrow is hypercellular, although there may be selective loss of one or another lineage, and typically there is left-shift in the marrow precursor pool, with residual progenitor growth in appropriate clonogenic assays.

ERYTHROCYTES

Pure Red Cell Aplasia (PRCA)

Anemia with absent reticulocytes and loss of the normoblast population has a number of causes, most of which have an immune basis and occur without abnormalities in the granulopoiesis or thrombocytosis; familial occurrence excludes this diagnosis. Historically, description of PRCA in 1922 by Kazzol was initially followed by confusion with the Josephs-Diamond-Blackfan syndrome, and a number of other terms emerged, including erythropoiesis, progressive postinfectious erythroblastosis, isolated aplastic anemia, anerythropoietic anemia, chronic erythropoietic hyperplasia, and primary pure red cell aplasia, but much of this experience appears to be anecdotal. Clinically, presentation is with anemia; symptoms and signs are determined by individual compensatory mechanisms.

The natural history identifies a small category of unknown origin and pathogenesis. In a further idiopathic group, pathologic immune globulins are found; these are directed either against normoblasts or, alternatively, against erythropoietin. The remainder of cases are secondary to associated disease (Table 4). Hematologically, there is normochromic normocytic anemia, which may occasionally be macrocytic and severe. Bone marrow typically has increased cellularity due to the persistence of granulocytes and megakaryocytes, but the loss of nucleated red cells is striking, and this arrest may occur at a particular stage. For example, if the target is intermediate normoblast, then the earlier basophilic forms remain abundantly present. The Coombs' test is negative, but during the hemolytic phase, lactate dehydrogenase and bilirubin may be transiently elevated.

Immunologically, a wide range of associations has been reported. In the primary group, an offending antibody can often be isolated. Others have the lesion attributable to dysfunctional lymphocytes, which may have a T-gamma phenotype and exert profound immunosuppressive effects, or, alternatively, may be a prominent, large, granular population with natural killer cell activity. Occasionally, such cytotoxicity appears to reside in less clearly defined mononuclear fractions.

Clonogenic assays demonstrate T-cell-mediated damage to erythroid precursors, with other cell lines in the GEMM-CFU assay being normal. Pathogenesis appears to be primarily through clonal expansion of T lymphocytes. Precedent from animal studies suggests that viral infections can generate a transmembrane glycoprotein capable of impeding erythropoiesis by interference with interaction between ligand and receptor or subsequent signal-transduction pathways. Diagnosis rests on the findings of distinctive peripheral blood and marrow morphology.

Management has seen erythropoietin largely replace red cell transfusions to control symptomatic anemia. The underlying immune lesion generally responds to prednisone, which is often given in escalated doses or combined with cyclosporin; other options are conventional cytotoxic drugs, antilymphocyte globulin and high-dose gamma globulin.

Transient Erythroblastopenia of Childhood

The distinctive feature is temporary reticulocytopenia and varying degrees of anemia, with absence of erythroblasts in the marrow, whereas white cell precursors and megakaryocytes are preserved.
Clinically, a previously healthy child, typically in the third year of life, is seen with profound anemia after a viral infection of the upper respiratory or gastrointestinal tract, often associated with seasonal clustering.

Hematologically, the red cell count is reduced and reticulocytes cannot be demonstrated, but the remainder of the count is normal, although thrombocytopenia and neutropenia are sometimes seen. Erythroblasts are absent from the marrow. During the recovery phase, children manifest stress erythropoiesis, releasing a cohort of fetal-like red cells because hemoglobin F levels are increased and expressing a antigen, but this is a transient phenomenon.

Pathogenesis is sometimes unknown, but in the majority of these children, evidence of parvovirus infection can be demonstrated. Management is conservative, with red cell transfusions occasionally needed, whereas intervention, as with prednisone, may generally be avoided.

**WHITE CELLS**

**Agranulocytosis**

Chronic idiopathic immunoneutropenia has parallels with lesions that may arise in red cells and platelets on an immunologic basis. The synonyms over the years have included congenital or genetic agranulocytosis and hypoplastic neutropenia.

The first description by Moeschlin goes back some 40 years, although the immune nature and the benign course have been recognized more recently. Clinically, although this disorder may occur in children, the average presenting age is 30 years, with a 3 to 1 female preponderance. No family history has been demonstrated. More than half the affected individuals had been exposed to agents known to cause neutropenia, but their withdrawal seldom altered the neutrophil count. Nevertheless, it is important to be sure that there has been no contact with cytotoxic or antithyroid drugs and the antplatelet agent, ticlopidine, which may cause damage in sensitized individuals. Of interest in this regard is the retention of toxic metabolites such as arene oxides, which can normally be broken down but accumulate in predisposed hosts that have microsomal abnormalities and suppress the marrow. Similarly, it is important to identify and exclude from consideration in this category individuals in whom an immune mechanism is secondary to Sjögren's or Felty's syndrome in the course of rheumatoid arthritis. Although infection occurred in 27% of the patients, typically when absolute counts were less than 0.5 × 10^9/L, there was a surprisingly low incidence of serious morbidity, attributed to compensation from humoral immunity involving lymphocytes, monocytes, and the recruitment of marginated neutrophils. In this context, there has been one case of enhanced serum bactericidal activity, but follow-up studies are lacking.

Hematologically, there are varying degrees of neutropenia, whereas the marrow has reduced myeloid to erythroid ratios, with the reserves of more mature neutrophils being decreased, as judged by lack of response to endotoxin, etiocholanolone, cortisone, and epinephrine. These static observations are substantiated by radionuclide kinetics, showing that free and margined cells, as well as turnover rates, were decreased, but interestingly, the half-life in the peripheral circulation was approximately normal. The way in which such changes arise remains controversial, with some evidence that production is reduced and marrow compensatory efforts are insufficient to correct the neutropenia. Other information supports adequate neutrophil release under conditions of stress but subnormal delivery in the basal state.

Immunologically, the neutropenia is primarily mediated by autoreactive or alloreactive neutrophil-specific antibodies of unknown origin. Although some studies have failed to demonstrate these, oligoclonal immunoglobulins can be incriminated, both quantitatively and functionally. Interestingly, there is light chain restriction of these granulocyte-binding proteins that probably does not reflect malignancy but suggests a somatic mutation. In a subset of patients, antibody titers are higher and combinations of IgG and IgM occur, with some of the latter fixing complement. This gives rise to additional cytopenias, associated splenomegaly, and more infections. Less clear-cut are individuals in whom inhibitory immunoglobulins are directed against precursor cells, whereas immune complex formation may provide yet another mechanism in certain individuals. Furthermore, expansion of a CD8⁺ lymphocyte subpopulation has been reported in a few of these patients, suggesting that widely differing etiologic mechanisms may result in the chronic immune neutropenias.

Clonogenic assays are generally normal, although in a single case, autologous plasma inhibited growth of both the patient's mononuclear cells and a heterologous target population. This finding is reminiscent of red cell aplasia, with an antibody having its major effect against committed progenitors.

Pathogenesis is probably variable, with the idiopathic neutropenia being due to an inhibitory autologous immunoglobulin in at least some cases. In others, an expanded CD8⁺ population is consistent with cell-mediated direct cytotoxicity that may be associated with prominent large granular lymphocytes. These can, on occasion, be leukemic, although the molecular defect may be via the elaboration of inhibitory cytokines.

Diagnosis is that of otherwise unexplained neutropenia, usually
with few complications, implying that significant compensatory mechanisms are effective.

Management requires the exclusion of nonbenign variants, and thereafter the patient needs to understand the nature of his or her disease, with the safest course being mastery inactivity. If infectious episodes occur and do not respond promptly to antibiotics, recombinant human growth factors are of clear benefit.

**PLATELETS**

Amegakaryocytic Thrombocytopenia

In most adults, unexplained and often profound reduction in platelet count occurs on an immune basis, with abundant megakaryocytes demonstrable, although there is unequivocal evidence that in some of these individuals, the marrow precursors may disappear; this is more common than was generally appreciated. A similar finding has been described with the ingestion of drugs and alcohol.

Historically, in patients with an isolated loss of megakaryocytes, the diagnosis has been confused with this hematologic abnormality, which occurs as a congenital or constitutional variant, and sometimes has overlapping associations such as immunoglobulin deficiency or the Wiskott–Aldrich syndrome. Currently, this notation should be reserved for individuals with an intrinsic defect at the level of the megakaryocytic progenitor or a circulating cytotoxic autoantibody directed against the corresponding CFU.

Clinically, patients with isolated thrombocytopenia, even with purpura, may be seen with anemia due to gastrointestinal tract blood loss. In these patients, the differential diagnosis includes immune mechanisms, with both hereditary or acquired marrow aplasia requiring exclusion, as do myelodysplasia and systemic lupus erythematosus. It should be recalled that a number of these cases may progress to global marrow failure, representing forms of bone marrow lesions typically associated with absent radii or reticular dysgenesis. The cyclic variant occasionally causes confusion, but the oscillating nature of the platelet count should resolve the dilemma. It appears that antibodies may selectively block the action of growth factors whose receptors are found on megakaryocytic progenitor, and peripheral blood mononuclear cells may periodically suppress megakaryocytic precursors. Rare correlations are with vitamin B₁₂ deficiency and certain anemias.

Hematologically, the blood count is normal apart from thrombocytopenia, whereas the marrow shows complete or partial absence of the large precursors.

Immunologically, antiplatelet antibodies may be directed against common antigens on the megakaryocyte membrane or, infre-

to their loss from the marrow. Occasionally an immunoglobulin may be generated that selectively blocks the action of GM-CSF, which, apart from its action on granulocytes and macrophages, affects these progenitors. Interestingly, determination of plasma glycocalicin may help with classification. Thus its significant reduction correlates with an absence of megakaryocytes, but platelet life span is unaffected. In contrast, normal levels of this fragment of glycoprotein Ib are found where thrombocytopenia results from immune-mediated peripheral sequestration; there is no overlap of values between these two groups.

Chromosomal analyses have shown an association with duplication of the long arm of chromosome 3, but no acquired clonal defects appear to have been reported.

Pathogenesis remains uncertain; this is probably a syndrome with diverse etiologies. In some, there is an intrinsic defect at the level of the progenitor, and in others, a comparable result is brought about by circulating cytotoxic antibodies or cell-mediated suppression of megakaryocytopenia.

Diagnosis is contingent on excluding all of the diseases that may lead to loss of precursors, most often through immunologic mechanisms. Of these, the lymphoproliferative disorders are sometimes overlooked, and it is worth stressing the correlation with systemic lupus erythematosus, particularly in population groups in which this disorder is frequently encountered.

Management centers on reversing the underlying mechanism, and remissions have been obtained with antithymocyte globulin. However, if thrombocytopenia is sufficient to cause bleeding, allogeneic platelets are of value in the short term, although their repeated infusion may result in immunization. Although tranexamic acid is reported to be of little benefit, our experience is that it may be helpful, particularly as a means of reducing the amount of replacement therapy needed. As a general rule, cytokines such as IL-3, -6, and -11 are of little benefit, and bone marrow transplantation, given the currently recognized causative mechanisms, is not a viable option.

**ACQUIRED DEFECTS: EVOLVING TO MARROW APLASIA**

**INTRODUCTION**

In previously normal individuals, the sudden and irreversible loss of hematopoietic cells is a surprisingly common and potentially lethal event. The tradition of referring to this as aplastic anemia has little to recommend it because, rather than selecting erythropoiesis, all cell lines are affected. It is even less logical to define a subcategory as being very severe on the basis of granulocyte counts; the more accurate and therefore preferable term is marrow anaplasia. An
additional confounding practice is the inclusion of varying levels of pancytopenia, reflecting hypoplasia outside the diagnostic criteria, in discussions of this entity. As a result, many reports attribute inflated response rates to a particular type of intervention. In contrast, it seems more scientifically sensible to ensure that only those patients meeting the internationally agreed definition form the basis for any study, although lesser degrees of damage can be accommodated in trials by proper stratification. In the vast majority of cases and in spite of a diligent search for causation, no exposure to recognized agents such as viral infection, which are increasingly important in acquired immunodeficiency disease, irradiation, or drugs can be uncovered. Such acquired idiopathic destruction of the blood-forming organ may, nevertheless, reflect the subtle impact of a critically damaging environmental insult on a genetically predisposed marrow. Clinical and experimental evidence supports the viewpoint that the final common pathway involves immunologic mechanisms, placing the majority of these patients in the broad category of autoimmune disease. However, the possibility of microenvironmental dysfunction should not be overlooked because, although not strictly applicable, precedent from anemic mouse strains has established that the identical phenotype may arise from mutations affecting distinct loci, which produce molecular lesions in either stem cell or stroma. It is also intellectually stimulating to speculate with the postulate that morphologic dysplasia and clonal hematopoiesis in the patient with aplastic anemia may be part of a spectrum that includes a hypoplastic variant of the classic myelodysplastic syndromes.

IDIOPATHIC MARROW APLASIA

Severe pancytopenia, defined as granulocytes and platelets less than 0.5 x 10^9/L and 20 x 10^9/L, with less than 1% reticulocytes when singly corrected for hemocrit, coupled with a bone marrow either less than 25% of normal cellularity or up to 50% of normal, provided more than 70% of the remaining cells are nonhematopoietic, remain the internationally accepted criteria for diagnosis. Recommendations to modify these criteria on the basis of different reticulocyte counts have had little support. Similarly, by definition, aplasia cannot have grades of severity. This uncritical terminology has crept in to explain varying outcomes associated with the use of antilymphocyte globulin (ALG) and should preferably be discarded or, at best, restricted to use in this specific context. It has no relevance in patients eligible for bone marrow transplantation. Additional prerequisites are the absence of any predisposing factor and exclusion of a congenital variant, although genetic heterozygosity predisposing to marrow failure may be difficult or impossible to demonstrate.

Equally subtle is the potential influence of certain class II histocompatibility antigens that identify a fragile marrow that is exquisitely sensitive to chloramphenicol and, by analogy, other less clearly defined environmental insults. These postulates are supported by the marked increase in RNA transcripts for the stem cell inhibitor gene in some of these patients, in whom relatively high expression in unstimulated lymphocytes suggests a mechanism for cytotoxic suppression through the arrest of progenitor cell cycling. Thus, although most cases remain idiopathic, the use of molecular techniques is steadily forging new links between seed and soil.

Historically, the association of fatty atrophy of the marrow with cytopenia should be attributed to Erdich, but the term aplastic anemia seems to have been first used by Chauffard in 1904. As the congenital syndromes were identified, it became possible to exclude them from this entity, although it was not until cellularity could be examined during life that the relationship between the peripheral blood and this compartment was clarified. A further advance was the shift away from pure morphology to a more dynamic approach that introduced new terms in the form of stem cells, hematopoietic micro-environment, and regulatory mechanisms. Almost immediately, it was appreciated that aplasia was the final common pathway for a number of insults, some perhaps on the basis of genetic susceptibility and others associated with immunologic disturbances. Such seminal observations underlie progress made in the last 20 years and have drawn support from refinement in animal experiments. These have been strengthened by the introduction of new technologies, prominent among which are culture systems. Last, and of particular importance, have been the results of immunologic manipulation and, indeed, bone marrow transplantation in patient management.

Clinically, global bone marrow failure is reflected in three major symptoms, of which anemia is usually prominent. Additionally, there is easy bruising or purpura, and neutropenia gives rise to sinopulmonary and urinary tract infections. Findings are otherwise unremarkable and, importantly, skeletal or vascular malformations that characterize the constitutional counterparts of this disease are absent. In recent years, this pattern has been modified by coexistent infection with the human immunodeficiency virus, so that hairy leukoplakia, oropharyngeal candidiasis, and even Pneumocystis carinii pneumonia may be early symptoms.

The natural history of idiopathic marrow aplasia in the untreated patient is one of rapid progression, with median survival in the range of 4 months, and only approximately 10% alive at 1 year, and even then the survival curve has not reached a plateau. Two additional facets are notable. First, epidemiology varies widely among countries because statistics are difficult to compile as a result of both poor data recording and a paucity of information but on death certificates. Even
using the international classification for diseases is not infallible because those individuals with the genetic variant are misdiagnosed and included in this category. Nevertheless, the incidence appears to be low in France whereas estimates for the United States are between two and five cases per million annually, with the result that these individuals will be encountered by most practicing physicians during their careers, often in the setting of prior drug therapy. Second, many features are shared between idiopathic aplasia and the myelodysplastic syndrome (MDS) or other clonal disorders of hematopoiesis, including paroxysmal nocturnal hemoglobinuria (PNH). This overlap assumes special relevance in patients receiving biologic immune response modulation with ALG, which is often given in combination with other agents, such as corticosteroids, in whom the longer survival is associated with the increased occurrence of MDS, PNH, and acute leukemia. 

Hematologically, variably variable pancytopenia is associated with a surprising degree of dyserythropoiesis in the form of macrocytosis, megaloblastic maturation, hypogranular neutrophils with Pelger-Huet anomaly of the nucleus, and platelets that may be large and stain abnormally. This morphology is reminiscent of classic myelodysplasia. The marrow findings differ with the stage of the disease. Typically, there is little recognizable hematopoietic tissue and prominence of adipocytes, with a scattering or lymphocytes and plasma cells. Paradoxically, there may be areas of intense blood formation, known as "hot spots." An additional feature is severe atrophy, which may be associated with acute inflammatory changes or myelitis, and is most evident during the early stages of the disease. Radiouclide kinetics are important to quantify residual hematopoiesis. Characteristically, clearance of the labeled iron is markedly prolonged, and effective red cell use is virtually absent. Such erythrocytes are as formed have a short survival, and external scanning shows virtual absence of isotope uptake in areas normally associated with blood formation; instead, accumulation is in the liver, spleen, and other reticuloendothelial tissues. Serologic studies are of little value other than in characterizing patients who have PNH. Positive acidified Ham's acidified serum lysine and sucrose tests can be used for this purpose. In this context, decay-accelerating factor and CD59 deficient populations, typically limited to the red cells, may first appear in granulocytes and monocytes.

Immunologically, the idiopathic variant is unremarkable apart from mild reduction in lymphocytes and monocytes or modest depression of plasma immunoglobulin levels, although no consistent differences from normal have been reported. The significance of circulating immune complexes remains controversial. Conversely, although not related to pathogenesis, profound changes arise in the patient with aplastic anemia when it is secondary to systemic lupus erythematosus or acquired immunodeficiency disease.

Biochemically, there is an increase in hemoglobin F, reflecting reversion to a fetal type of hemoglobin. A rare family defect in cellular folate uptake has been said to cause severe aplasia that reversed on treatment with folic acid. Chromosomal analysis is often apparently normal, but abnormalities may be uncovered in those individuals with clonal hematopoiesis. In children, this has been demonstrated by the patterns of X-linked genes. Furthermore, lymphocytes have increased strand breaks in DNA supporting the contention that some individuals may have either forms frustes or heterozygous variants of Fanconi's anemia. Conceptually, this situation can be regarded as functional hypoplasia, in which residual stem cells have a reduced capacity for self-renewal that fails when they are exposed to some otherwise trivial insult.

Clonogenic assays have shown a deficiency of early stem cells, whereas suppression in growth is mediated by T cells or immunoglobulins. Most of the evidence, including cross-culture experiments from my laboratory, is consistent with these patients having a normal hematopoietic microenvironment. In contrast is a report that, at least in some Chinese patients who have received prior chloramphenicol, there is also demonstrable stromal damage. A defect at this level could adversely affect production of IL-1, with a consequential decrease in release of CSFs from fibroblasts and endothelial so that the hematopoietic progenitors fail to grow. Similarly, IL-3 generation by mononuclear cells is significantly lower in these patients, correlates with disease severity, and has been postulated to be a predictor of outcome. A comparable situation has been reported with the ligand for the c-kit receptor. Attempts to dissect pathogenesis further using stromal cell lines have, to date, been of only limited value. Nevertheless, there is precedent derived from murine models in which a common phenotype, albeit one that is limited to anemia rather than to marrow aplasia, can result from a defect in the stem cell or the stroma. It follows that because an immune-mediated lesion may operate at either level, it would be prudent to keep an open mind to the possibility that, at least in some cases, the defect may lie primarily in the hematopoietic-inductive microenvironment. In support of this theory, we have recently shown that patients who have morphologically normal peripheral blood and bone marrow and are undergoing transplantation nevertheless still have a profound reduction in the clonogenic capacity of their CD34 progenitors; importantly and in parallel, the stroma becomes more slowly confluent whereas, in cross-culture experiments, it is functionally subnormal (Novitzky N, Jacobs P, unpublished).
Pathogenesis in its simplest clinical context represents pancytopenia with chronic fatty atrophy of the red marrow. Experimental hematologists favor a more dynamic stimulation, in which output from this tissue is inadequate to meet even basal trilineage requirements. From either standpoint, aplasia is seen as the common expression for a variety of lesions that may arise at any point in the complex pathway needed to produce mature cells. Understanding this is helped by recalling the progenitor cell model (Fig. 1).

Conceptually, stem cells may be constitutionally predisposed or primed for bone marrow failure by the complement of genes they carry. Inheritance could, therefore, create a fragile population that need progress no further but that is susceptible to environmental insults that may be subtle and unrecognized, so that self-replication fails and hematopoiesis is lost.

Even if one accepts such an intrinsic defect of the hematopoietic tissue, the mechanism leading to overt damage remains speculative, but accumulating clinical and experimental evidence favors a role for the immune system. Support is found in the occurrence of hypogammaglobulinemia, reports of antibody-mediated aplasia, and a range of cytotoxic phenomena residing in lymphocytes or in the monocytes and macrophages. Such immunologic mechanisms have been demonstrated in a wealth of data from culture studies.

A further attraction of this postulated autoimmunity is that it refocuses attention on the inseparable interdependence of stem cells and the microenvironment, from which there is reduced growth factor production or local generation of negative regulators such as gamma interferon. It also gives credence to the suggestion that the many defects in stromal function, although not necessarily immediately causative, play a significant and often aggravating role in the pathogenesis of aplasia. Undoubtedly, however, we have not heard the last word on this topic.

Diagnosis presents little difficulty, and here it need only be emphasized that adherence to internationally accepted criteria is mandatory if proper classification is to be the basis for optimum treatment and stratification to trials.

Management is dictated by a high index of clinical suspicion, followed immediately by confirmatory marrow examination and avoidance, at all costs, of well-intentioned delays in anticipation that spontaneous recovery will occur. Specifically, multiple red cell and platelet transfusions are to be discouraged because immunization adversely affects the outcome after transplantation. Similarly, protracted and inappropriate administration of erythropoietin or recombinant growth factors is not rational, because, in controlled trials, they do no more than transiently raise counts without altering the natural history of the disease with contrasting experience being anecdotal.

Yet another important caveat is that hypoplasia, best quantitated by combining trephine biopsy with ferrokinetic studies, is excluded from this discussion because such patients will generally respond to androgenic and steroids. In the individual in whom aplasia has been correctly defined, matched sibling allogeneic bone marrow transplantation is the treatment of choice, particularly in children younger than 5 years. In these patients, immunosuppressive therapy produces very poor results. Outcome after grafting has been improved by the use of recombinant human growth factors, which have relatively few side effects and in controlled clinical trials have reduced morbidity and cost. Although platelet recovery with G-CSF and GM-CSF has been slow, this is likely to be reversed by the use of IL-3, -6, and -11, perhaps in conjunction with early-acting cytokines such as the stem cell factor. Since the first description, the principles of bone marrow transplantation have been largely standardized. Infusion of fractionated marrow is preceded by conditioning with cyclophosphamide as a single agent and is followed by graft rejection in up to 50% of patients, with little benefit derived from further conditioning with total nodal irradiation. It is noteworthy that in some of these individuals, autologous recovery may nevertheless occur, as reflected in their becoming chimeras.

The technique used for aspiration is important, and the rate of engraftment is best when the largest number of clonogenic precursors are obtained. After infusion, clonogenic precursors home to marrow niches or sometimes to extramedullary sites, as determined by recognition systems with galactosyl and mannose specificities. Approximately 14 days later, discrete clusters of hematopoietic tissues are evident. In most cases, these are polyclonal, but occasionally monoclonality exists, thereby proving that, under normal circumstances, single stem cells are able to repopulate both lymphoid and myeloid compartments. Of interest is the continuing debate about the origin of stromal cells, including the endothelium. Similarly, the role of adhesion molecules, and particularly, the influence of heparan sulfate in the matrix as determinants for engraftment are important areas in which further information is needed.

Morphologic reconstitution is generally easy to recognize, although early on it may also be present in the spleen, suggesting that substantial injury to the marrow has taken place during conditioning. This is consistent with the abnormal production of cytokines during this period. Furthermore, neutrophils may be dysfunctional and thus contribute to infection during the recovery phase. To some extent, these deficiencies can be overcome by quantitatively optimizing the graft and attempting to avoid exposure to agents that, applicable to autologous but not allografting, may damage the precursors.

Turning attention now to immunologic recovery, there are three
major issues. The first is that of graft failure or subsequent rejection, and here pancytopenias are found, especially when there is a mismatch between donor and recipient in ABO or Rh systems. This may be T-cell mediated and, in an HLA-DR restricted way, a specific subset that is CD3+, HNK1+, CD8+, and DR+, appears to be either in- 
hibited or responsible. Of relevance is that this particular phenotype is present at extremely low concentrations, but even so, has the requisite inhibitory capacity, which is perhaps related to the exquis- 
ite sensitivity of these lymphocytes being able to recognize host differ-
ences as small as a single amino acid. Second, recovery of immu-
nity is variable and requires vigilance to treat aggressively infections when they arise and, in the longer term, to consider suitable vacci-
nation programs. Third is the unique phenomenon of acute or 
chronic GvHD, in which incoming lymphocytes destroy skin kerati-
nocytes, biliary endothelium, and enterocytes, predominantly in the 
small bowel. The morbidity and mortality of the more severe 
grades, designated II through IV, are prohibitive and span a variety 
of immunosuppressive regimens. Initially this was based on a canine 
model, documenting benefit from methotrexate, although more re-
cent additions have included combinations with cyclosporin and 
and/or prednisone. In spite of a reduction in the incidence and severity of 
both acute and chronic GvHD, these remain major complications and 
and have led to the exploration of alternative approaches, primarily in the 
form of T-cell depletion. In most cases, monoclonal antibodies were 
administered to patients singly or as cocktails, with uneven results.

Although morbidity from GvHD diminished, this was offset by an 
increased incidence of graft loss. When these recipients also received 
Campath 1G intravenously both before and after the procedure, graft 
loss appears to be prevented. In our patients with aplastic anemia, 
graft rejection was initially encountered when first transplanted and a number of individuals required one or more retransplants. Our 
numbers are small; however, our outcome differs significantly from 
that of a much larger experience reported by the Aplastic Anemia Working Party. The addition of the same monoclonal antibody, 
given to the recipient around the time of the procedure, has over-
come this limitation. It is noteworthy that in this context, no other 
immunosuppressive agents are used. The discrepancy between some 
of the published results and our own may relate to our inclusion of 
total irradiation as a routine procedure. Although concerns have been 
raised about the use of this modality in patients who do not have 
malignant disease, they do not appear, for the moment, to be suffi-
cient to discontinue the practice.

When there is no suitable sibling to donate bone marrow, alternatives include the use of marrow from partially matched donors or 
from a matched, unrelated source. These approaches, however, carry a much higher incidence of rejection and GVHD. Nevertheless,
The use of ALG has been advocated as first-line therapy, but there are a number of caveats. Its outcome is less satisfactory when given to young girls. Furthermore, there is an association with the later development of clonal or malignant disease, including myelodysplasia, although the abnormal clone may disappear. Indeed, the same hematologic lesions may be present in patients who never received this form of treatment. Further complication is the occurrence of PNH, in which a complement-regulating glycoprotein renders erythrocytes exquisitely sensitive to lysis. Molecular techniques have established that these patients develop a glycosylphosphatidylinositol-anchoring defect, and if PNH were to be defined by this criterion, its incidence would probably be much higher. Furthermore, those with this molecular defect are likely to have a less good outcome when given immunosuppressive therapy. The link between PNH and myelodysplasia is controversial also because the preleukemia is thought by some to have arisen in the PNH clone and by others to derive separately from the injured marrow. Of note is the demonstration that a concurrent deficiency exists for the urokinase-type plasminogen activator receptor, which may account for the high incidence of venous thrombosis in these patients.

A further point is the relatively low response rate to ALG when it is used alone, and it should not be forgotten that this product leads to the development of serum sickness, in which severe arthralgia may be present. In an attempt to modulate these symptoms and to obtain an additional immunosuppressive effect, ALG was given with high-dose methylprednisolone. Given together, these drugs produce responses exceeding 70%, but the dose of steroid may well not be critical. A combination of ALG and anabolic androgens is effective beyond 4 months, particularly in female patients with low neutrophil counts. Unfortunately, this treatment has little benefit on short-term survival. The role of testosterone is additionally helpful in that it may reduce the amount of complement sensitivity and so perhaps influence outcome in those destined to develop PNH. Because cyclosporin is approximately equivalent to ALG with steroids, these three agents were used in a single regimen, with apparent benefit. However, the low response rates for their control group, for example, when compared to the Cape Town data, raise a question about the adequacy of the reference arm in the study by Frickhofen et al. When extended to a multicenter trial, it was shown that cyclosporin alone was approximately equivalent to ALG and steroids.

The critical study remains to be done. This would use ALG of proven efficacy with either standard or high-dose methylprednisolone, and patients would be randomized to receive an addition of cyclosporin or anabolic androgens. Until these data become available, the relative effect of the latter agents remains an open issue. For centers that have small patient numbers and therefore are unable to embark on randomized trials, it would be reasonable to join a multicenter study or to use the four drugs together, as is our current practice.

No discussion on the contemporary management of bone marrow failure would be complete without reference to the role of interleukins and stimulatory peptides. Anecdotal suggestions of bilineage response rests on long-term administration of the recombinant granulocyte growth-facilitating molecule to adults and children, although much larger than conventional doses may be needed. Additionally, the administration of stem cell factor provides results that, at least in vitro, are consistent with the defects residing at stem cell level. This contrasts with the failure to obtain benefit in the constitutional variants, such as that described by Fanconi, in which there is an intrinsic lesion of progenitor cells. In view of its early action in the differentiation pathway, this particular molecule, if it has any effect at all, is anticipated to exert this synergistically when given in a cocktail.

SECONDARY MARROW APLASIA

Systemic Lupus Erythematous

The classic syndrome is idiopathic and is considered to be autoimmune, in spite of hints at a viral etiology. A closely allied entity occurs with the administration of procainamide and prazotol, with other agents sometimes implicated. For the most part, hematologic defects are limited to peripheral blood and take the form of cytopenias. Only very rarely has aplasia or amegakaryocytic thrombocytopenia been reported.

Viral Infections

Hepatitis A typically causes mild leukopenia and thrombocytopenia, but aplasia has been recognized for some 40 years and, based on syngeneic allograft data, an autoimmune reaction is postulated. Hepatitis B was first implicated in 1978, with in vitro studies demonstrating infection of human bone marrow cells, although a causative mechanism remained obscure. The same syndrome has been documented in the non-A, non-B infection and may be transient or irreversible; aplasia has been reported after orthotopic liver transplantation for this particular viral disease. Currently, involvement by the type C virus is increasingly diagnosed. Hepatitis C is responsible in at least some cases and at present is probably underdiagnosed. In all of these individuals, the final common pathway is conjectural, but immunologic defects are thought to play a significant role, with opportunities to study pathogenesis in those areas such as Taiwan, where frequencies are high. Epstein-Barr virus has been reported to destroy hematopoiesis, as
has rubella, although much more rarely. Parvovirus typically produces a transient aplastic crisis, which may, on occasion, be persistent and irreversible.

The human immunodeficiency virus gives rise to red cell aplasia, but more ominously, this may extend to involve the whole marrow. The worldwide impact of this epidemic has led to extensive studies on hematopoiesis, with cytopenias being most common and attributable to abnormalities in humoral and cell-mediated pathways, in which the myelosuppressive effects of current treatment regimens may well aggravate the symptoms. Frustratingly, attempts to improve outcome with erythropoietin or a variety of growth factors have been, at best, transient.

Human herpesvirus 6 can cause chronic bone marrow suppression, but more often than not, chronic bone marrow suppression occurs concurrently in patients with acquired immunodeficiency disease.

**DRUGS**

Blood dyscrasias can be ascribed to many different and commonly used agents, although, not infrequently, their administration is unrecognized. In a number of cases, these cause aplasia but, fortunately, death seems to be relatively rare or underreported.

Chloramphenicol consistently damages the marrow if dosage is excessive, and there is little reason for this to occur. In contrast, a rare idiosyncratic variant in some individuals causes irreversible hematopoietic destruction and has a high mortality rate, with such genetically predisposed individuals difficult to anticipate, and even eye drops containing a small amount of chloramphenicol are sufficient to cause this lesion. The erythrocytic changes are well recognized and correlate with the rate at which a test dose of the antibiotic is cleared from the plasma. The first abnormalities are ultrastructurally demonstrated vacuoles in the pronormoblasts and immature myeloid cells, but these soon become evident on light microscopy. It is interesting that the clinical syndrome frequently has a period of jaundice that antedates the hematologic abnormalities and may lead to the mistaken diagnosis of viral hepatitis. The intraerythrocytic metabolic pathways are affected not only by the parent substance, chloramphenicol, but also by its derivatives, including thiaphenicol. These lesions have been demonstrated using marrow-culture studies or by examining the aminolevulinic acid synthetase pathway in rabbit reticulocytes. Chloramphenicol remains an excellent drug; but it is important to appreciate the risks, which can be significantly reduced by keeping within the prescribed total dose and concurrently monitoring patients with serum iron and percentage saturation of transferrin.

The H₂ receptor blockers, first in the form of metiamide, produced **TABLE 5. Miscellaneous aplasia-producing agents**

*In many cases, the evidence is poorly documented and anecdotal. Nevertheless, when prescribing any form of medication, the clinician should be aware of dose-related constraints, even genetically determined idiosyncratic constraints are impossible to anticipate.*

granulocytopenia and led to withdrawal of the agent. However, cimetidine and ranitidine are also capable of suppressing the marrow and may lead to agranulocytosis. It appears that these drugs act directly on the hematopoietic precursors, although irreversible marrow failure seems to be uncommon.

The antithymic drugs exemplified by azathioprine...
thimazol, cause aplasia. Such marrow damage should not arise with proper dosage and, because the damage is immunologically mediated, it is usually reversible.

Many other medications and an assortment of environmental insults have also been incriminated in the production of bone marrow failure (Table 5).

SUMMARY AND CONCLUSIONS

Any imbalance between requirements for mature blood cells and their supply, whether at the basal level or after stimulation by stress, is defined as bone marrow failure. Bone marrow failure can be thought of as a spectrum ranging from subtle alterations within a single lineage to gross and life-threatening pancytopenia due to aplasia. When all of the variants are considered, this entity occurs rather frequently. It follows that all practitioners need to remain vigilant to such a possibility in their patients and, once it is considered, can confirm the diagnosis by the use of relatively simple investigations. Thereafter, it is important to initiate appropriate supportive care and, should spontaneous resolution not take place, to plan for allogeneic bone marrow transplantation.

Because manifestations are protean, the different syndromes often appear at first sight to be unrelated. Each syndrome represents breakdown at a particular point on a common hematopoietic pathway that can usefully be described as the progenitor cell model.

Such a pathophysiologic approach is helpful because it begins by focusing on the peripheral blood and the marrow examination—two sets of morphologic criteria with which most physicians are familiar. From this vantage point, clonogenic assays and long-term culture techniques have revealed the influence of stimulatory peptides and their counterbalancing negative regulators. Both sets of molecules are generated by the stroma or the inductive microenvironment and are presented to their cognate receptors, which are expressed on the surface of hematopoietic progenitors. These membrane glycoproteins then transduce the signal through a series of cytoplasmic substrates to the nucleus. Some of these steps are, for the moment, obscure, but they lead to synthesis of a transcription factor that has a particular conformation or motif that binds to DNA. In this way, genes are activated, and their products direct further cellular function. Options range from entering the cycle to proliferate and mature, diversion to G₀, or programmed cell death. These fundamentals can be used to understand and classify clinical problems.

The first major subdivision is between those having constitutional or acquired defects. Of those with constitutional defects, some will manifest no further than to involve a single lineage in these patients, it is a matter of experience and fine judgment as to what intervention, if any, is appropriate. In others, there may be relentless progression to aplasia so that replacement of the defective organ is unavoidable.

In contrast, otherwise healthy individuals may be seen with anemia, leukopenia, or thrombocytopenia and a relatively normal marrow. In many instances, an immunologic mechanism is operative, exemplified by hemolytic anemia, drug-mediated agranulocytosis, or HIV-associated thrombocytopenia. This category is included in our broad definition for the sake of completeness.

Another group of patients considered to have idiopathic disease are those in whom global marrow function may be profoundly impaired, as with cytotoxic drug therapy, but in whom recovery is the rule. Untoward or unanticipated prolongation in the pancytopenia may occasionally be found, but care in a reverse-isolation unit coupled with judicious antibiotic administration is all that is required. It should be emphasized that only rarely will it be necessary to resort to the use of recombinant human growth factors or interleukins. It is mandatory that these valuable pharmacologic agents not be abused, as this is cost-ineffective and tarnishes their deservedly good reputation.

Penultimately, aplasia may arise suddenly and inexplicably. Once it is clear that spontaneous remission will not occur, allogeneic bone marrow transplantation is the treatment of choice. In some circumstances, this will not be possible, and although response can be obtained with antilymphocyte globulin in combination with immunosuppressive drugs and anabolic androgens, this is not always complete and may be complicated by the emergence of clonal hematopoiesis, including leukemia.

Two concluding comments are appropriate. First, when all these variants are considered, it is surprising how little attention this important topic has attracted. Nevertheless, order and a sensible classification can be imposed on the many eponymously characterized entities, based simply on defining the molecular level at which hematopoietic regulation is disrupted. This information allows a well-reasoned and cost-effective algorithm to be developed for management. Second, it is fitting that very different experimental approaches, carried out over decades, should start fitting together like the parts of a jigsaw puzzle to provide a solid foundation for clinical practice, with the beneficiary of these collaborative efforts being our patients.

ACKNOWLEDGMENTS

I thank Christine Dilling for her very great assistance in compiling the bibliography, Wayne Jacobs for the art work, and Jackie Davies for her dedication and professional help in the preparation and typing of this manuscript.

Severe Aplastic Anemia: A Prospective Study of the Effect of Early Marrow Transplantation on Acute Mortality

By Bruce M. Camitta, E. Donall Thomas, David G. Nether, George Santos, E. C. Gordon-Smith, Robert P. Gale, Joel M. Rappeport, and Rainer Starb

A prospective randomized trial of therapy for severe aplastic anemia was designed to compare early bone marrow transplantation with conventional treatments. All patients with a sibling matched at the major histocompatibility region were transplanted. Transplantation was performed within 17–100 (median 33) days of original diagnosis. Conventional treatments included transfusion support with or without androgens. Twenty-four of 36 patients entered on the transplant arm are alive after 4–20 (median 9) mo with full marrow reconstitution. Only two are limited by chronic graft-versus-host disease. In contrast only 12 of 31 conventionally treated patients are alive. Six of these survivors have improved, five incompletely. The 19 nontransplant deaths have occurred within 1–11 (median 3) mo of diagnosis. Compared to nontransplant regimens, early transplantation more effectively restores normal marrow function and decreases the acute mortality of severe marrow aplasia (p = 0.006). Pending longer follow-up, early marrow transplantation appears to be the most effective available treatment for severe aplastic anemia.

The appropriate treatment for aplastic anemia remains controversial. An effect of androgens in marrow aplasia was reported in 1961. However, despite several confirmatory studies, other investigators have been unable to demonstrate the efficacy of anabolic agents. These conflicting results were probably due to the small size of some series and to the use of historical rather than concurrent controls. In addition, patients were not uniformly stratified according to the severity of their presenting disease. When such stratification was performed, it was found that patients with severe disease usually had a short lethal course regardless of treatment. In contrast, patients with milder aplasia often had prolonged courses with more frequent responses to androgens.

Recent reports indicate that bone marrow transplantation from a histocompatible donor is effective therapy for severe aplastic anemia. Most patients have been transplanted after apparent failure of androgens and transfusion support. Delay of transplantation predisposes to morbidity from infection and hemorrhage and increases the chances of patient sensitization to blood products or to donor transplantation antigens. Thus, transplantation earlier in the course of severe aplasia, before failure of conventional treatments, might improve the chances of success.

This paper was prepared for the International Aplastic Anemia Study Group. See the Appendix for participating centers and grant support.

Blood, Vol. 48, No. 1 (July), 1976
In order to determine the relative merits of different therapies for severe aplastic anemia, a cooperative prospective randomized trial was designed. The objectives were (1) to compare the efficacy of early bone marrow transplantation with more conventional treatment, and (2) to evaluate (in patients given transfusion support) the role of androgens in treatment of severe marrow aplasia. This communication reports results relevant to the first question.

MATERIALS AND METHODS

Definition

To qualify as severely aplastic, patients had to have at least two of the following three peripheral blood values: (1) granulocytes < 500/cu mm (2) platelets < 20,000/cu mm and (3) reticulocytes < 1% (corrected for hematocrit). In addition the marrow had to be either markedly hypoplastic (< 25% of normal cellularity) or moderately hypoplastic (25%-30% of normal cellularity with < 30% of remaining cells being hematopoietic) as estimated from biopsies.

Histocompatibility Typing

As soon as possible after diagnosis the patient and all members of his/her family were typed for the serologically detected HLA-A and HLA-B antigens. Cells from HLA-A/HLA-B matched siblings were then studied with patient cells in mixed leukocyte culture (MLC). Non-reactivity confirmed matching at the HLA-D locus. All donors were compatible with recipients in these tests.

Eligibility and Patient Randomization

Only newly diagnosed cases of severe aplastic anemia were eligible for this study. Patients were observed for 10 days to determine the presence of an underlying illness, to establish baseline blood counts, to detect early spontaneous hematologic improvement, and to complete histocompatibility typing. During this time prednisone (10 mg/sq m/day) was given, in an attempt to detect underlying leukemia.21 Patients with pancytopenia due to nutritional deficiency, malignancy, preleukemia, myelofibrosis, or Fanconi's anemia and patients with other life-threatening diseases were excluded from the study.

The outline of the protocol is given in Fig. 1. All patients with matched siblings were scheduled to receive a marrow transplant. Patients without matched siblings were randomized to one of three arms: (1) no androgen, (2) oral androgen (oxymetholone), or (3) intramuscular androgens (nandrolone decanoate).

![Fig. 1. Randomization: See text for neontransplant rerandomization criteria.](image)
Transplantation Procedures

Protocols for pretransplant immunosuppression are given in Fig. 2. The rationales for and details of doses and schedules used have been previously published. Cyclophosphamide (CY) was used alone for conditioning for engraftment, except in patients thought to be presensitized to their donors or who had rejected a prior marrow graft. Antithymocyte serum could be used in place of antithymocyte globulin (+).

Patient Care

Transplanted and nontransplanted patients were given transfusions of blood components as required. HLA-matched products were utilized for refractory patients (when available). All patients were watched carefully for infection and treated with appropriate antibiotics when infection occurred. Nontransplanted cases were managed as outpatients except for the frequent complications. Prednisone, 10 mg/kg/day, was continued in a few nontransplanted cases at the discretion of the patient’s physician. Isolation procedures for transplanted patients varied from simple reverse precautions to laminar air flow isolation with sterile diet and gut sterilization depending on institutional facilities.

Criteria for Improvement

Complete response was defined as the return of all blood counts to normal values. Partial response meant improvement so that the patient no longer qualified for severe status and no longer required transfusions.

Informed Consent

Informed consent of the patient, the donors, and the involved family members was obtained utilizing procedures and consent forms approved by the ethical review committees of the various institutions involved.

RESULTS

The transplanted and nontransplanted patients were compared for factors felt to have prognostic significance in aplastic anemia (Table 1). The groups were comparable except for four patients over the age of 45 in the nontransplant group.

Transplanted Patients

Thirty-six patients entered the transplant arm during the first year of the study (Table 2). Twenty-six received CY alone and ten CY plus ATG and PCB in preparation for engraftment. Although the protocol specified that pretransplant immunosuppression begin by day 21, suppression usually began later (median 33, range 12–97 days). These delays were due to practical problems involved in diagnosis, histocompatibility typing, informed consent, and (not infrequently) waiting for an available bed at a transplantation center.

Two patients died of sepsis during pretransplant immunosuppression. The remaining 34 patients were successfully engrafted. Twenty-four of these 34 (67%) of all patients entered on the transplant arm are now alive with complete marrow restoration after 4–20 (median 9) mo (Table 3). Two long-term survivors are physically limited by severe chronic GVHD. The others returned to regular activities within 3–12 mo after transplantation. In this limited number of patients, there was no correlation of transplant success with patient age or sex, etiology of aplasia, transplant center, or transplantation regimen.

CAMITTA ET AL.
Eight patients rejected their grafts within 4-5 wk after transplantation. Another lost marrow activity during adenine arabinoside therapy begun 23 days post-transplantation for disseminated Herpes zoster. One of these nine died before retransplantation could be attempted. A second patient developed increasing granulocytes during retransplant immunosuppression with ATG and PCB. CY and marrow were not administered. Complete autologous (documented by sex chromosome analysis) marrow recovery ensued. Seven patients who rejected their initial grafts were retransplanted with two successes.

**Nontransplanted Patients**

Thirty-one patients were assigned to nontransplant regimens: 7 NO, 17 PO, and 7 IM androgens. Results to date have been similar in these small groups and they are reported together (Table 3). Seven patients improved, (one complete and six partial), but one partial response was only transient. Responses began from 1 to 3 mo after randomization. Each responder showed improvement in all three cell lines. Compared to transplanted patients, the response rate in nontransplanted patients was significantly decreased (p < 0.001, Wilcoxon).

Nineteen nontransplanted patients died. Time to death was 1.11 (median 3) mo after randomization. The cause of death was hemorrhage in ten, sepsis in seven, and a combination of sepsis plus hemorrhage in two. Figure 3 is a life-table plot of survival of transplanted and nontransplanted patients. Compared with transplanted patients, mortality in nontransplanted patients was significantly increased (p = 0.006, Wilcoxon).

![Fig. 3. Life table plot of the effect of treatment on survival in severe aplastic anemia. Triangles indicate duration of follow-up of current survivors.](image-url)
Nonrandomized Patients

Two patients improved before randomization. One relapsed after 2 mo and died of hemorrhage. The second relapsed after 4 mo and remains aplastic.

DISCUSSION

The present study has confirmed the short lethal course of most patients with severe aplastic anemia when treated with conventional nontransplant regimens. In contrast, mortality in transplanted individuals was significantly decreased. Although we did not evaluate early versus late transplantation, the results reported here were superior to the prior series in which most patients were transplanted after failure of conventional treatment. It would appear that the small chance of early recovery on conventional therapy was probably more than offset by the morbidity, mortality, and sensitization by transfusion that delay must entail.

This study did not evaluate the role of intensive support in the management of severe aplastic anemia. Marrow transplant patients require intensive support during pretransplant immunosuppression and during the 2–3-wk period of total aplasia before the transplanted marrow begins to function. Some of our transplanted cases were managed in protected environments and received oral non-absorbable antibiotics. Such regimens have decreased morbidity in myelosuppressed leukemic patients, but their value in a transplant setting is not yet established. However, since hematologic recovery in severe aplasia is usually slow, if it occurs at all, short periods of isolation would probably have little effect on eventual mortality of nontransplanted patients. The physical, financial, and personnel resources required for trials of long-term intensive environmental support of large numbers of nontransplanted severely aplastic patients are not currently available.

The better outcome of our transplanted patients might also be attributed to superior granulocyte and platelet transfusion support available at transplant centers. However, nontransplanted individuals managed at transplant centers fared no better than similar patients treated elsewhere. However, it is still possible that mortality in nontransplanted severe aplastic anemia could be decreased by wider availability of HLA matched nonfamily blood product support.

The importance of long-term follow-up of surviving patients with aplastic anemia must be emphasized. Patients who recover after conventional treatment may relapse and die months or years later. Similarly, although promising in the short-term management of severe aplasia, transplantation may have adverse long-term sequelae that have not yet been encountered. Nevertheless, in the Seattle series of 23 aplastic anemia patients who survived more than 1 yr after allogeneic marrow transplantation, only one patient has died, one has chronic GVHD, and one has almost completely recovered from chronic GVHD. The other 20 patients are in good health with normal marrow function after 2 to 4 yr follow-up.

Despite the above caveats, this study shows that prompt bone marrow transplantation significantly decreases the early mortality of severe aplastic anemia.
That finding in itself is an important reason for application of this complex treatment in a devastating disease.

Effectiveness of Immunosuppressive Therapy in Older Patients with Aplastic Anemia

André Tichelli, MD; Gérard Socié, MD; Michel Henry-Amar, MD; Judith Marsh, MD; Jakob Passweg, MD; Hubert Schrenzmeier, MD; Shaun McCann, MD; Jill Hows, MD; Per Liujman, MD; Pedro Martin, MD; Aruna Raghavachar, MD; Anna Luceaciuili, MD; Alois Gratwohl, MD; and Andrea Bacigalupo, MD, for the European Group for Blood and Marrow Transplantation Severe Aplastic Anaemia Working Party

Background: Immunosuppressive therapy has been used for successful treatment of severe aplastic anemia, but little information is available on outcome in older patients.

Objective: To evaluate outcome in patients older than 50 years of age who received immunosuppressive therapy for aplastic anemia.

Design: Retrospective cohort study.

Setting: 56 centers of the European Group for Blood and Marrow Transplantation (EBMT).

Patients: 810 patients with aplastic anemia reported between 1974 and 1997. Patients were evaluated according to age group: 60 years of age or older (n = 127), 50 to 59 years of age (n = 115), and 20 to 49 years of age (n = 568; reference group).

Intervention: Antilymphocyte globulin, cyclosporine, or both.

Measurements: Survival, cause of death, response to treatment, relapse rate, and risk for late complications were analyzed in all patients and by age group.

Results: The 5-year survival rate was 57% (95% CI, 46% to 66%) in patients 50 to 59 years of age and 50% (CI, 39% to 60%) in patients 60 years of age or older compared with 72% (CI, 58% to 76%) in patients younger than 50 years of age (P < 0.001). Response to therapy, relapse rate, and risk for clonal complications were similar in all three age groups (P > 0.2). Age was significantly associated with an increased risk for death (relative risk compared with patients 20 to 49 years of age, 1.80 [CI, 1.29 to 2.52] for patients 50 to 59 years of age and 2.57 [CI, 1.87 to 3.53] for patients ≥ 60 years of age), mainly because of bleeding or infection (P = 0.02). Response to immunosuppressive therapy in all patients at 12 months was 62% (CI, 58% to 66%); no difference was seen among the age groups in multivariate analysis (P > 0.2). Sixty-six of the 379 responding patients (17%) subsequently had relapse. The risk for clonal disorders at 10 years was 20% (CI, 15% to 27%).

Conclusions: Response to immunosuppression in aplastic anemia is independent of age, but treatment is associated with increased mortality in older patients.

Aplastic anemia is defined as peripheral blood pancytopenia associated with unexplained hypopcellularity of the bone marrow without excess of blast cells. If aplastic anemia goes untreated, patients die of bleeding or infections caused by aplasia. Bone marrow transplantation and immunosuppressive treatment have improved outcome, with remission rates of 60% to 80% (1–4). The decision between immunosuppressive therapy and bone marrow transplantation depends largely on the availability of a bone marrow donor.

In many centers, the upper age limit for allogeneic bone marrow transplantation in patients with aplastic anemia has been set at 40 to 55 years (5–8). This limit is traditionally less stringent for immunosuppressive treatment (2, 9–14). However, data are scarce, and no study has specifically addressed outcomes in older patients with aplastic anemia. After immunosuppressive treatment, hematologic recovery is slow and often incomplete (15), and clonal transformations, such as myelodysplastic syndromes, paroxysmal nocturnal hemoglobinuria, or solid tumor, may occur (16–21). As a consequence, fear of life-threatening complications during prolonged aplasia as well as concerns about increased risk for clonal transformations, particularly in older patients, prevail.

We sought to 1) determine the outcome of patients 50 years of age or older receiving immunosuppressive therapy for aplastic anemia and 2) investigate the response and complication rate among these patients compared with that of younger patients.

Methods

Design

This retrospective cohort study used data from 56 centers reporting to the European Group for Blood and Marrow Transplantation (EBMT) Severe Aplastic Anaemia Working Party between 1974 and 1997. Collected data included demographic information, pretreatment blood values, type of immunosuppressive therapy, date and number of courses of immunosuppressive therapy, response to therapy, date of last known vital status, cause of death, and

©1999 American College of Physicians–American Society of Internal Medicine
type and date of late complications for every patient. Follow-up was completed by June 1997.

Patients

We included 810 patients from the EBMT Registry in whom acquired severe aplastic anemia was diagnosed according to current criteria (22), adequate immunosuppressive therapy (antilymphocyte globulin, cyclosporine, or both) was instituted, and bone marrow transplantation was not performed as second-line treatment. For the purpose of this analysis, patients were separated into three age groups: 50 to 59 years of age (n = 115), 60 years of age or older (n = 127), and 20 to 49 years of age (n = 568). The latter patients served as the reference group. The Severe Aplastic Anemia Working Party regularly stipulates the definitions for disease and late complications to its participants. No central slide review was performed.

Outcome Measures

Outcome measures analyzed were overall survival, causes of death, response to immunosuppressive therapy, rate of relapse in responders, and late complications. Late complications were defined as secondary development of a myelodysplastic syndrome, leukemia, paroxysmal nocturnal hemoglobinuria, or solid tumor. Cause of death was classified as related to aplastic anemia or its treatment (bleeding or infection), secondary to late complications, unrelated to aplastic anemia, or unknown. Response to immunosuppressive therapy was defined as reaching complete independence from transfusions. Relapse was defined as dependence on transfusions after 3 months of independence from transfusions.

Statistical Analysis

Group differences were analyzed by using the Kruskal-Wallis test for continuous variables and the Fisher exact test for categorical variables. Survival probabilities were calculated by using the Kaplan-Meier estimator. Time at risk started at the date of first treatment and ended at the date of an event (response to immunosuppressive therapy, relapse, complication, or death) or the date of last known vital status, whichever came first. We calculated 95% CIs of survival probabilities according to the method of Rothman and Boice. Variables significantly associated with the risk for death were assessed by univariate and multivariate analysis. A two-sided log-rank test was used for comparisons. Because patients were treated at 56 centers, the possibility that center-specific differences in supportive care and patient selection would bias the results cannot be excluded. Therefore, univariate survival comparisons between age groups were made by using the log-rank test stratified on center. Sixty-eight percent of patients were treated at 6 centers (39 to 191 patients per center); 32% of patients were treated at 50 centers (1 to 24 patients per center). Grouping the latter patients led to 7 centers that were used for stratification. Proportional hazards regression analysis was used to assess the effect of known risk factors on survival. Variables considered were sex, age group, disease severity (reflected by neutrophil count at diagnosis), type of treatment (antilymphocyte globulin, cyclosporine, or both), and calendar year (1974 to 1979, 1980 to 1989, or 1990 to 1997). A backward stepwise procedure was used to eliminate nonsignificant variables (cut-off value, P > 0.2).

To adjust for the inherently increased risk for death with older age, the number of deaths observed after immunosuppressive treatment for aplastic anemia was compared with the expected number of deaths in a general European population matched for sex and age. The standardized mortality ratio (observed deaths/expected deaths) was calculated for each year after treatment. The 95% CI of the standardized mortality ratio was calculated by assuming a Poisson distribution of the number of observed deaths. The changes in risk for events over time were computed for the whole study sample as well as for the three groups separately. Statistical analysis was performed by using the SPSS statistical program (SPSS for Windows, release 6.1, SPSS, Inc., Chicago, Illinois).

Role of the Funding Source

The funding source had no role in the collection, analysis, or interpretation of the data or in the decision to submit the paper for publication.

Results

Patients

Demographic and disease characteristics of all 810 patients are listed in Table 1. Significant differences were seen among age groups. More female patients were 60 years of age or older, and more men were in the reference group (P < 0.001). Fewer cases of viral-associated aplastic anemia were seen in patients 50 to 59 years of age, and no cases were seen in those 60 years of age or older (P = 0.008). More patients 60 years of age or older received cyclosporine alone, and more patients in the reference group received antilymphocyte globulin (P < 0.001). The proportion of older patients increased continuously over time: Until 1979, 13% of the patients were 50 years of age or older; this proportion increased to 27% from 1980 to 1989 and to 38% since 1990. Hence, the median follow-up

* Number of mortal cases

was 47 months for surviving patients 50 to 59 years of age and 31 months for patients 60 years of age or older compared with 44 months in reference patients (P < 0.001). Severity of disease, as reflected by neutrophil counts at diagnosis and number of courses of immunosuppressive treatment, did not significantly differ among the groups.

Multiple interrelations were found among calendar year, type of immunosuppressive therapy, neutrophil count at diagnosis, and age. Calendar year was significantly associated with type of treatment (Table 1). Before 1980, all patients received antithymocyte globulin alone; since 1990, 51% patients received antithymocyte globulin and cyclosporine, 31% received antithymocyte globulin alone, and 18% received cyclosporine alone (P < 0.001). Since 1990, however, the type of immunosuppressive therapy was not equally distributed among the age groups (Table 1). Patients 60 years of age or older more often received cyclosporine alone (32%), whereas most patients in the reference group received a combination of antithymocyte globulin and cyclosporine (61%) (P < 0.001). Finally, disease severity was associated with age and calendar year.

Before 1980, neutrophil counts less than 0.2 x 10^9 cells/L were encountered in 44% of patients in the reference group. 20% of patients 50 to 59 years of age, and none of the patients 60 years of age or older. Since 1990, low neutrophil counts were observed in 19% of patients in the reference group. 15% of patients 50 to 59 years of age, and 55% of patients 60 years of age or older.

Survival

At the time of last follow-up, 552 of 810 patients (68%) were alive and 258 (32%) had died (survival rate at 5 years, 67% [95% CI, 65% to 69%]). Survival was influenced by age: The older the patients were at diagnosis, the lower the survival rate (Table 2). Survival also improved over time; the 5-year survival rate was 52% (CI, 39% to 64%) in patients treated before 1980 compared with 65% (CI, 60% to 69%) in patients treated from 1980 to 1989 and 73% (CI, 66% to 88%) in patients treated since 1990 (P < 0.001). This improvement was most pronounced in the reference group (P < 0.001) and was not statistically significant in patients 60 years of age or older (Table 2).

* Reference group
† Two-year rate not adjusted on death rate
‡ Less than 2 patients were at risk.

Causes of Death

Two hundred fifty-eight patients (32%) died. The mortality rate was 39% (45 of 115) for patients 50 to 59 years of age and 43% (55 of 127) for patients 60 years of age or older compared with 22% (158 of 684) for patients in the reference group. The main cause of death was directly related to aplastic anemia: Bleeding or infection occurred in 205 of 258 patients (79%). Thirty of 258 patients (12%) died of late complications, and 23 of 258 patients (9%) died of causes unrelated to aplastic anemia or its treatment. In all three age groups, bleeding or infection was the main cause of death (Table 3). The excess of mortality in older patients was due to aplasia-related deaths (mortality rate: 32% in patients 50 to 59 years of age; and 43% in patients 60 years of age and older: P < 0.02) and to causes unrelated to the disease or its treatment (mortality rate: 13% in patients 50 to 59 years of age, 4% in patients 60 years of age, and 2% in patients 20 to 49 years of age: P = 0.0019) but not to late complications (4% for all three age groups; P > 0.2).

Response to Immunosuppressive Therapy, Relapse of Aplastic Anemia, and Late Complications

Of 810 patients, 721 (89%) were evaluable for hematologic response. Of these patients, 379 (53%) responded to therapy and reached independence from transfusion. Response to therapy was slow: The median time to independence from transfusion was 6 months. Probability of response to immunosuppressive therapy was 11% (CI: 9% to 14%) at 1 month, 38% (CI: 33% to 42%) at 3 months, 48% (CI: 44% to 52%) at 6 months, and 62% (CI: 58% to 65%) at 12 months (Table 3). In univariate analysis, the probability of response was slightly lower in patients 60 years of age or older than in patients in the reference group (P = 0.0287); this difference was not significant in multivariate analysis (P > 0.2).

Relapse occurred in 66 of the 379 patients who reached independence from transfusion. The cumulative probability of relapse was 21% (CI: 17% to 26%) at 5 years (Table 3). The three age groups did not differ in this regard (P > 0.2).

Seventy of the 810 patients (9%) developed a late complication. Twenty-five patients had a myelodysplastic syndrome or leukemia, 28 patients had a paroxysmal nocturnal hemoglobinuria, 14 patients had a solid tumor, 2 patients had paroxysmal nocturnal hemoglobinuria and myelodysplastic syndrome, and 1 patient had solid tumor and myelodysplastic syndrome (Table 3). The cumulative probability of a late clonal disorder at 10 years was 20% (CI: 15% to 27%). The three age groups did not differ for rate of late complications (P > 0.2).

Risk Factor Analysis

Factors influencing survival, as assessed by univariate analysis, are summarized in Table 2. In any age group, a neutrophil count less than 0.2 x 10^9 cells/L was associated with a lower survival rate (P = 0.01). The effect of age on survival persisted for the degree of neutropenia (Table 2). Significant differences for calendar year of treatment were seen in patients 50 to 59 years of age (P = 0.03) and in the reference group (P < 0.001). In patients 60 years of age or older, survival did not differ significantly by year of treatment (P > 0.2). In the refer-
ence group only, combination therapy with antilymphocytic globulin and cyclosporine was associated with increased survival compared with antilymphocytic globulin therapy alone or cyclosporine therapy alone (P = 0.0018). Sex was not associated with survival. Data analyzed with and without adjustment on center did not differ, excluding center-specific differences of the results (Table 2).

Multivariate analysis confirmed an increased relative risk for death in patients 50 to 59 years of age (relative risk, 1.80 [CI, 1.29 to 2.52]; P < 0.001) and those 60 years of age or older (relative risk, 2.57 [CI, 1.87 to 3.53]; P < 0.001) compared with patients in the reference group. Other significant covariates were a neutrophil count less than 0.2 x 10^9 cells/L (relative risk, 3.41 [CI, 2.50 to 4.67]; P < 0.001), a neutrophil count of 0.20 to 0.50 x 10^9 cells/L (relative risk, 1.47 [CI, 1.06 to 2.04]; P = 0.019), and treatment before 1990 (relative risk, 1.87 [CI, 1.37 to 2.50]; P < 0.001). The relative risk for death was not increased according to sex, type of treatment, or number of courses of immunosuppressive therapy. No significant interactions were seen among age group, neutrophil count at diagnosis, and calendar year. When calendar year was excluded as a risk factor, the risk for death was higher in patients who received antilymphocytic globulin alone (relative risk, 1.52 [CI, 1.08 to 2.15]; P = 0.017) than in those who received antilymphocytic globulin and cyclosporine (baseline relative risk, 1.0). The risk for death among patients treated with cyclosporine alone was not significantly increased (relative risk, 1.33 [CI, 0.72 to 2.44]; P > 0.2). The 5-year survival curves by age group adjusted for neutrophil count and calendar year of treatment are shown in the Figure.

Comparison of Patients with the General Population
The standardized mortality ratio observed in all patients relative to that expected in the general population was 18.64 (CI, 16 to 21; P < 0.001) for a total of 258 observed deaths. The standardized mortality ratio was highest in the first year (60.49 [CI, 52 to 70]); it decreased progressively during the first decade and remained between 5 and 10 in long-

P < 0.0003 between patients older than 60 years of age and patients 20 to 49 years of age.
term survivors (>10 years of follow-up). The standardized mortality ratio decreased with increasing age (Table 4). It was highest in the reference group (33.69 [CI, 29 to 39]), intermediate in patients 50 to 59 years of age (15.75 [CI, 11 to 20]), and lowest in patients 60 years of age or older (9.05 [CI, 6.7 to 12]). In all three age groups, a similar decrease in the standardized mortality ratio was observed over time from the start of immunosuppressive therapy.

Because the year in which treatment was started influenced survival (Table 2), the standardized mortality ratio was also analyzed by calendar period and by calendar period and age group. Standardized mortality ratios were 28.37 (CI, 20 to 40) in 1974 to 1979, 18.63 (CI, 16 to 21.6) in 1980 to 1989, and 14.79 (CI, 10.9 to 19.6) in 1990 to 1997. In 1980 to 1989, standardized mortality ratios were 36.17 (CI, 30 to 43), 13.38 (CI, 9.1 to 19), and 7.64 (CI, 5.1 to 11) in patients aged 20 to 49 years, 50 to 59 years, and 60 years or older, respectively. In 1990 to 1997, the standardized mortality ratios were 24.05 (CI, 15.6 to 40) in patients aged 20 to 49 years, 17.04 (CI, 8.1 to 31) in patients aged 50 to 59 years, and 11.31 (CI, 7.2 to 17) in patients aged 60 years or older.

**Discussion**

This retrospective, multicenter study, based on data from 810 patients, shows that response of aplastic anemia after immunosuppressive therapy is independent of patient age at time of treatment. However, survival differs by age; rates were 57% in patients 50 to 59 years of age and 50% in patients 60 years of age or older compared with 72% in patients 20 to 49 years of age. The relative risk for death was 1.83 in patients 50 to 59 years of age and 2.52 in patients 60 years of age or older. At any age, deaths were mainly due to the primary disease (bleeding and infection). In patients whose disease responded to immunosuppressive therapy, the relapse rate and the probability of late complications, such as the myelodysplastic syndrome, leukemia, paroxysmal nocturnal hemoglobinuria, or solid tumors, did not differ by age. The probability of reaching independence from transfusion at 12 months was greater than 50% for patients at any age.

The effect of age on survival is mainly disease related and is most pronounced in the first year after treatment. Thirty-two percent of patients 50 years of age or older died of hemorrhage or infectious complications compared with 23% of patients in the reference group. Severity of disease was not more pronounced in older age groups, but patients 50 years of age or older are less likely to tolerate the consequences of bleeding and infection, which complicate the management of older patients undergoing immunosuppressive therapy. To evaluate the contribution of expected age-related deaths to the decrease of survival after immunosuppressive

*Reference group.*
therapy in older patients, the mortality rate was compared with that of a general population matched for sex and age. Compared with the general population, the risk for death was elevated at all times and in all age groups; the highest ratios were observed in the first year after treatment. Compared with younger patients, older patients had a lower standardized mortality ratio because of the inherent higher risk for death in elderly healthy persons. Therefore, to some extent at least, the decrease in survival among older patients is due to the deaths that can be expected in older persons in a general population.

As for bone marrow transplantation (4, 7, 23), outcome after immunosuppressive therapy has improved over the years from a 5-year survival rate of 52% before 1980 to a rate of 73% since 1990. This improvement in outcome is more pronounced in young patients and is marginal in patients 50 years of age or older. We assume that changes in type of immunosuppressive therapy and patient selection partially explain the strong year-of-treatment effect. Since 1990, overall, the use of combined immunosuppressive therapy with antithymocyte globulin and cyclosporine has increased, whereas most older patients received cyclosporine alone. In a randomized study, combined treatment was shown to be more effective than antithymocyte globulin alone (10), but no difference was found between antithymocyte globulin alone or cyclosporine alone (24). Patient selection has changed as well: Before 1980, younger patients with very low neutrophil counts were usually treated; since 1990, more older patients with less severe disease received immunosuppressive therapy. Apparently, with increasing experience, centers have progressively increased their age limit for immunosuppressive therapy and have begun to institute treatment earlier in the course of disease. Our results contrast with those of a recent single-center study from the Seattle Bone Marrow Transplant Team (25) in which the year of treatment did not affect survival in 227 patients treated with immunosuppressive therapy. In that series, however, cyclosporine was not included in the antithymocyte globulin-based treatment regimen, and the observation time ended in 1991.

Previous studies have reported severity of disease as the main factor affecting outcome in patients treated with immunosuppressive therapy (12, 25). We confirmed the worse prognosis of patients with very severe disease; the relative risk for poor outcome was 3.36 in patients with neutrophil counts less than $0.2 \times 10^9$ cells/L and 1.47 in those with counts between 0.2 and $0.5 \times 10^9$ cells/L compared with patients with higher neutrophil counts. Data on the effect of age on outcome of patients treated with immunosuppressive therapy are sparse. They are mostly focused on children or younger adults (9, 25, 26), and patients 50 years of age or older have not been specifically evaluated. We show that in all age groups, survival is worst in patients with very low neutrophil counts at diagnosis. However, in patients 60 years of age or older, higher neutrophil counts are less clearly associated with outcome, suggesting that increasing age partially eliminates the effect of severity of the disease. No effect of age or disease severity on the development of late complications was seen, despite the fact that older patients are expected to develop more malignant disorders and despite the known increased risk for late clonal disorder among patients with aplastic anemia (17, 19, 27-31).

Some limitations apply to our study, largely because of the retrospective, multicenter character of the analysis. It covered a 23-year period and included 56 participating centers; during this time, changes occurred in supportive care, and concomitant drugs, such as androgens, corticosteroids, or growth factors, have often been administered with immunosuppressive therapy. Different brands and doses of antithymocyte globulin and cyclosporine were administered by the centers. Although the repercussions of these variables on the outcome of patients with aplastic anemia remain largely undetermined, these factors may affect the results of therapy (3, 32-34). Furthermore, potential confounding due to center effect was assessed in part by stratifying the survival comparisons on large centers between age groups (after the small centers were grouped). Finally, younger patients are more often selected for bone marrow transplantation when a donor is available. This selection may bias the reference group and affect our data.

Despite these limitations, immunosuppression is a feasible and effective treatment in older patients,
and there is no reason to withhold treatment in older patients with aplastic anaemia solely because of their age. The decision to treat older patients should depend on the medical condition of the individual patient rather than a fixed age limit.

Summary:

Outcome results of observational databases are frequently criticized as relying on incomplete information from incomplete patient populations. Few data are available to dispute these arguments of selection bias. The European Group for Blood and Marrow transplantation (EBMT) decided to address this question by evaluating the hematopoietic stem cell transplants performed in 1993. A comprehensive survey was launched in an effort to collect informations on all transplants for hematological malignancies performed throughout Europe during the year 1993. The main goals of this effort were to compare the group of spontaneously reported patients with the group of retrospectively solicited patients, and to give an accurate estimate of the outcome of all patients. For the year 1993, the annual EBMT activity survey indicated 6336 transplants performed for hematological malignancies in Europe. A total of 5651 transplants could be analyzed; 2595 were reported spontaneously by the teams (group A) and 3056 were retrieved on solicitation (group B). Patients and transplant characteristics for group A and B were very similar for most parameters with a few exceptions. There was no statistical difference for outcome at 3 years between groups A and B: disease-free survival (DFS) was 45 ± 1% and 44 ± 1%, relapse incidence (RI) 41 ± 1% and 42 ± 1%, transplant-related mortality (TRM) 23 ± 1% and 23 ± 1%, and overall survival (OS) 54 ± 1% and 55 ± 1%, respectively, for group A and group B. The real outcome at 3 years for the 5651 patients (group A + group B) transplanted in 1993 was 44 ± 1%, 41 ± 1%, 23 ± 1%, and 54 ± 1%, for DFS, RI, TRM and OS, respectively. The outcome at 3 years by transplant modality, autologous or allogeneic transplants, and by disease categories showed no difference between groups A and B.

Bone Marrow Transplantation (2002) 30, 637–643. doi:10.1038/sj.bmt.1703712

Keywords: hematopoietic stem cell transplantation; observational vs solicited data; actual outcome

A considerable number of scientific observations and analyses have been obtained from data collected retrospectively at centralized registries, which have contributed to the progress of medicine in various ways. In the field of hematopoietic stem cell transplantation, information for the past 20 years has been obtained essentially from two registries, the International Bone Marrow Transplantation Registry (IBMTR)1,2 based in Milwaukee (USA), and the disease-oriented registries of the European Group for Blood and Marrow transplantation (EBMT)3–7 handled by working parties in various locations throughout Europe with centralized management offices in Paris and London. These registries have contributed to the identification of numerous prognostic factors for the treatment of various diseases and to the design of technical improvements for successful transplants. Several prospective randomized studies have been built from and have indeed confirmed many observations first obtained from the registries.

Analyses from registries have been criticized as relying on suboptimal and nonconsecutive data reporting from voluntary teams only, with lack of internal or outside data quality controls. Suspicion has been raised that reported data are biased and have not in fact been an objective reflection of the reality.

The EBMT has two independent data collection procedures. The first, the EBMT activity survey has provided information on the total number of patients transplanted in Europe by each team, year by year, since 1990, according to diagnosis, donor type and stem cell source. The second has consisted of collecting detailed information on patients, diseases, transplant and outcome for retrospective scientific
analyses. This second procedure has not concerned all transplants and has depended on interest, commitment and possibilities of individual teams, on a regular voluntary basis.

In 1995, a comprehensive survey was launched in an effort to collect standardized information on all transplants for all diseases performed throughout Europe during the year 1993. The main goals of this effort were to compare the group of patients reported spontaneously with the group of those solicited retrospectively and to give an accurate estimate of outcome following autologous or allogeneic hematopoietic stem cell transplantation for hematological malignancies by providing a precise picture of what really occurred to these patients transplanted in Europe during the year 1993.

Patients and methods

Study design

This is a retrospective study which focused on patients transplanted with autologous or allogeneic hematopoietic stem cells in 1993 for hematological malignancies.

The first endpoint was to assess and to compare two separate cohorts of patients: a group of patients whose data were present in the database and were spontaneously reported by the teams on a voluntary basis (group A, spontaneous group) and a group of patients whose data were retrieved on solicitation by the study committee (group B, solicited group). Information on missing data was obtained from the EBMT activity survey 1993.4

The second endpoint was to give the real outcome of patients with hematological malignancies transplanted with autologous or allogeneic hematopoietic stem cells in Europe in 1993.

For the year 1993, the annual EBMT activity survey indicated 6336 hematopoietic transplants performed in Europe for hematological malignancies, consisting of 3557 autologous transplants and 2779 allogeneic transplants.

Of these 6336 transplants, 3172 (50.06%) were reported spontaneously; 3164 transplants (49.94%) were missing. EBMT teams were requested to forward the missing information for all patients not yet reported and at the same time to give an updated follow-up for all patients. Teams were contacted repeatedly by the investigators until delivery of the full data.

Data collection

Data were collected by standardized questionnaire or electronic database system according to the Minimum Essential Data A form which includes information on patient identification, disease characteristics, transplant details on donor type, stem cell source and minimal information on outcome.

Definition of endpoints

Both groups were compared for distribution of patients and disease characteristics including patient age, gender, diagnosis, stage of disease at transplant, time from diagnosis to transplant (days), source of stem cells and total body irradiation (TBI) in the conditioning regimen.

Outcome analysis concentrated on probabilities of survival (OS), transplant-related mortality (TRM), relapse incidence (RI) and disease-free survival (DFS). DFS was defined as survival without evidence of relapse, the event under study being death or relapse. To evaluate the probability of RI, patients dying either from direct toxicity or from any other cause not related to leukemia were censored. TRM was defined as death while in complete remission. Patients were censored at the time of relapse or at the last follow-up.4 Probabilities at 3 years were evaluated first for all patients transplanted in 1993 whatever the type of transplant and disease category, then separately for autologous and allogeneic transplantation whatever the disease category, and finally for autologous and allogeneic transplantation by disease category. For each of these evaluations results were given the population A and B. Outcome between population A and B was compared.

Outcomes for allogeneic transplantation were separated between outcome of genoidentical allogeneic transplants and outcome of other allogeneic transplants comprising syngeneic, other family related and unrelated allogeneic transplants. When the number of patients in a subgroup was too small (below 30), outcome was not analyzed. To avoid false interpretations, we used the two-tailed $P$ values.

Statistical analysis

All analyses were performed with the SPSS computer program (SPSS Inc, Chicago, IL, USA). Values reported for quantitative variables were median and range. Comparisons of the two groups A and B were with the chi-square and the Mann–Whitney $U$-test. DFS, RI, TRM and OS were estimated by the product-limit method.9 The significance of differences between curves was estimated by the log-rank test (Mantel–Cox).

Results

Population

By June 1998, a total of 5945 patient data forms had been collected from 323 teams in Europe (see appendix) corresponding to 93.8% of the 6336 transplants reported in 1993. From these 5945 transplants, 294 second or subsequent transplants were removed for the analysis. The final analysis was restricted to a population of 5651 patients with first transplants: 2595 patients in group A and 3056 patients in group B.

Distribution

The total population (A + B) of 5651 patients consisted of 60% males and 40% females, with a median age of 34 years (range: 1–70); 16% were children (age ≤16 years old). Autologous transplantation was performed for 3171 patients (56%) and allogeneic transplantation for 2480 (44%). Almost half of the patients (44%) were transplanted
in first complete remission (or in first chronic phase for CML). For autologous transplantation, 57% of patients received bone marrow as source of stem cells, 34% peripheral blood and 9% both. For allogeneic transplantation, 99.3% of patients received bone marrow and 0.7% peripheral blood.

Distribution of autologous transplants, allogeneic transplants and disease categories in the total population A + B, group A and group B is shown in Table 1.

Comparison of distribution between group A and group B indicated no statistical difference for age, sex ratio, source of stem cell except for a higher proportion of autologous transplants in group A (59%) than in group B (54%) (P < 0.0001) and more allogeneic transplantation done in first complete remission in group A (59%) than in group B (45%) (P < 0.0001).

Comparison of distribution by disease between group A and group B

Comparison showed that for autologous transplantations performed for hematological malignancies, both groups were similar for most disease characteristics with a few exceptions listed below shown in group A compared to group B:

- In non-Hodgkin's lymphomas: a shorter median time from diagnosis to transplant (320 versus 398 days, P = 0.001), more TBI (63% vs 29%, P < 10^-4); marrow more frequently used as the source of stem cells (50% vs 44%, P < 10^-4).
- In Hodgkin's disease: a lower proportion of children (2% vs 1%, P = 0.01) and less TBI (8% vs 56%, P < 10^-4).
- In multiple myeloma: more patients classified as responding to chemotherapy at the time of transplant (77% vs 65%, P = 0.03) and less TBI (35% vs 76%, P < 10^-4).
- In acute leukemias: more TBI for acute myeloid leukemia (78% vs 52%, P < 10^-4) and for acute lymphocytic leukemia (92% vs 54%, P < 10^-4), and more patients transplanted in first complete remission for acute lymphocytic leukemia (75% vs 51%, P < 10^-4).

Comparison for allogeneic transplants for hematological malignancies indicated no difference for most parameters with a few exceptions listed below, shown in group A compared to group B:

- In acute myeloblastic leukemia: a longer median time from diagnosis to transplantation (202 vs 160 days, P < 10^-4) and a higher proportion of allogeneic identical sibling transplantation (91% vs 82%, P = 0.002).
- In acute lymphocytic leukemia: a higher median age (20 vs 15 years old, P < 10^-4) and fewer children (42% vs 55%, P = 0.003); a shorter median time from diagnosis to transplantation (242 vs 549 days, P = 0.0001); more patients transplanted in first complete remission (64 vs 35%, P < 10^-4), and a higher proportion of identical sibling allogeneic transplants (76% vs 67%, P = 0.02).
- In myelodysplastic syndromes: a higher median age (38 vs 31 years old, P = 0.03); less patients receiving TBI (63% vs 88%, P = 0.003).
- In chronic myeloid leukemia: more patients transplanted in first chronic phase (76% vs 66%, P = 0.005).
- In multiple myeloma: more female donors (56% vs 33%, P = 0.04).

Outcome at 3 years

On comparison of outcome between groups A and B at 3 years, with all patients combined, whatever the type of transplant and the disease category, there was no statistical difference.

Disease categories in first complete remission (or in first chronic phase for CML). For autologous transplantation, 57% of patients received bone marrow as source of stem cells, 34% peripheral blood and 9% both. For allogeneic transplantation, 99.3% of patients received bone marrow and 0.7% peripheral blood.

Distribution of autologous transplants, allogeneic transplants and disease categories in the total population A + B, group A and group B is shown in Table 1.

Comparison of distribution between group A and group B indicated no statistical difference for age, sex ratio, source of stem cell except for a higher proportion of autologous transplants in group A (59%) than in group B (54%) (P < 0.0001) and more allogeneic transplantation done in first complete remission in group A (59%) than in group B (45%) (P < 0.0001).

Comparison of distribution by disease between group A and group B

Comparison showed that for autologous transplantations performed for hematological malignancies, both groups were similar for most disease characteristics with a few exceptions listed below shown in group A compared to group B:

- In non-Hodgkin's lymphomas: a shorter median time from diagnosis to transplant (320 versus 398 days, P = 0.001), more TBI (63% vs 29%, P < 10^-4); marrow more frequently used as the source of stem cells (50% vs 44%, P < 10^-4).
- In Hodgkin's disease: a lower proportion of children (2% vs 1%, P = 0.01) and less TBI (8% vs 56%, P < 10^-4).
- In multiple myeloma: more patients classified as responding to chemotherapy at the time of transplant (77% vs 65%, P = 0.03) and less TBI (35% vs 76%, P < 10^-4).
- In acute leukemias: more TBI for acute myeloid leukemia (78% vs 52%, P < 10^-4) and for acute lymphocytic leukemia (92% vs 54%, P < 10^-4), and more patients transplanted in first complete remission for acute lymphocytic leukemia (75% vs 51%, P < 10^-4).

Comparison for allogeneic transplants for hematological malignancies indicated no difference for most parameters with a few exceptions listed below, shown in group A compared to group B:

- In acute myeloblastic leukemia: a longer median time from diagnosis to transplantation (202 vs 160 days, P < 10^-4) and a higher proportion of allogeneic identical sibling transplantation (91% vs 82%, P = 0.002).
- In acute lymphocytic leukemia: a higher median age (20 vs 15 years old, P < 10^-4) and fewer children (42% vs 55%, P = 0.003); a shorter median time from diagnosis to transplantation (242 vs 549 days, P = 0.0001); more patients transplanted in first complete remission (64 vs 35%, P < 10^-4), and a higher proportion of identical sibling allogeneic transplants (76% vs 67%, P = 0.02).
- In myelodysplastic syndromes: a higher median age (38 vs 31 years old, P = 0.03); less patients receiving TBI (63% vs 88%, P = 0.003).
- In chronic myeloid leukemia: more patients transplanted in first chronic phase (76% vs 66%, P = 0.005).
- In multiple myeloma: more female donors (56% vs 33%, P = 0.04).

Outcome at 3 years

On comparison of outcome between groups A and B at 3 years, with all patients combined, whatever the type of transplant and the disease category, there was no statistical difference.

Outcome of HSC transplants in 1993

Figure 1 Outcome at 3 years of patients transplanted in Europe in 1993 for hematological malignancies from group A (2595 patients) and group B (3086 patients). Figure (a) shows DFS, (b) RI and (c) TRM. Results show that outcome between the two groups are identical reflecting the actual outcome of all patients (group A + group B).

was 49 ± 1%, 29 ± 1%, 31 ± 1% and 54 ± 1% for DFS, RI, TRM and OS, respectively.

For other autologous transplants DFS was 32 ± 3% and 31 ± 3% (P = 0.97), RI 34 ± 5% and 34 ± 3% (P = 0.84), TRM 51 ± 4% and 52 ± 3% (P = 0.86) and OS 37 ± 3% and 39 ± 3% (P = 0.6) for group A and group B, respectively. The real outcome at 3 years of all other autologous transplants (group A + group B) was 31 ± 2%, 34 ± 3%, 52 ± 2% and 38 ± 2% for DFS, RI, TRM and OS, respectively.

Outcome at 3 years by disease category

Table 2 shows results on DFS, RI, TRM and OS for autologous transplants, Table 3 for genoidentical autologous transplants and Table 4 for other autologous transplants.

Results by disease category and by transplant modality showed no difference for outcome between group A and B.

Discussion

This study was undertaken to test whether the outcome of patients with hematological malignancies transplanted during 1 year, the year 1993, reported spontaneously to the EBMT did indeed reflect the outcome of all patients transplanted during the same year. For this purpose, additional information was retrieved by solicitation. Results showed very similar Figures for both groups. The observation is important, since the large population of patients in this study allows a very high statistical power. This work has provided reassuring information that patients reported to a transplant registry are representative of all patients and are not a selected group.

A second important consequence of this study has been to produce highly reliable indicators of outcome following transplantation in various diseases, taking advantage of an optimal registry with all consecutive data reported, and a minimum follow-up of 5 years. This has been a considerable effort not only for the investigators who were assigned the task of tracking all transplants done in Europe for the year 1993, but also for all EBMT teams.

With the implementation of the new telematic network designed by the EBMT, it is foreseen that complete consecutive automatic data reporting will be routinely achieved yearly by 2002 and a search such as this will no longer be necessary. The effort has been fruitful since, by all indi-

Indicators available, including the yearly EBMT caseload reports, the 5945 transplants collected for this study probably represents 93.8% of all transplants done in Europe for hematological malignancies during the year 1993. What happened to these patients provides information of potential importance not only in terms of therapeutic management, but also in terms of epidemiology and public health. Indeed, more than 50% of patients with hematological malignancies treated by hematopoietic stem cell transplantation during the year 1993 have experienced long-term survival.

This study indicates that the numerous scientific analyses that have been carried out to date on EBMT registries, which contain incomplete information, have nonetheless generated reliable information.

While this observation is reassuring, it must however be emphasized that the conclusions are from a retrospective study and that it would not support by any means that non-exhaustive collection of supposedly representative data from selected centres would constitute the bases for future analysis. Electronic data collection aiming to pick up all transplants is the EBMT goal for the beginning of this century.

Increasing utilization of bone marrow transplantation. II. Results of the 1985-1987 survey.

Bertin MM, Rimm AA.

Department of Medicine, Medical College of Wisconsin, Milwaukee 53226.

The International Bone Marrow Transplant Registry conducts periodic surveys to determine activity in the field of allogeneic and syngeneic bone marrow transplantation. Data were reported to the IBMTR by 258 institutions in 41 countries regarding their patients who received bone marrow transplants during the period 1985-1987. To the best of our knowledge, the data represent essentially all bone marrow transplants (exclusive of autologous transplants) performed in the past 3 years. A total of 10,887 patients received bone marrow transplants; 73% were for leukemia, 11% for other malignant diseases, 9% for severe aplastic anemia and related disorders, 3% for immune deficiency diseases, 2% for thalassemia major, and 2% for genetic, metabolic, and several other rare diseases. 161 (62%) of the 258 institutions performed fewer than one transplant per month. More than 50% of the patients were transplanted in 37 institutions. 46% of the world's bone marrow transplants were performed in North America, 42% in Western Europe, 5% in Asia, 3% in Australia and New Zealand, 2% in the Middle East and Africa, 1% in South and Central America, and 1% in Eastern Europe and the USSR. The data reflect continued growth in utilization of allogeneic and syngeneic bone marrow transplantation and quantify the annual increases in the number of patients receiving transplants.

Severe Aplastic Anaemia: A Prospective Study of the Effect of Androgens or Transplantation on Haematological Recovery and Survival

BRUCE M. CAMITTA
E. DONNALL THOMAS

for the International Aplastic Anaemia Study Group*

In 1959 Shahidi and Diamond published their article on the use of androgens for treatment of marrow aplasia. Two years later the same authors reported haematological improvement in 9 of 17 children with aplastic anaemia who were treated with testosterone (Shahidi and Diamond, 1961). Confirmatory studies, utilizing a variety of anabolic agents, followed (Sanchez-Medal et al., 1969). However, other workers were unable to demonstrate that androgens modified the course of aplastic anaemia (Heyn, Ertel and Tubergen, 1969; Li, Alter and Nathan, 1972; Williams, Lynch and Cartwright, 1973).

These conflicting results probably reflected the small size of many series, use of historical instead of concurrent controls, and failure to assess adequately disease severity. Thus, androgen responsiveness was seen primarily in patients with milder marrow aplasia (Duarte et al., 1972; Lynch et al., 1975). In contrast, patients with severe marrow aplasia fared poorly whether or not androgens were utilized.

In order to determine the efficacy of androgens for treatment of severe aplastic anaemia, a prospective randomized trial was designed. The results indicate that androgens, as utilized in this study, are not effective treatment for severe aplastic anaemia.

STUDY DESIGN

Only patients with newly diagnosed severe aplastic anaemia were eligible for this study (Table 1). The protocol is outlined in Figure 1. Following diagnosis, patients were observed for 10 days to exclude the presence of an underlying illness, to establish baseline haematological values, to detect early

*See appendix for contributing institutions and physicians.

spontaneous improvement and to complete histocompatibility studies. During this time prednisone (10 mg/m²/day) was given to some patients in an attempt to detect underlying leukaemia (Melhorn, Gross and Newman, 1970). Patients with aplasia secondary to nutritional deficiency, malignancy, irradiation, chemotherapy, preleukaemia, myelofibrosis or Fanconi's anaemia, and patients with other life-threatening diseases, were excluded from the study.

**Bone marrow:**
- Severely hypocellular (< 25% of normal) or
- Moderately hypocellular (25-50% of normal) with > 70% of remaining cells being non-haematopoietic

On day 10, patients with persistent severe aplasia were assigned to treatments after obtaining informed consent. Patients without matched siblings were randomized to receive no, oral (oxymetholone, 3 to 5 mg/kg/day) or intramuscular (nandrolone decanoate, 3 to 5 mg/kg/week) androgen. Some physicians were unwilling to randomize patients to no androgens. Their patients were randomized to oral versus intramuscular androgens, resulting in fewer patients on the no androgen treatment as compared to the two androgen regimens.

![Figure 1. Therapeutic guidelines for Aplastic Anaemia Study.](image)

Prednisone (10 mg/m²/day) could be continued at the discretion of the patient's physician. Antibiotics and transfusion support were administered as needed. The initial regimen was continued for at least four months. If no response had occurred, patients could be re-randomized between the remaining regimens. Usually they remained on their initial treatment.

Patients with histocompatible siblings were scheduled for marrow transplantation (to begin on day 21 or as soon thereafter as possible). Details of transplantation procedures have been published previously (Camitta et al, 1976).
Complete response was defined as the return of all haematological values to normal. Partial response meant improvement so that the patient no longer qualified for severe status and no longer required transfusions.

RESULTS

Between July 1, 1974, and June 30, 1977, 111 patients were entered into this study. Treatment groups were comparable for characteristics thought to have prognostic significance in aplastic anaemia (Table 2) except for a slight difference in sex ratio of the no androgen patients. During the 10 d observation period, six patients died and four improved. One of the latter subsequently developed acute lymphocytic leukaemia; a second became severely aplastic and died several months later; the remaining two patients are haematologically normal. These 10 patients were not entered into the study.

Responses and survival of 64 non-transplanted patients are summarized in Table 3 and Figure 2. There are no significant differences in survival times amongst the three regimens. Six living patients have shown no improvement. Twelve patients improved. Responses began after 1 to 13 months with 6 of

12 responses occurring within two months. There were no differences in time of response amongst the regimens. Reticulocytosis and a decreased red cell transfusion requirement were usually the first sign of improvement. Platelets responded slowly and often incompletely. With one exception responses were progressive, albeit at variable rates. No complete responder was dependent on androgen for maintenance of response. Similarly, almost all partial responders on androgen regimens have been able to discontinue or substantially decrease androgen doses without a haematological relapse.

Forty-six non-transplanted patients died. Time to death was 1 to 33 (median three) months. The causes of death were haemorrhage (23), infection (14) and infection plus haemorrhage (9). There were no differences between regimens in median time to, or cause of, death.

Toxicities of both androgen regimens were mild and in general were overshadowed by complications from the disease per se. Virilization was modest.

---

Figure 2. Life table survival plot of non-transplanted patients according to initial treatment regimen. Squares, triangles and circles indicate duration of follow-up of current survivors.
probably because of the short duration of therapy in most patients. No patient required discontinuation of oxymetholone for hepatocellular dysfunction. Severe haematomas following nandrolone decanoate injection occurred on two occasions but did not require a change of therapy. An abscess developed at the site of injection on only one occasion.

Table 3 and Figure 3 summarize the results in the 48 patients treated with marrow transplantation. Twenty-seven of these patients are alive with complete haematological recovery but four have chronic graft-versus-host disease of mild to moderate severity. The probability of survival following transplantation was slightly greater for children than for adults, but this difference was not significant ($P = 0.10$).

**DISCUSSION**

This study does not support the use of androgens for treatment of severe aplastic anaemia. Time of response, rate of response, percentage responding, median survival time and long-term survival were similar in all three non-transplant regimens. Patient age, sex and initial blood counts did not affect patient survival or response.

It is still possible that a small advantage for androgens might exist. Androgen dependency in aplastic anaemia has been reported (Duarte et al, 1972). However, many of these cases were mild or no details were given regarding severity. Androgen dependency was not demonstrated in this series. Furthermore, the ability of androgens to increase granulopoiesis and thrombopoiesis may be limited. In severe aplastic anaemia, responses of these blood elements are usually delayed (Sanchez-Medal et al, 1969). Since the high early mortality in severe marrow aplasia is due to haemorrhage and/or infection,
more rapidly effective early therapy is necessary. Awaiting androgen responses decreases the zeal with which such alternative treatments are sought.

Survival times of transplanted patients were greater than those of non-transplanted patients \( (P < 0.001) \). If an appropriate donor exists, marrow transplantation is currently the treatment of choice for children and young adults with severe aplastic anaemia. For older patients \( (> 25 \text{ years}) \) in this study, survival times tended to be longer for those transplanted, but not significantly so.

Criteria for severity were devised from data available at the time and confirmed by more recent sophisticated analysis \( (\text{Lynch et al., 1975}) \). The aim was to maximize recovery of all patients while minimizing transplantation of patients who would spontaneously recover \( (\text{Camitta et al., 1975}) \). Clearly the criteria did define a population with a grim prognosis. Preliminary analysis of presenting characteristics has failed to distinguish survivors from non-survivors in our severely affected patients.

Eight individuals with milder aplasia were also followed. In contrast to the severely affected patients, five \( (\text{four of whom received androgens}) \) have shown complete or partial improvement, one remains stable on androgens and two \( (\text{treated with androgens}) \) became severe and died. Mildly affected patients who become severe seem to have the same prognosis as individuals severely affected initially \( (\text{Camitta et al., 1975}) \). Interestingly, one of the complete responders is androgen dependent.

Alternative approaches are needed for patients with severe aplastic anaemia who do not have a compatible sibling marrow donor. Because of the variable and often unpredictable course of aplastic anaemia, it is important that trials be designed prospectively to maximize the probability that meaningful answers are obtained, regardless of the therapy being investigated.

**SUMMARY**

A prospective study was performed \((1)\) to evaluate the role of androgens in treatment of severe aplastic anaemia, and \((2)\) to compare the efficacy of early bone marrow transplantation with more conventional therapy for severe marrow aplasia. Results fail to support a beneficial effect of androgens on the course of patients with severe aplastic anaemia. In contrast, histocompatible bone marrow transplantation significantly improves survival and hematological recovery. Alternative therapies should be carefully evaluated for non-transplantable patients with severe marrow aplasia.

Registry report

Report from the International Bone Marrow Transplant Registry

Advisory Committee of the International Bone Marrow Transplant Registry

Summary:

The International Bone Marrow Transplant Registry (IBMTR) receives and analyses detailed information contributed by transplant teams at more than 175 institutions worldwide. This collaborative research effort has grown rapidly; there are now more than 8000 cases in the database. This is a summary of the current status of bone marrow transplantation in leukemia and severe aplastic anemia, a brief summary of key findings reported by the IBMTR during the past year, as well as studies planned for the coming year.

The International Bone Marrow Transplant Registry (IBMTR) began in 1970 as a branch of the American College of Surgeons/National Institutes of Health Organ Transplant Registry. Initially, only basic information was collected for transplants performed after 1 January, 1968. In 1973 the Advisory Committee of the IBMTR decided to convert the IBMTR into a research organization. The concept was that by collecting, pooling and analysing detailed data from teams worldwide, progress in the field would be accelerated. That this approach was effective and continues to be perceived as worthwhile is evidenced by the fact that more than 75% of all transplant teams in the world (see Appendix) voluntarily report comprehensive information regarding their consecutive bone marrow transplant patients. It should be noted, however, that many reputable centers do not participate in the IBMTR research program. The IBMTR now has detailed data on more than 8000 patients who received bone marrow transplants and continues to grow both in the number of cases being reported and the number of teams participating in this unique example of international scientific cooperation.

In this report, the IBMTR presents the current status of bone marrow transplantation in leukemia and severe aplastic anemia, a brief summary of several key findings from recent analyses, as well as studies planned for the next year.

Operation of the IBMTR

In brief, data are reported to the Statistical Center of the IBMTR for recipients of allogeneic or syngeneic transplants. Five specialized reporting forms, each containing 450–500 questions, are used to collect information regarding the following: (1) leukemia, lymphoma and other malignant diseases; (2) severe aplastic anemia, Fanconi anemia, pure red cell aplasia, osteopetrosis, paroxysmal nocturnal hemoglobinuria and other related conditions; (3) immunodeficiency diseases; (4) hemoglobinopathies; and (5) genetic and metabolic disorders. Protocols for uniform reporting of data are incorporated into the forms. The reporting forms are updated periodically to eliminate questions for which data are no longer needed and to add questions that take into account advances in the field. Reporting forms are formulated at the Statistical Center by staff members with members of the Advisory Committee and individuals with special expertise acting as consultants. Follow-up forms for each of the five disease categories contain approximately 150 questions, are similarly prepared and are submitted every 6–12 months. To help offset their administrative expenses, teams are reimbursed $100 for an initial report of a transplant, $50 for a report of a second transplant on the same patient and $15 for each follow-up report. Reimbursement is not made until all questions are answered and any ambiguities clarified.

Scientific validity of IBMTR analyses requires that teams report successive cases and that the quality of the reports is high. Several methods are used to ensure consecutive reporting of cases by each team and to evaluate the quality of the data submitted. Teams assign unique patient numbers as patients are transplanted. These numbers are monitored at the Statistical Center. Team leaders are notified when numbers are missing and are required to explain any gaps in the unique patient numbers. Numerous checks are built into the reporting forms to test the quality of the data. Explanations or corrections are requested when inconsistencies are detected.

Several measures also are employed to assure quality management of the data at the Statistical Center. Case reports are registered, coded independently by two different data entry operators and reviewed by a physician to evaluate the quality of the report and to answer questions raised by the data entry operators. When necessary, teams are requested to provide missing information, clarification of ambiguities, explanations for data outside the anticipated range or non-consecutive reporting. The corrected data are then entered into the
Results

Acute lymphoblastic leukemia (ALL)

Life table analyses were performed regarding 1242 consecutive reports of patients with ALL receiving bone marrow transplants from HLA-identical siblings between January, 1978 and December, 1987 to determine the risk of relapse and the probability of leukemia-free survival (Figure 1). The 5-year actuarial probabilities of relapse and leukemia-free survival for these patients are shown in Table I. These data demonstrate the highly significant association between disease status at the time of transplantation and outcome.

Bone marrow transplantation is being used in first remission of ALL for selected patients considered to be at high risk of relapse if treated with chemotherapy. Criteria used by transplant centers to define these patients include: age less than 2 years or older than 15 years, WBC \( \geq 50 \times 10^9/1 \), CNS involvement, B cell or L3 phenotype, or the specific chromosome abnormalities t(4;11), t(8;14) or t(9;22). Analyses were conducted to evaluate outcome following bone marrow transplantation for high-risk ALL. Of 444 patients having these high-risk features at diagnosis, 236 were transplanted while the disease was still in first remission and 208 in second remission. The 4-year probability of relapse was 26±12% (95% confidence interval) for transplants in first remission and 56±11% for transplants in second remission \( (p<0.0001) \). Leukemia-free survival was 45±9% and 22±7%, respectively \( (p<0.0002) \). Also available for study were data on 97 patients having none of the high-risk features at diagnosis and who were transplanted in second remission. Their 4-year probability of relapse was 49±14%, not significantly different from patients with high-risk leukemia at diagnosis transplanted in second remission. Their probability of leukemia-free survival was 36±11%, significantly better \( (p<0.0006) \) than high-risk patients transplanted in second remission.

These data indicate that survival after transplantation for high-risk ALL in first remission was clearly superior to survival after transplantation in second remission. Since a certain number of patients will be cured with chemotherapy alone, and a certain number never achieve second remission after relapse, further studies are needed to determine whether patients with high-risk ALL should receive transplants during first remission or should initially receive chemotherapy, reserving transplantation for patients who relapse.

Acute myelogenous leukemia (AML)

The probability of relapse and leukemia-free survival was determined for 1429 consecutive reports of patients with AML receiving transplants from HLA-identical siblings between 1978 and 1987 (Figure 2). The data at 5 years post-transplant are presented in Table II. The strong association between disease status at transplant and outcome is also shown here.

Figure 2  Life table analysis among patients with acute myelogenous leukemia showing probability of (a) relapse and (b) leukemia-free survival following bone marrow transplantation from HLA-identical siblings by disease status at transplant.

Chronic myelogenous leukemia (CML)

Disease status at the time of transplant was also found to be significantly correlated with outcome among 1082 patients with CML receiving bone marrow from HLA-identical siblings, 1978-87 (Figure 3). Actuarial 5-year probabilities of relapse and leukemia-free survival are presented in Table III.

Data from 405 consecutive reports of patients with CML who received bone marrow transplants from HLA-identical siblings while in the first chronic phase were analysed to identify factors predicting relapse and survival. The 4-year probability of relapse was 19±8% and of survival, 55±5%. In multivariate analysis the probability of remaining in remission was lower for patients receiving bone marrow depleted of T lymphocytes compared with patients receiving T cell-replete grafts, irrespective of the grade of acute or chronic graft-versus-host disease (GVHD) (relative risk 5.4, p<0.0001). The probability of remaining in remission also was lower for patients who did not have chronic GVHD compared with those who did, irrespective of whether the bone marrow was or was not depleted of T
cells (relative risk 3.1, \( p < 0.01 \)). The probability of survival was lower among patients who developed moderate to severe acute GVHD than in those with no or mild acute GVHD (relative risk 3.7, \( p < 0.0001 \)), and in patients \( > 20 \) years of age than in younger patients (relative risk 2.6, \( p < 0.0002 \)). Duration of disease before transplant was not significantly associated with outcome.

The data indicate that bone marrow transplantation performed in the chronic phase of CML offers some patients a prolonged period of leukemia-free survival. Once transformation into the accelerated or blastic (acute) phase occurs, the results of bone marrow transplantation are significantly poorer. Since transplantation offers the only possibility of cure, the opportunity should not be lost by prolonged delay, especially in younger patients with an HLA-identical sibling.

**Severe aplastic anemia (SAA)**

The actuarial probability of survival among 732 patients with SAA following bone marrow transplantation for HLA-identical siblings between 1978 and 1987 is shown in Figure 4. The 5-year probability of survival was 57\( \pm \)4\% (95\% confidence interval).

Graft failure was analysed in 625 patients receiving allogeneic bone marrow transplants from HLA-identical sibling donors between 1978 and 1986 as treatment for severe aplastic anemia.5 Sixty-eight (11\%) had no or only transient engraftment. Second bone marrow transplants were successful in achieving extended survival in 16 of 27 patients with transient initial engraftment but in none of 10 patients with no sign of engraftment after the first transplant. The major factors associated with a reduced risk of graft failure were use of radiation for pretransplant immunosuppression, and use of cyclosporine rather than methotrexate or T cell depletion of the donor bone marrow for prophylaxis against GVHD. Among 266 patients prepared for transplantation with cyclophosphamide alone, the risk of graft failure was increased in patients who received previous transfusions and reduced in those who received corticosteroids for previous therapy. Neither cell dose nor administration of donor buffy coat cells affected the probability of engraftment. Although use of radiation in conditioning reduced graft failure, survival was not improved. Post-transplant treatment with cyclosporine and avoiding pretransplant blood transfusions were associated with improved survival.

**Risk factors for acute GVHD**

Acute GVHD is another major complication of allogeneic bone marrow transplantation. Data from 2036 consecutive reports of HLA-identical sibling bone marrow transplants for leukemia or aplastic anemia were analysed to identify factors associated with the risk of moderate to severe acute GVHD.6 Patients receiving grafts that were depleted of T cells were excluded from analysis. All patients survived \( > 21 \) days and were thus considered to be at risk of GVHD. The incidence of moderate to severe acute GVHD was 45\( \pm \)2\%, the actuarial risk at 6 months 46\( \pm \)2\%, the case fatality rate 48\% and the mortality rate 22\%. Variables associated with the risk of GVHD are shown in Table IV. The risk of developing acute GVHD was 16\% when none of the adverse risk factors was present. The cumulative probability of moderate to severe acute GVHD with all adverse risk factors added was 87\% and the relative risk was 5.4 times higher than in patients with none of the adverse risk factors.

There was no significant difference in the 44\( \pm \)3\% incidence of GVHD among 1235 patients given methotrexate to prevent or modify GVHD versus the 46\( \pm \)4\% incidence in 710 patients given cyclosporine. Age of the patient at transplant was a significant risk factor for GVHD (relative risk 1.6, \( p < 0.001 \)) ranging from 39\( \pm \)4\% in the lowest age quartile to 52\( \pm \)4\% in the highest. This age effect appeared to be due primarily to the high incidence of GVHD in female--male transplants from previously pregnant or transfused (allo-immune) donors in comparison with similar donors for female recipients (66\( \pm \)9\% versus 39\( \pm \)9\%, respectively.

**Figure 4** Life table analysis among patients with severe aplastic anemia showing the probability of survival following bone marrow transplantation from an HLA-identical sibling.
relative risk 2.9, p < 0.0001, Figure 2b). The cohort of 59 older female→male transplants from parous or transfused donors had an incidence of GVHD of 75%, which was the highest seen in this study. Multivariate analysis of all 1818 patients except alloimmune female→male transplants showed that age no longer remained as a significant risk factor for GVHD: 39±3% in younger patients versus 47±3% in older patients (p = 0.30).

Results of this study should be useful in estimating the risk of GVHD in individuals with a single risk factor or a specific profile of risk factors. The data also should prove useful in developing future approaches and in designing randomized clinical trials testing alternative methods of preventing GVHD. For example, if the randomization was not stratified for the prognostic variables identified here, it conceivably would be possible to observe rates of moderate to severe acute GVHD of 16 to >85% by chance alone in either or both arms.

**HLA associations with leukemia**

Although a strong association between H-2 and leukemia in mice has been recognized for more than 20 years, there have been no convincing reports of an association between HLA and leukemia in humans. Previous studies had <200 patients available for analysis. Only one, testing 44 patients, examined a possible role between HLA-C and the risk of leukemia; no correlation was found. This issue was addressed using the large database of the IBMTR where HLA phenotypes are known for all patients.

Frequencies of 35 HLA A, B, C, and DR antigens were determined in 1834 leukemic Caucasoids to evaluate possible associations between HLA and leukemia.\(^5\) In comparison with the frequencies of HLA antigens in published controls, the frequency of Cw3 was significantly higher in 727 patients with ALL (relative risk 2.64, p < 0.0002), 665 patients with acute myelogenous leukemia (relative risk 1.92, p < 0.0007), and 442 patients with CML (relative risk 2.07, p < 0.002; p values adjusted for multiple comparisons). The frequency of Cw4 was elevated in patients with ALL (relative risk 2.01, p < 0.0003), AML (relative risk 2.06, p < 0.0002) and CML (relative risk 2.14, p < 0.0008). The frequency of Aw19 was significantly decreased in patients with AML (relative risk 0.68, p < 0.01) and CML (relative risk 0.59, p < 0.005). The overall associations between HLA and ALL, AML and CML, combined, are presented in Table V. None of the other 32 HLA antigens investigated had a statistically significant association with leukemia.

The data suggest that Cw3 and Cw4 antigens or the genes encoding them are, or are closely linked with, possible leukemia susceptibility genes. The observed increased risk of leukemia in siblings of leukemia patients may be due in part to an increased frequency Cw3 and Cw4 within the family. The findings in this study indicate that HLA C genes have hitherto unrecognized properties. Further studies are required to determine whether HLA C also will be found to be associated with other malignant and non-malignant diseases.

**Studies in progress**

Several analyses presently are in various stages of completion. The results will be submitted for publication within the 12 months. The investigators with primary responsibility for these studies and the tentative titles are listed below.

1. Robert C. Ash, USA: Bone marrow transplantation using donors other than HLA-identical siblings.
2. Kerry Atkinson, Australia: Risk factors for chronic GVHD.
5. Mortimer M. Bortin, USA: Temporal relationship between major complications of allogeneic bone marrow transplantation.
6. Robert Peter Gale, USA: Bone marrow transplantation or chemotherapy for acute myelogenous leukemia in first remission.
7. Eliane Gluckman, France: Effect of treatment regimen upon survival after bone marrow transplantation for severe aplastic anemia.
10. Alberto M. Marmont, Italy: Results of bone marrow transplantation using T cell-depleted grafts in leukemia.

Comment

The use of bone marrow transplants continues to increase rapidly. There is no generally accepted bone marrow transplant protocol; new treatment strategies are frequently introduced. The large database of the IBMTR makes analyses possible evaluating the strengths and weaknesses of these new approaches in comparable patients. This is particularly helpful in those instances when prospective clinical trials at single centers are difficult or not possible, e.g. in adult ALL. Risk factors associated with the complications of bone marrow transplantation have been identified that can be useful in estimating the risk to a particular patient, in modifying treatment and in designing appropriately stratified clinical trials. Finally, `state of the art' analyses such as presented here, provide a benchmark against which individual teams can compare their results. Teams wishing to participate in the IBMTR research program should send their request to the Statistical Center.

Acknowledgments

This 55th report from the IBMTR was prepared for the Advisory Committee: Robert Peter Gale, University of California at Los Angeles (Chairman); Kerry Atkinson, St Vincent's Hospital, Sydney; Fritz H. Bach, University of Minnesota, Minneapolis; A. John Barrett, Hammersmith Hospital, London; Dirk W. van Bekkum, Radiobiological Institute, Rijswijk; James C. Biggs, St Vincent's Hospital, Sydney; Karl G. Blume, City of Hope National Medical Center, Duarte; Mortimer M. Bortin, Medical College of Wisconsin, Milwaukee; Karel A. Dicke, M. D. CHAPTER 10

Current Status of Bone Marrow Transplantation

MORTIMER M. BORTIN AND MARY M. HOROWITZ

INTERNATIONAL BONE MARROW TRANSPLANT REGISTRY
Medical College of Wisconsin
Milwaukee, Wisconsin

GROWTH IN THE FIELD OF BONE MARROW TRANSPLANTATION

The International Bone Marrow Transplant Registry (IBMTR) is a voluntary working group conducting research to determine factors affecting success and failure of bone marrow transplantation. In addition to these clinical epidemiologic investigations, the IBMTR conducts occasional surveys to assess worldwide utilization of allogeneic and syngeneic bone marrow transplantation. Our previous survey covered the period 1955-1984 (1). We now report continued growth during 1985-1987 (2).

Data were reported to the IBMTR by 258 institutions in 41 countries regarding their patients who received bone marrow transplants during the period 1985-1987. To the best of our knowledge, the data represent essentially all bone marrow transplants (exclusive of autologous bone marrow transplants) performed in this 3-year interval. Between 1985 and 1987, a total of 10,887 patients received bone marrow transplants: 73% were for leukemia, 11% for other malignant diseases, 9% for severe aplastic anemia and related disorders, 3% for immune deficiency diseases, 2% for thalassemia major, and 2% for genetic, metabolic, and other rare diseases. Forty-six percent of the world's bone marrow transplants were performed in North America, 42% in Western Europe, 5% in Asia/India, 3% in Australia/New Zealand, 2% in the Midd-

estimate predicts that approximately 7,600 patients will receive allogeneic or syngeneic bone marrow transplants in 1995.

RESULTS OF BONE MARROW TRANSPLANTATION AND FACTORS AFFECTING OUTCOME

Acute Lymphoblastic Leukemia

Comprehensive data from 1,657 patients with acute lymphoblastic leukemia treated with high-dose chemoradiotherapy and bone marrow transplants from HLA-identical sibling donors between January 1, 1980 and December 31, 1988 were reported to the IBMTR by 141 transplant centers, worldwide. The data were analyzed to determine factors associated with the probability of leukemia-free survival and the probability of leukemia relapse. The 5-year actuarial probability (±95% confidence interval) of leukemia-free survival was 44±6% for 514 patients transplanted in first complete remission (CR), 30±4% in 762 patients transplanted in 2nd-8th CR, and 14±5% in 381 patients transplanted when their disease was more advanced (Fig. 2). The 5-year actuarial probability of relapse for this same patient population was 28±6%, 50±6%, and 68±7%, respectively (Fig. 3). The principal causes of death among the 230 acute lymphoblastic leukemia patients transplanted in first remission are shown in Figure 4.

Disease status at the time of transplantation was the most important predictor of outcome in acute lymphoblastic leukemia. It should be noted that these relapse and survival curves, as well as others in this chapter, are based on raw data; they are not adjusted for other factors that might influence outcome such as patient age; preparative antileukemic, immunosuppressive conditioning regimen; method used to prevent graft-versus-host disease (GvHD); or other factors reported to be associated with outcome. It should be noted further that most of the patients transplanted in first remission were adults whereas most of the patients transplanted in second or subsequent remission were children.

In first remission adults, non-T cell phenotype, male-to-female donor-recipient sex-match, and GvHD were associated with decreased leukemia-free survival; inclusion of corticosteroids in the regimen to prevent GvHD was associated with a higher probability of leukemia-free survival (3). Variables associated with decreased leukemia-free survival among second remission transplants were age ≥16 and relapse occurring while on therapy (3). Variables associated with increased probability of relapse were similar for first and second remission transplants and included GvHD prophylaxis without methotrexate (4), and the absence of GvHD (3). In first remission transplants, leukocyte count ≥50 x 10⁹/l at diagnosis was also associated with an increased risk of relapse; in second remission transplants, relapse while receiving chemotherapy was also associated with increased posttransplant relapse. These data emphasize the importance of both disease and transplant-related variables in predicting outcome after bone marrow transplantation in acute lymphoblastic leukemia. The data may be useful in helping to explain differences among studies, to design prospective controlled clinical trials, and to identify persons most likely to benefit from bone marrow transplantation.

Acute Myelogenous Leukemia

Comprehensive data regarding 2,018 patients transplanted for acute myelogenous leukemia were reported to the IBMTR by more than 151 transplant centers. All were treated with high-dose chemotherapy with or without total body radiation. All received bone marrow transplants from their HLA-identical siblings during the period January 1, 1980 to December 31, 1988. Disease status at the time of transplant was the most important factor influencing the probability of leukemia-free survival (Fig. 5) and relapse (Fig. 6). The 5-year actuarial probability of leukemia-free survival was 50±3% for 1,259 patients transplanted in first CR, 27±6% in 301 patients transplanted in 2nd-4th CR, and 18±5% in 458 patients with more advanced disease. The 5-year probability of relapse in this same patient population was 21±3%, 45±10%, and 63±7%, respectively (Fig. 6). The principal causes of death among the 526 patients transplanted in first remission are shown in Figure 7.

A controversial issue in the management of patients with acute myelogenous leukemia who have achieved first remission and who have an HLA-identical sibling donor is whether to continue chemotherapy or to perform a bone marrow transplant. The reported 5-year probability of leukemia-free survival with chemotherapy ranges from 20-50%; in most reports, HLA-identical sibling bone marrow transplants are associated with 5-year leukemia-free survival rates of 35-60%. This problem of overlapping results is further complicated by censoring patients who relapse before transplants can be done, and by selective data reporting. Some centers recom-
Figure 5. Probability of leukemia-free survival for patients with acute myelogenous leukemia following high-dose chemotherapy with or without total body radiation and bone marrow transplantation from HLA-identical siblings based on disease status at time of transplant.

Figure 6. Probability of relapse for patients with acute myelogenous leukemia following high-dose chemotherapy with or without total body radiation and bone marrow transplantation from HLA-identical siblings based on disease status at time of transplant.

Figure 7. Principal causes of death for patients transplanted in first remission of acute myelogenous leukemia.
mend transplants only for patients for whom a poor response to chemotherapy is predicted.

To evaluate the wisdom of this latter strategy, data from 704 recipients of HLA-identical sibling transplants for acute myelogenous leukemia in first remission were analyzed (5). Improved leukemia-free survival was associated with younger age and lower white blood cell counts at diagnosis. These prognostic variables are similar to those reported to affect outcome after chemotherapy. These findings suggest that a strategy of treatment assignment based on risk factor analysis is unlikely to resolve the controversy of transplant versus chemotherapy for AML in first remission.

**Chronic Myelogenous Leukemia**

Data were analyzed for 1,613 patients with chronic myelogenous leukemia who were treated with high-dose chemotherapy and/or total body irradiation followed by bone marrow transplantation from HLA-identical sibling donors. The transplants were performed between January 1, 1980 and December 31, 1988 by 143 teams, worldwide. As in acute leukemia, disease status was an important predictor of outcome. The 5-year probability of leukemia-free survival was 42±5% for 980 patients transplanted in first chronic phase; 21±8% for 445 transplanted in accelerated phase; and 15±6% for 188 transplanted in blast phase (Fig. 8). The 5-year probability of relapse was 25±6%, 48±11%, and 52±13%, respectively (Fig. 9). The principal causes of death after transplantation in chronic phase are shown in Figure 10.

Earlier multivariate analyses of 405 patients transplanted in first chronic phase disclosed that probability of relapse was higher for recipients of T cell depleted transplants in comparison with recipients of non-T cell depleted bone marrow (relative risk 5.4, p<0.0001) (6). The probability of relapse was also higher for patients who did not develop chronic GvHD in comparison with patients who did (relative risk 3.1, p<0.01) (6). Despite these problems, bone marrow transplantation in chronic phase, in contrast to any other therapy, offers some patients the possibility of prolonged leukemia-free survival (Fig. 8). Once blast transformation has occurred, the results of transplantation are significantly poorer. Therefore, the opportunity for cure should not be lost by prolonged delay and the attendant risk of transformation, especially in younger patients with an HLA-identical sibling.

**Severe Aplastic Anemia**

Comprehensive data from 971 patients with severe aplastic anemia treated with high-dose chemotherapy with or without radiotherapy and bone marrow transplantation from HLA-identical donors between January 1, 1980 and December 31, 1988 were reported to the IBMTR by 124 transplant teams. The 5-year actuarial probability of survival was 59±3%. Both age (Fig. 11) and acute GvHD (Fig. 12) had highly significant associations with survival following bone marrow transplants from HLA-identical sibling donors. The 486 patients aged 19 or under had a 5-year probability of survival of 67±5%; the probability was 51±5% among the 485 older patients (p<0.0001). The 5-year probability of survival among 559 patients who developed no or only mild acute GvHD was 80±4%; this was significantly higher (p<0.0001) than the 39±6% probability of survival among 334 patients who developed moderate to severe acute GvHD. The principal causes of death among the 364 severe aplastic anemia patients who died after transplant are shown in Figure 13.

A major cause of treatment failure following bone marrow transplantation for severe aplastic anemia is no or only transient engraftment of the donor bone marrow. Graft failure was analyzed in 625 patients receiving allogeneic bone marrow transplants from HLA-identical sibling donors (7). Sixty-eight (11%) had graft failure. Second bone marrow transplants were successful in achieving extended survival in 16 of 27 patients with transient initial engraftment but in none of 10 patients with no sign of engraftment after the first transplant. The major factors associated with reduced risk of graft failure were use of radiation for pretransplant immune suppression and use of cyclosporine (CsA) rather than T cell depletion of the donor marrow or methotrexate for prophylaxis against GvHD. Among 266 patients prepared for transplantation with cyclophosphamide alone, the risk of graft failure was increased in patients who had received transfusions previously and reduced in those who received corticosteroids for previous therapy. Neither cell dose nor administration of donor buffy coat cells affected the probability of engraftment. Although use of radiation for conditioning reduced graft failure, survival was not improved. Posttransplant treatment with CsA and avoidance of pretransplant blood transfusions were associated with improved survival.
Figure 8. Probability of leukemia-free survival for patients with chronic myelogenous leukemia following high-dose chemotherapy with or without total body radiation and bone marrow transplantation from HLA-identical siblings based on disease status at time of transplant.

Figure 9. Probability of relapse for patients with chronic myelogenous leukemia following high-dose chemotherapy with or without total body radiation and bone marrow transplantation from HLA-identical siblings based on disease status at time of transplant.

Figure 10. Principal causes of death for patients transplanted in first remission of chronic myelogenous leukemia.
Figure 11. Probability of survival for patients with severe aplastic anemia following bone marrow transplantation from HLA-identical sibling donors based on age of patient in years.

Figure 12. Probability of survival for patients with severe aplastic anemia following bone marrow transplantation from HLA-identical sibling donors based on severity of acute GvHD posttransplant.

Figure 13. Principal causes of death for patients transplanted in first remission of severe aplastic anemia.
These data point to several modes of treatment associated with reduced graft failure. In conjunction with information regarding the impact of these therapies on other transplant-related complications, this suggests that some measures may improve the outcome of bone marrow transplantation for severe aplastic anemia.

Regimens containing CsA appear to have an advantage over methotrexate. If possible, transfusions should be withheld or minimized prior to the initiation of the immune suppressive preparative regimen, especially if regimens without radiation are to be used.

**Summary**

Utilization of bone marrow transplantation as a therapeutic modality continues to increase. More and more institutions are initiating bone marrow transplant programs. During the 33-year period between 1955 and 1987, more than 20,000 patients received allogeneic bone marrow transplants; more than 50% of these were performed in the 3 years, 1985-1987. Transplantation is an effective therapy for acute leukemia; in some instances it is the preferred treatment. In chronic myelogenous leukemia, severe aplastic anemia, and some genetic and immune deficiency diseases, bone marrow transplantation provides the only possibility for cure. Bone marrow transplantation is associated with serious problems such as graft-versus-host disease (GvHD), graft failure, interstitial pneumonitis and, until recently, the requirement for an HLA-identical sibling donor. In the past few years, an increasing number of transplants have been performed using HLA-partially matched related or unrelated donors with some success, the level of which is yet to be determined. The development of acute GvHD (8) and interstitial pneumonitis (9,10) can often be predicted by risk factor assessment. Special precautions can then be taken for patients at high risk of these complications. In this report, current data from the International Bone Marrow Transplant Registry were summarized and several risk factors affecting outcome were identified.

Management of aplastic anaemia — P. Jacobs, N. Novitzky

P. Jacobs, Professor and Head, N. Novitzky, Specialist Haematologist, University of Cape Town Leukaemia Centre and Department of Haematology, Groote Schuur Hospital, Observatory

The clinical syndrome of bone marrow failure is characterised by anaemia, neutropenia and thrombocytopenia. Classically, damage to haematopoietic stem cells by a variety of mechanisms results in pancytopenia and a variable degree of haematopoietic hypocellularity, best assessed by examination of the bone marrow trephine biopsy specimen. Internationally accepted criteria exist to define the most severe form of this lesion, known as aplastic anaemia, and its distinction from lesser degrees of haematopoietic failure is of practical importance, since therapeutic options differ depending on whether hypoplasia or aplasia is present.

Diagnostically, the cardinal clinical rules apply. A meticulous history must be taken with special attention to other involved family members, prior viral diseases or exposure to radiation and a wide range of drugs, including cytotoxic and anti-inflammatory agents, certain antibiotics, and potentially myelotoxic industrial toxins such as benzene. While the physical examination should be carefully conducted, these patients are, with the exception of those with congenital lesions, usually unremarkable apart from some degree of pallor, thrombocytopenic purpura or the occurrence of pyrexia associated with infection.

The key investigations are haematological. The full blood count will define the extent of the pancytopenia and, while bone marrow aspiration is of limited value, the proper interpretation of an adequate trephine biopsy specimen is usually diagnostic. Inflammatory changes have been well described and stated to have both aetiological and prognostic significance. The most striking morphological feature is a virtual absence of recognisable haematopoietic tissue, although the stromal elements including adipocytes, plasma cells and lymphocytes may be prominent.

The pathogenesis is variable and in certain cases immune mechanisms may be operative while in others the micro-environment may be functionally abnormal. Not surprisingly, the range and complexity of diagnostic techniques has widened to include immunological and culture studies in order to select subgroups of patients for different forms of treatment.

The therapeutic options are influenced by prior supportive therapy, age, and the availability of a donor for bone marrow allografting. It is unfortunately true that many patients are referred only after trials of haematinics and transfusion of red cells or other blood components. While such management may be well intentioned, it can immunise the recipient and may even compromise the outcome of therapy. It is therefore emphasised that immediate referral to a specialised centre is desirable.

Once a reliable diagnosis of aplastic anaemia has been established, what might constitute a reasonable approach to management? In those patients where drug-related lesions, usually immunological, are responsible for the aplasia, these will generally resolve spontaneously within 2–3 weeks and are excluded from further consideration.

Bone marrow transplantation remains the preferred form of treatment for patients under the age of 40 years who have an HLA identical and MLC non-reactive sibling and patients who have not received blood transfusion are regarded as having an excellent probability of long-term survival and a normal life. This approach needs to be tempered with the recognition that successful transplantation may be complicated by acute or chronic graft-versus-host disease (GVHD), particularly in patients with aplastic anaemia. To try to overcome this difficulty, ex vivo T-lymphocyte depletion has been employed and it now has to be established to what extent this modification may increase the risk of non-engraftment or early rejection. It may be speculated that T-lymphocyte depletion removes a specific suppressor population from the donor marrow so that partial autologous reconstitution may occur following infusion, which leads to the emergence of a cytotoxic clone with the capacity to recognise and reject the new graft. It is a matter of pressing importance that this hypothesis be critically tested to determine whether intensified conditioning regimens or post-transplantation immunosuppression is needed to influence engraftment favourably and to contribute to further reduction of GVHD.

An alternative therapeutic option is suggested by the observation that in some transplanted patients clinical improvement occurs despite allograft rejection, and this can be correlated with autologous reconstitution. This phenomenon raises the possibility that intensive immunosuppression with high-dose corticosteroids, antilymphocyte globulin, antithymocyte globulin, or monoclonal antihuman T-cell antibodies may offer alternative therapeutic regimens. Although the mechanism of action of these products is not clearly defined, response rates appear to be in
excess of 50%, being highest when treatment commences as soon as possible after diagnosis and in patients where adequate doses are given. It should be noted that this group of products is difficult to standardise and there is at least some evidence suggesting that apparently similar biological products may vary in their activity.

In these circumstances it would seem reasonable to offer the young and previously non-transfused patient (with a suitable donor) bone marrow allogenic grafting following T-lymphocyte depletion as the first option. However, such patients would be in the minority, particularly since compatible siblings are limited and most individual clients reach referral centres after varying degrees of immunosuppression consequent upon red cell or blood component infusion. In these patients a combination of high-dose corticosteroids combined with an adequate dose of biologically active antilymphocyte globulin would seem appropriate. It does, however, need to be borne in mind that allogeneic platelet support is unavoidable during this period of treatment because of further falls in platelet count, and that there may be additional discomfort of immune-complex arthralgia. It is our experience that an initial clinical and haematological response can be detected as early as 4 weeks, although the median time to response is reached in 12 weeks. Non-responding patients might then be considered for allogeneic bone marrow transplantation if this option has not already been exercised or, as a second choice if no donor is available, a second course of antilymphocyte globulin could be given with the likelihood that a significant response rate might still be achieved. Non-responding patients should be offered splenectomy, since this can be carried out with acceptable risk, may modify the course of the disease, and can in any case be expected to reduce dependence upon blood transfusion.

REFERENCES

Opsomming

Die hantering van aplastiese anemie

Beenuurversing kom, soos hartversing of nierversing, in wisselende grade voor. Die ernstigste graad is bekend as aplastiese anemie en dit is belangrik dat hierdie vorm van minder ernstige grade van versing ondersteek word omdat die therapie verskil.

Hierdie artikels beskryf die diagnose, wat op 'n nouteletende geskiedenis en hematologiese onderzoek gegrond moet word. Beenuurasperasie se waarde is beperk en 'n toereikende treinbeeldspreke is gewoonlik diagnosties. Die opvolgende stemeken van die biopsiemuster is 'n feitlike afwasging van herkenbare hematopiese weefsel. Hierbenevans kan daar d.m.v. immunologie en kultuurstudie moontlike subgroep paie se onderzoek word vir verskillende behandelaans.

SPECIAL REPORT

The EBMT activity survey 2006 on hematopoietic stem cell transplantation: focus on the use of cord blood products

A Gratwohl1, H Baldomero1, K Frauendorfer2, V Rocha3, J Apperley4 and D Niederwieser5, for the Joint Accreditation Committee of the International Society for Cellular Therapy ISCT and the European Group for Blood and Marrow Transplantation EBMT (JACIE)

1Hematology, Department of Medicine, University Hospital Basel, Basel, Switzerland; 2Institute for Operations Research and Computational Finance, University of St Gallen, St Gallen, Switzerland; 3Eurorcord, Department of Haematology, Hopital St Louis, Paris, France; 4Department of Haematology, Hammersmith Hospital, London, UK and 5Division of Hematology/Oncology, Department of Internal Medicine, University Hospital, Leipzig, Germany

This report describes the hematopoietic stem cell transplantation (HSCT) activity in Europe in 2006 by indication, donor type and stem cell source. It illustrates differences compared to previous years and concentrates on the use of cord blood transplants. In 2006, there were 25,050 first HSCT, 9,661 allogeneic (39%), 15,389 autologous (61%) and 3,690 additional re- or multiple transplants reported from 605 centers in 43 participating countries. Main indications were leukemias (7,963 (32%); 85% allogeneic)), lymphomas (11,469 (56%); 89% autologous)), solid tumors (1,564 (6%); 95% autologous)), non-malignant disorders (1,242 (5%); 90% allogeneic)) and non-classified ‘others’ (112 (1%)). There was an increase in allogeneic HSCT of 9% when compared to 2005, while autologous HSCT numbers remained similar. There were 544 allogeneic cord blood HSCT, which corresponds to 5% of all allogeneic HSCT. The majority, 67%, were used for patients with leukemia. The highest percentage of cord blood transplants, 27%, was seen for inherited disorders of metabolism. No autologous cord blood transplants were reported. The highest increase in allogeneic HSCT was observed for AML, which comprises 31% of all allogeneic HSCT. Numbers of autologous HSCT remained similar in most main indications. This data provide an update of the current HSCT experience in Europe.

Bone Marrow Transplantation (2008) 41, 687–705; doi:10.1038/sj.bmt.1705956; published online 17 December 2007

Keywords: hematopoietic stem cell transplantation; Europe; transplant rates; cord blood transplants; unrelated transplants

Introduction

In 1990, the European Group for Blood and Marrow Transplantation (EBMT) introduced the activity survey as a novel instrument to capture comprehensive information on transplant numbers and to distribute this information rapidly. All EBMT members and affiliated teams report since then on an annual basis their number of patients transplanted by indication, stem cell source and donor type. By now, it has evolved as a mandatory self-reporting system and forms an integral part of the comprehensive quality assurance program Joint Accreditation Committee of the ISCT and EBMT (JACIE) (http://www.JACIE.org). It provides the basis for counseling on the individual patient level as well as for health-care institutions and administrative agencies in the field of stem cell transplantation.

Besides a report of the data from the past years, the activity survey has focused each year on a different aspect of hematopoietic stem cell transplantation (HSCT). This includes the description of trends, the introduction of new techniques or the changes in techniques as well as the analysis of economic factors related to HSCT. In 2006, the focus was on the use of cord blood as stem cell source. The first report of a successful cord blood transplant for a patient with Fanconi's anemia gave the basis for the building of cord blood banks all over the world. By 2007, nearly 300,000 cord blood products are available for use together with the more than 11 million unrelated donors from the 75 stem cell donor registries worldwide (www.bmdw.org). Carefully conducted retrospective analyses have confirmed the value of cord blood transplants under well-defined conditions compared to other family donor transplants or unrelated transplants. The present report gives now most recent information on the use of cord blood transplants in Europe in 2006 within the context and in comparison with other stem cell sources.

Patients and methods

Data collection and validation

Participating teams reported their data for 2006 by indication, stem cell source and donor type as listed in
Table 1. Data were validated by three independent systems: through confirmation by the reporting team, which received a computer printout of the entered data; by selective comparison with MED-A data sets in the ProMISE data capture system of the EBMT (www.mbsf.nl/Promise) and by cross-checking with national registries where they exist. Onsite visits of selected teams were part of the quality control program (www.jacie.org).

Teams
In total, 615 active transplanting teams in 43 countries (38 European and 5 affiliated countries) were contacted for the 2006 report, of which 605 reported their numbers. This corresponds to a 98% return rate of active teams and includes 498 active EBMT member teams reporting to the survey. Ten teams known by the investigators to have been performing HSCT in 2006 were also contacted, but chose not to reply or, for unknown reasons, failed to reply in spite of several efforts to reach them. No major transplant team in Europe is missing from this list. All contacted teams are listed in the Appendix in alphabetical order according to country, city and EBMT center code. We received information that in 2006 no blood or marrow transplants were performed in the following European countries: Albania, Andorra, Armenia, Georgia, Liechtenstein, Malta, Moldova, Monaco, San Marino, and The Vatican. Non-European countries include, by EBMT tradition, Algeria, Iran, Israel, Saudi Arabia, South Africa and Tunisia. Their data are in part included in some of the analyses.

Definitions
Transplant numbers. The EBMT survey focused, as in previous years, on the number of patients treated for the first time with HSCT. Information on additional transplants, for instance, a second, third or fourth HSCT in a patient with a previous HSCT was collected by disease category only for those patients with a planned double autologous after autologous transplants; for all other situations this information was collected generically only. The following definitions were used:14 Re-transplants (autologous or allogeneic) were defined as an unplanned HSCT for rejection or relapse after a first HSCT. Multiple transplants were defined as being part of a planned double or triple autologous or allogeneic transplant protocol. Information on stem cell source was collected as bone marrow, peripheral blood or cord blood. Combined bone marrow, peripheral blood and cord blood transplants were reported as peripheral blood HSCT. The possibility for reporting cord blood transplants by indication and donor type was introduced for the first time in this year's survey. Information on reduced intensity conditioning was collected as a total for each team only and not for individual transplants. Definitions for reduced intensity conditioning (RIC) HSCT followed the recently published definitions.

Transplant rates. Transplant rates were computed as number of HSCT per 10 million inhabitants as previously defined.2 Transplant rates refer to the number of transplants in a given country compared to its own population. The survey cannot make adjustments for patients who cross borders and receive their HSCT in a foreign country. Population data were obtained from the US census office (http://www.census.gov).

Economic factors. Economic factors considered in the analysis followed the previously defined rules. Countries were categorized by their gross national income per capita according to the World Bank definitions into high-income (Australia, Belgium, Cyprus, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Netherlands, Norway, Portugal, Slovenia, Spain, Sweden, Switzerland and UK), middle-income (Croatia, Czech Republic, Estonia, Hungary, Latvia, Lithuania, Poland and Slovakia) and low-income countries (Azerbaijan, Belarus, Bosnia and Herzegovina, Bulgaria, Macedonia, Romania, Russia, Serbia and Montenegro, Ukraine and Turkey). The latter category refers to the World Bank definition of 'lower middle income' (http://www.worldbank.org) as previously used.

Non-European countries that traditionally participate in the EBMT activity survey (Algeria, Iran, Israel, Saudi Arabia, South Africa and Tunisia) are included in the overall data presentation. They were not included in the analysis on economic factors. The same applies to Iceland and Luxemburg, because of some missing data over the time span.

Results
Participating teams
Of the 605 teams reporting HSCT in 2006, 361 (60%) did both allogeneic and autologous transplants; 227 (37%) restricted their activity to autologous, 8 teams (1%) to allogeneic transplants only. Nine teams (2%) reported having performed no transplants in 2006.

In total, 211 teams (34%) did fewer than 20 HSCT in 2006, 210 teams (35%) between 20 and 50 HSCT, 132 teams (22%) between 50 and 100 HSCT and 52 teams (9%) >100 HSCT.

In total, 136 teams reported at least one cord blood HSCT in 2006 and 23 teams reported >5.

Number of HSCT in 2006
First transplants 2006. A total of 25050 first transplants, 9661 (39%) allogeneic and 15389 (61%) autologous were carried out in 2006 (Table 1). Overall, this corresponds to a slight increase in the number of HSCT compared to 2005, when there were 24168 first transplants. Number of allogeneic HSCT increased by 9% from 8890 in 2005 to 9661 in 2006, while the number of autologous HSCT remained similar; 15278 in 2005 and 15389 in 2006.

Additional transplants 2006
There were 1557 re-transplants (772 allogeneic/785 autologous) and 2133 additional planned multiple transplants (711 allogeneic/2062 autologous). Thus, there were a total of 28740 HSCT procedures; 10504 allogeneic (37%) and 18236 autologous (63%) transplants were performed in 2006. This corresponds to an overall increase of 93 re-transplants (74 allogeneic and 19 autologous) or 6% as

Abbreviations: BM = bone marrow; MDS = myelodysplastic syndromes; MM = multiple myeloma; MPS = myeloproliferative disorders; PBPC = peripheral blood progenitor cells; SAA = severe aplastic anemia; sec. AL = secondary acute leukemia; thal = thalassemia.

«These differences relate to all transplants (Figure 1a), to allogeneic HSCT (Figure 1b) and to autologous HSCT (Figure 1c). Differences between Eastern and Western European countries have been previously reported. Of interest to note is that countries with similar total transplant rates had similar transplant rates for allogeneic HSCT as well as for autologous HSCT.»

Transplant rates in 2006. There were marked differences in transplant rates between European countries and countries affiliated with EBMT as presented in Figure 1.

These differences relate to all transplants (Figure 1a), to allogeneic HSCT (Figure 1b) and to autologous HSCT (Figure 1c). Differences between Eastern and Western European countries have been previously reported. Of interest to note is that countries with similar total transplant rates had similar transplant rates for allogeneic HSCT as well as for autologous HSCT.

Disease indications

Indications for HSCT in 2006 are listed in detail in Table 1. Main indications were lymphoproliferative disorders with 14,169 patients (56%), 1,597 patients with allogeneic HSCT.

Compared to 2005. Regarding the planned double autologous-allogeneic HSCT, there were a total of 531 procedures. Compared to 2005, when there was a total of 671 planned double autologous-allogeneic HSCT, this corresponds to a decrease of 21%. Main indications for the planned double transplant programs were, as in the previous year, multiple myeloma, non-Hodgkin’s lymphoma and Hodgkin’s disease.17,20

Bone Marrow Transplantation
Figure 1 Transplant rates (number of HSCT per 10 million inhabitants) in European countries in 2006. (a) All HSCT combined, (b) allogeneic HSCT only and (c) autologous HSCT only.

(11%), 12,572 with autologous HSCT (89%); leukemias with 7,963 patients (32%), 6,784 patients with allogeneic (85%), 1,179 with autologous (15%) HSCT; solid tumors with 1,564 patients (6%), 85 with allogeneic HSCT (6%), 1,479 with autologous HSCT (95%) and non-malignant disorders with 1,242 patients (5%), 1,115 with allogeneic HSCT (90%), 127 with autologous HSCT (10%). The latter, autologous HSCT for non-malignant disorders predominantly include patients (119) with autoimmune disorders. An additional 112 patients (1%), 80 with allogeneic HSCT and 32 with autologous HSCT were listed as 'other indications'.

Stem cell source
Of the 15,389 autologous first transplants, 256 (2%) were bone marrow derived, 15,133 (98%) from peripheral blood stem cells or from combined bone marrow and peripheral blood stem cell transplants (Table 1). Of the 9,661 allogeneic first transplants, 24% were bone marrow, 71% were peripheral blood and 5% were cord blood transplants (Figure 2). This corresponds to a slight decrease in the proportion of peripheral blood as stem cell source compared to the 74% in 2005. The proportion of peripheral blood as stem cell source varied depending on donor type. It was 72% for HLA-identical sibling donor transplants, 67% for unrelated donors, 81% for HSCT from other family members and, 74% for twin donors. Within allogeneic HSCT, the only disease indications with more bone marrow than peripheral blood donors were stem cell source were bone marrow failure syndromes (57% bone marrow) and congenital disorders (58% bone marrow) (Figure 2a). The proportion of main indications varied as well within the three stem cell sources. Non-malignant disease represented about a quarter of all indications for bone marrow and cord blood, but only a small fraction among the peripheral blood transplants (Figure 2b).

Donor type
For the 9,661 allogeneic first transplants, HLA-identical siblings were used as donors for 4,838 (50%) of the recipients, other family members for 5,39 (5.5%) of the recipients, a syngeneic twin for 43 (0.5%) of the recipients and an unrelated volunteer donor for 4,241 (44%) of the recipients.
Conditioning
Numbers of RIC HSCT continued to increase from 3301 in 2005 to 3350 in 2006 at the same rate as allogeneic HSCT. They were used in 34% of all allogeneic HSCT. This information is collected only in a generic way; no information on disease distribution is possible by the activity survey.

Cord blood transplants
A total of 544 allogeneic HSCT were cord blood transplants compared to 395 in 2005, 283 in 2004 and 86 in 1997 when this item was introduced into the activity survey. The development over the last 10 years, and the massive increase in the last four years, is illustrated in Figure 3. This increase was largely observed in countries of the high-income World Bank category. Of the 507 cord blood HSCT reported as first transplants, the majority, 458 (90.5%), were from unrelated donors. There were 45 (9%) HLA-identical and 4 (0.5%) non-identical family transplants. There were no autologous cord blood transplants reported.

Overall, the 544 cord blood transplants correspond to 5% of all allogeneic HSCT. However, there were marked differences in the use of cord blood depending on disease indication (Table 2). Of the 507 cord blood HSCT reported by indication, a higher proportion was for non-malignant disorders (total 11%), specifically for congenital bone marrow failure syndromes (7%), immune deficiencies (15%) or inherited disorders of metabolism (27%). Cord blood was rarely used for solid tumors (4%) and lymphoproliferative disorders (2%). Cord blood was used
more frequently in advanced leukemias than in early leukemia’s.

There were also major differences in the use of cord blood HSCT between the European countries. This refers to absolute numbers compared to the population (cord blood transplant rates) (Figure 4) as well as to the proportion of cord blood as stem cell source among the allogeneic HSCT (data not shown).

Donor lymphocyte infusions
There were 1920 patients reported as having received donor lymphocyte infusions in 2006. This corresponds to about two-thirds of the number of reported patients with RIC HSCT. No information on the disease indication of those patients with DLI is available from the activity survey.

Major changes over the last decade
Allogeneic HSCT. The ongoing increase in allogeneic HSCT continued at the same rate as has been observed over the last decade for almost all indications (Figure 5). Clear increases were seen in the acute leukemias, as illustrated for AML (Figure 5a) and ALL (Figure 5b). There were stable numbers for CML and lymphoproliferative disorders when compared to 2005.

Autologous HSCT. In contrast to the development in allogeneic HSCT, numbers in general remained stable for autologous HSCT overall (Figure 6) as illustrated for plasma cell disorders (PCD) (Figure 6a). However, the continuing decline in autologous HSCT for ALL is still evident (Figure 6b).

Discussion
This report presents the current state of the art of HSCT in Europe in 2006. It documents the diversity of the procedure, which includes autologous and allogeneic stem cells from the three main sources, bone marrow, peripheral blood and cord blood for a broad range of malignant and non-malignant disorders. Allogeneic HSCT continue to increase for most indications in all countries and in countries with high and middle income by World Bank categories. This increase is most pronounced in patients with acute leukemia and is observed in related and unrelated HSCT as well. In contrast to allogeneic HSCT, numbers of autologous HSCT remained similar in most disease indications when compared to 2005.

For the first time since the introduction of the EBMT activity survey, detailed information was collected concerning cord blood transplants. The data confirm the increasing use of cord blood in general. They permit a rapid presentation of current use by indication and donor type. The data show marked differences in cord blood use between European countries. These differences are not explained solely by economic factors such as gross national income per capita or World Bank category. Most likely, these differences reflect the activities of the major cord blood banks in Europe and the impact of their leaders on the transplant activities with their countries.

Bone Marrow Transplantation
non-malignant disorders, absence of GvHD is never deleterious since no graft-versus-disease effect is required.\textsuperscript{11}

The most frequent use of cord blood overall was for acute leukemias. The rapid increase in use might be due to the introduction of new technologies, for example, the use of double cord blood products to increase the number of stem cells given or the use of combined haploidentical cord blood transplants.\textsuperscript{94, 95} The survey does not provide data on these technologies; reports from the registries need to be analyzed to confirm this hypothesis. The fact that more cord blood HSCTs were used for advanced acute leukemias than for early leukemias might reflect this attitude and might reflect some of the reservations concerning general use of cord blood HSCT instead of an HLA-identical sibling or well-matched unrelated HSCT. It is also important to note that none of the teams reported an autologous cord blood HSCT in 2006.

As usual, the activity survey does not provide any outcome data. This is not the purpose of this data collection, whose focus is on the rapid dissemination of
trends. Outcome data will be reported later and elsewhere.
In contrast, this data give a clear overview on the status quo in 2006 and on the developments to be expected in the near future. As such, they provide a basis for patient counseling and health-care planning.

Rituximab maintenance improves clinical outcome of relapsed/resistant follicular non-Hodgkin lymphoma in patients both with and without rituximab during induction: results of a prospective randomized phase 3 intergroup trial

We evaluated the role of rituximab (R) both in remission induction and maintenance treatment of relapsed/resistant follicular lymphoma (FL). A total of 485 patients were randomized to induction with 6 cycles of cyclophosphamide, doxorubicin, vinristine, and prednisone (CHOP) (every 3 weeks) or R-CHOP (R: 375 mg/m² intravenously, day 1). Those in complete remission (CR) or partial remission (PR) were randomized to maintenance with R (375 mg/m² intravenously once every 3 months for a maximum of 2 years) or observation. R-CHOP induction yielded an increased overall response rate (CHOP, 72.3%; R-CHOP, 85.1%; \( P < .001 \)) and CR rate (CHOP, 15.8%; R-CHOP, 29.6%; \( P < .001 \)). Median progression-free survival (PFS) from first randomization was 20.2 months after CHOP versus 33.1 months after R-CHOP (hazard ratio [HR], 0.65; \( P < .001 \)). Rituximab maintenance yielded a median PFS from second randomization of 51.5 months versus 14.9 months with observation (HR, 0.40; \( P < .001 \)). Improved PFS was found both after induction with CHOP (HR, 0.33; \( P < .001 \)) and R-CHOP (HR, 0.54; \( P = .004 \)). R maintenance also improved overall survival from second randomization: 85% at 3 years versus 77% with observation (HR, 0.32; \( P = .011 \)). This is the first trial showing that in relapsed/resistant FL rituximab maintenance considerably improves PFS not only after CHOP but also after R-CHOP induction.

Introduction

For patients with follicular lymphoma (FL) chemotherapy alone has not resulted in improved overall survival (OS) over the past 30 years. Although in most patients complete remissions (CRs) or partial remissions (PRs) can be obtained with either single agents or combination chemotherapy, the clinical course is characterized by a high relapse rate. After relapse, both the response rate and relapse-free survival after subsequent salvage treatment regimens steadily decrease, resulting in a median survival of only 4 to 5 years after first relapse. Therefore, new treatment modalities resulting in increased progression-free survival (PFS) and OS are urgently required. Optimal treatment of patients relapsed after 1 or 2 chemotherapy regimens is largely unknown.

Rituximab (R) is a chimeric murine/human anti-CD20 monoclonal antibody capable of killing CD20+ lymphoma cells. Effector mechanisms include complement-mediated cytotoxicity, antibody-dependent cellular cytotoxicity, and possibly direct induction of apoptosis. In the nonrandomized pivotal study in 166 relapsed low-grade lymphoma patients, monotherapy with rituximab resulted in a response rate of 48%, with a 62% complete remission (CR) rate and a median time to progression in responding patients of 13 months. Toxicity was generally mild to moderate (grade 1 or 2) and occurred primarily with the first infusion. In a subsequent phase 2 study, the combination of R with cyclophosphamide, doxorubicin, vinristine, and prednisone (R-CHOP) was shown to be safe and effective.

Treatment results in FL might not only be improved by more effective induction regimens, but also by maintenance treatment defined as continued treatment beyond induction therapy. Maintenance treatment with cytotoxic agents has been shown to improve PFS but not OS. This prolongation of PFS was achieved at the cost of increased toxicity, reduced patient well-being, and increased risk of secondary malignancies. In a recent meta-analysis, interferon maintenance treatment showed a survival benefit in FL when given in conjunction with intensive chemotherapy and at certain dose levels. However, the benefit of maintenance was not consistent across all studies, and toxicity was considerable.

Because of its efficacy as monotherapy and its favorable pharmacokinetic and safety profile, maintenance treatment with rituximab might be both effective and well-tolerated.

In view of (1) the efficacy of rituximab monotherapy in relapsed low-grade lymphoma,11 (2) the feasibility of combining rituximab with cytotoxic drugs,12 and (3) the theoretical potential of such combinations to clear minimal residual disease, we decided in 1998 to launch a phase 3 randomized clinical trial in patients with relapsed or resistant FL with 2 main objectives: first, to compare response rates with CHOP and R-CHOP and, second, to establish the effect of maintenance treatment with rituximab on progression-free survival (PFS).

Patients, materials, and methods

Patients

This randomized (1:1) open-label phase 3 intergroup study was conducted at 130 centers in Canada, Australia/New Zealand, Europe, and South Africa from November 1998 to April 2004. Patients eligible for the study were older than 18 years of age with a CD20+ grade 1 to 3 FL, Ann Arbor stage III or IV at initial diagnosis, and relapse after or resistance to a maximum of 2 monotherapies containing systemic chemotherapy regimens. A previous regimen was defined as at least 2 months of single-agent therapy (eg, chlorambucil) and at least 2 consecutive courses of polychemotherapy (eg, cyclophosphamide, vincristine, and prednisolone [CVP] or purine analogs). Patients had to have at least 1 bidimensional measurable mass by either clinical or radiologic examination. World Health Organization (WHO) performance status had to be 2 or below. Major exclusion criteria were prior treatment with chemotherapy, rituximab, or autologous or allogeneic stem cell transplantation; more than 10 × 10^9/L circulating tumor cells; histologic transformation; known HIV positivity; symptomatic central nervous system (CNS) lymphoma; IgG levels below 3 g/L; and severe concomitant disease. Patient information and written informed consent were obtained according to the rules of the respective country and institute. The study was conducted according to the Declaration of Helsinki and the Guidelines for Good Clinical Practice.

Study design and treatment

Eligible patients were randomized to remission induction with either 6 cycles of standard CHOP (cyclophosphamide 750 mg/m^2 intravenously, day 1; doxorubicin 50 mg/m^2 intravenously, day 1; vincristine 1.4 mg/m^2 intravenously, maximum 2 mg, day 1; and prednisone 100 mg orally daily, days 1 to 5; cycle every 3 weeks) or CHOP plus rituximab (R) (375 mg/m^2 intravenously at day 1 of each cycle of CHOP). After 2 cycles of CHOP with or without R, patients were evaluated for response. Those with stable disease or progression went off study. Responders received another 3 cycles of the assigned treatment. Patients with a CR or a PR after 6 cycles of therapy underwent a second randomization to either no further treatment [observation] or maintenance treatment with rituximab (375 mg/m^2 intravenously once every 3 months until relapse or for a maximum of 2 years). Exclusion criteria for second randomization were no CR or PR upon induction treatment, IgG levels below 3 g/L, and active infection.

First randomization was stratified by center, previous treatment with purine analogs, age, number of previous induction treatments, and best response previously obtained (CR/PR/no change [NC]/progressive disease [PD]), time since diagnosis (more than 2 years or 2 years or less), and bulky disease (more than 10 cm or 10 cm or less) using a minimization procedure.

The second randomization was stratified according to the treatment allocated by the first randomization, the quality of the response obtained after induction (CR/PR), and center. Responses after induction treatment were evaluated by physical examination, hematology and chemistry, computed tomography (CT) scans (obligatory), and bone marrow biopsies (when indicated) and assessed according to the Lymphoma Expert's Confirmation of Response (LEXCOR) criteria.18 Patients lacking bone marrow evaluation but with evidence of disease on physical examination and CT scans were scored as partial remissions.

During the 2 years of R maintenance/observation, physical examination and hematology and chemistry were performed at least every 3 months and thereafter once every 4 to 6 months. In this large multicenter international study it was decided to adhere as much as possible to the daily practice in the participating countries. Thus, during maintenance/observation CT and bone marrow examinations were performed only on indication. A central pathology review was performed by all participating groups.

The trial was designed to detect a 10% difference (from 90% to 80%) in the overall response rate to induction chemotherapy and to recruit 500 patients (alpha = 0.05, beta = 0.22, 2-sided test). The final analysis of maintenance was performed after 501 progressions or deaths to detect a 14% difference in the 2-year PFS (from 40% to 54%; alpha = 0.05, beta = 0.2, 2-sided test). An interim analysis of safety was planned after inclusion of 50 patients and 2 interim analyses of efficacy after inclusion of 300 and 400 patients (Haybittle and Peto strategy, P < .001).

Statistical analysis

All primary analyses were conducted following the intention to treat (ITT) principle. The primary end point for the induction phase was the response to treatment. Secondary end points were PFS and OS from first randomization. Response rates were compared using the Mantel-Haenszel test for trend on 4 ordered categories (CR/PR/NC/ND). For the primary analysis, nonassessable patients were excluded. For sensitivity analyses, nonassessable cases were considered as progressions. The primary end point for the maintenance phase was PFS defined as interval between the date of second randomization and date of first relapse, progression, or death, and the secondary end point was OS from second randomization. The principal analysis of PFS and OS was done with the log-rank test and sensitivity analyses done with Cox regression analysis with adjustment for type of induction treatment and response. Kaplan-Meier curves were calculated to graphically show the differences between the treatment arms. All P values given are 2-sided.

In February 2004, a preplanned second interim analysis of the present study was reviewed by the Independent Data Monitoring Committee (IDMC) of this study. At that time, 461 patients had been included (569 evaluable for response) and 319 patients had been randomized for maintenance treatment (268 evaluable). The results revealed that the primary end points for both the induction and maintenance phase of the study had been reached, and the formal criteria for stopping the trial had been met. Subgroup analysis as requested by the IDMC continued the benefit of R maintenance in the CHOP subgroup but not yet in the R-CHOP subgroup. It was therefore suggested to amend the protocol with all patients receiving R-CHOP for induction treatment followed by randomization to R maintenance therapy or no further treatment. Hence, recruitment to the trial was suspended in April 2004 during preparation of a major protocol amendment. In the meantime, all data were retrospectively monitored on site, and all pending queries were solved to perform a final analysis including all patients recruited to the study by April 2004. Because the study was conducted at 130 sites and by 8 clinical study groups, the monitoring and data cleaning process was only completed in September 2005. Thus, an updated data set with additional 19 months of median follow-up was available for the final analysis. After reviewing the data of this final analysis, the IDMC recommended not to reopen the trial because the primary question of the amended protocol had already been answered.

Results

Patients

A total of 474 patients with relapsed/resistant FL were randomly assigned to receive induction treatment with CHOP or R-CHOP. Nine patients had to be excluded because of missing informed consent forms. Therefore, all analyses are restricted to 465 patients.

* Assessed retrospectively.

(231 CHOP and 234 R-CHOP). Recruitment was stopped after the preplanned second interim analysis for efficacy because the criteria for early discontinuation were met both for induction and maintenance. Baseline demographics and other characteristics of the 2 groups were well balanced (Table 1). Because the Follicular Lymphoma International Prognostic Index (FLIPI) was only published in 2004,18 the FLIPI score was assessed retrospectively for our patients and thus was not used as a stratification factor. However, both study arms were well balanced, with 70% of the patients having intermediate (FLIPI score 2) or high-risk (FLIPI score 3 or higher) disease at study entry (Table 1). According to local pathology, 98% of the patients had FL. Central pathology data are available for 82% of all patients. The overall concordance rate between local and central assessment for all subtypes of FL was 93% in both treatment arms.

In both groups, about 80% had received only one prior treatment, almost equally consisting of single-agent therapy or polychemotherapy. In both arms, only 9% of the patients had been treated previously with purine analogs. Best response to prior treatment was similar in both study arms. A total of 17% and 16% of patients were resistant to their prior treatment in the CHOP and R-CHOP arms, respectively (Table 1). Three randomized patients never started protocol treatment—1 because of rapid progression and 2 refusals. The 6 cycles of protocol therapy could be completed in 81% of the patients in the CHOP arm and in 85% in the R-CHOP arm. Dose density for doxorubicin and cyclophosphamide was similar in both arms. Most protocol discontinuations occurred at the time of the first response evaluation, after the third cycle of treatment.

The 334 patients randomized to the maintenance phase were well balanced for baseline characteristics at study entry, FLIPI score (2 or higher in 70% and 66% in the observation and maintenance arms, respectively), type of induction treatment received, and response to induction (in both arms, 39% CR and 71% PR). In both arms, more patients had received R-CHOP during induction (59% in the observation arm and 55% in the maintenance arm), reflecting the higher efficacy of R-CHOP as compared with CHOP in terms of response induction. Maintenance treatment was started a median of 7 weeks (range, 3 to 16 weeks) after the end of the last induction cycle.

Efficacy: induction phase

The addition of rituximab significantly increased both overall response and complete remission rates. Overall response rates were 72.3% and 85.1% after CHOP and R-CHOP induction treatment, respectively (P < .001). The CR rate was 15.6% in patients receiving CHOP and 29.5% in patients treated with R-CHOP (P < .001) (Table 2). The partial response rate was 56.7% in the CHOP arm and 55.6% in the R-CHOP arm (non-significant [NS]). With a median follow-up from first randomization of 39.4 months, median PFS from first randomization was 20.2 months in the CHOP group versus 33.1 months in the R-CHOP group (P < .001, log-rank test; Figure 1A). Hazard ratio (HR) for the R-CHOP group was 0.65. OS at 5 years from first randomization was 71.9% in the CHOP arm and 82.5% in the R-CHOP arm (P = .096, log-rank test; HR, 0.74; Figure 1B).

Efficacy: maintenance phase

Of the 366 patients having responded to induction treatment (with either CHOP or R-CHOP) 32 were not randomized for maintenance treatment—17 because of low IgG levels (9 in the CHOP arm, 8 in R-CHOP); 8 patients because they were still on CHOP induction when the trial was put on hold because of the results of the first interim analysis (these patients received R maintenance treatment on a compassionate use basis; they were included in the analysis of response to induction but were excluded from the analysis of maintenance treatment); 1 because of a secondary neoplasia; and 1 because of active infection. There were 2 refusals and 2 ineligibilities due to administrative problems.

A total of 334 eligible patients were randomly assigned to R maintenance treatment (n = 167) for 2 years or observation (n = 167). In each study arm, 1 patient did not start allocated treatment because of progression immediately after randomization. At the time of last follow-up, 41 patients were still under maintenance treatment or observation. With a median follow-up from second randomization of 33.3 months, median PFS from second randomization was 51.5 months in the R maintenance arm versus 14.9 months in the observation arm (P < .001, log-rank test). The hazard ratio for R maintenance treatment compared with observation was 0.40; P < .001 (Figure 2A). Because the difference in PFS was highly significant, a further analysis was carried out to evaluate whether the benefits of maintenance applied to patients treated both with CHOP and R-CHOP. After CHOP induction, R maintenance resulted in a median PFS from second

Figure 1. Effect of addition of R (rituximab) to CHOP remission induction on progression-free survival and overall survival. Kaplan-Meier plots of progression-free survival and overall survival from first randomization. (A) Progression-free survival after CHOP (n = 231) and R-CHOP (n = 234) remission induction treatment. (B) Overall survival after CHOP (n = 231) and R-CHOP (n = 234) remission induction treatment.

randomization of 42.2 months versus 11.6 months in the observation arm (HR, 0.30; P < .001). After R-CHOP induction, the figures were 51.8 months and 23.0 months, respectively (HR, 0.54; P = .004) (Figure 3). Similarly, R maintenance resulted in a highly significant increase in PFS both in patients who had a FR after induction treatment and those who had obtained a CR (data not shown).

R maintenance treatment increased 3-year overall survival rates (from second randomization) from 77.1% in the observation group to 85.1% in the R maintenance group (P = .011, log-rank test; Figure 2B). The hazard ratio for R maintenance compared with observation is 0.52. All sensitivity analyses confirmed the results of the principal analyses.

Safety

Induction. Grade 3-4 neutropenia was the most frequent adverse event (AE); 48.2% grade 3-4 in the CHOP arm and 54.7% in the R-CHOP arm (NS). More patients on R-CHOP experienced grade 3-4 allergy (CHOP, 0 patients; R-CHOP, 8) and skin reactions (CHOP, 17 patients; R-CHOP, 31). Six patients in the CHOP arm and 8 patients in the R-CHOP arm withdrew from treatment because of toxicity. Treatment-related mortality occurred in 2 patients in the CHOP group (1 sepsis, 1 respiratory distress syndrome) and in 1 patient in the R-CHOP group (pneumonia). During induction, hypogammaglobulinemia developed in about 5% of the patients. Indeed, 17 of the 366 responders to induction treatment were not eligible for second randomization because of IgG levels below the predefined threshold of 3 g/L. However, we did not find a correlation between the incidence of bacterial infections and decreased IgG levels.

Maintenance. During R maintenance treatment, neutropenia was the only significant AE: 10.8% in the R maintenance arm versus 5.4% in the observation arm (NS; 95% CI = 0.07, 0.10). This probably contributed to the increased grade 3-4 infection rate: 9% in the maintenance group and 2.4% (P = .009, 95% CI) during observation, with most of these in the ear-nose-throat area. During maintenance 6 patients with therapy-related grade 3-4 adverse events (infection) were hospitalized. They fully recovered.

Only 6 of the 167 patients withdrew from R maintenance treatment because of toxicity (4 of the 6 due to infections). According to protocol, IgG (but not IgA and IgM) levels were measured every 3 months during maintenance treatment/observation. At second randomization the median IgG levels were just below the normal range in both arms (6.6 g/L in the observation arm and 6.5 g/L in the maintenance arm). Whereas during 2 years of observation the median IgG levels increased to within the normal range (7.3 g/L). IgG levels remained stable in the maintenance arm (6.3 g/L). Maintenance dose was delayed in only 1 patient and omitted in 2 patients at least once, because of low (below 3 g/L) IgG levels. No patient had to be withdrawn from R

BLOO, 15 NOVEMBER 2008 · VOLUME 108, NUMBER 10

RITUXIMAB MAINTENANCE IN FOLLICULAR LYMPHOMA 3299

[Graphs and charts]

Figure 3. Effect of R (rituximab) maintenance treatment on progression-free survival after remission induction with either CHOP or R-CHOP. Kaplan-Meier plots of progression-free survival from second randomization. (A) Progression-free survival after CHOP remission induction (n = 145). (B) Progression-free survival after R-CHOP remission induction (n = 189).

maintenance treatment due to persisting IgG levels below 3 g/L. There were no deaths related to R maintenance treatment.

Discussion

The final analysis of the European Organisation for Research and Treatment of Cancer (EORTC) 20981 Intergroup study has shown several important findings. Firstly, in patients with relapsed/resistant FL, remission induction with R-CHOP results in a highly significant increase in CR rate as compared with CHOP; secondly, R maintenance treatment significantly improves PFS and OS in patients responding to induction treatment; thirdly, R maintenance treatment achieves a considerable increase in PFS not only after remission induction with chemotherapy (CHOP) but also after immunotherapy (R-CHOP).

Since the start of the trial in late 1998, a considerable amount of data on efficacy and safety of rituximab in combination with different chemotherapy regimens as induction therapy for both previously untreated and pretreated patients has been published.2234 There is a strong rationale for this combination because cytotoxic drugs and rituximab both have proven efficacy but different mechanisms of action and nonoverlapping toxicities. In addition, in vitro data have shown that rituximab may increase sensitivity of lymphoma cells to cytotoxic agents.9

In indolent lymphoma, remission induction with the combination of rituximab and chemotherapy has been shown to be superior to chemotherapy alone in several randomized phase 3 trials, both in previously untreated as well as in relapsed patients. In previously untreated patients, the addition of R to chemotherapy results in significantly better overall response and complete remission rates and improved PFS22 23 and OS.22,24 Our finding of a superior CR rate after R-CHOP in relapsed FL patients is in line with the results of the German Low Grade Lymphoma Study Group, which showed in a mixed group of relapsed/refractory indolent non-Hodgkin lymphoma (NHL) and mantle cell lymphoma patients that R-FCM (rituximab-fludarabine, cyclophosphamide, and mitoxantrone) yields significantly higher ORR and CR rates and prolongs PFS and OS when compared with FCM alone.25 In all these studies, addition of rituximab to chemotherapy did not result in increased toxicity.

In the past decades, maintenance therapy over a period of 12 to 24 months after induction treatment was evaluated using cytotoxic agents such as chlorambucil or cyclophosphamide10 11 or interferon-α.12,13,26 However, no consistent long-term benefit in terms of OS could be demonstrated, and prolonged administration of both chemotherapy and interferon-α are associated with significant toxicity and patient inconvenience.

Two randomized trials have investigated the efficacy of induction therapy with single-agent rituximab followed by rituximab maintenance treatment. Hainsworth et al randomized patients with relapsed or refractory indolent NHL to R maintenance or R retreatment at disease progression and found an approximate 4-fold increase in PFS for the former (31.1 months versus 7.4 months).27 However, the rituximab benefit (defined as date of study entry to date of next lymphoma treatment) was similar in both groups (31.3 versus 27.4 months, respectively). Because this was not part of our study, we do not have systematic information on the retreatment of patients who relapsed after either R maintenance or observation. However, because rituximab was registered and available in all participating countries, it has to be assumed that many patients will have received a rituximab-containing regimen, notably those who received rituximab neither during induction nor maintenance.

Indeed, a preliminary analysis showed that in the patients in the observation arm, first post-protocol treatment (n = 85) was R monotherapy in 29% and R-chemo in 19%, versus 11% and 5%, respectively, in patients in the maintenance arm requiring post-protocol treatment (n = 56). The Swiss Group for Clinical Cancer Research (SAKK) 35-98 study showed an almost 2-fold increase in median event-free survival (EFS) by R maintenance in patients with untreated and relapsed FL (from 12 to 23 months).28

The efficacy of R maintenance therapy has also been investigated following treatment with different chemotherapy regimens. In previously untreated patients with indolent lymphoma (Eastern Cooperative Oncology Group [ECOG] 1496). R maintenance treatment after remission induction with CVP increased PFS by almost 3 years and improved OS in patients with high tumor burden.29 In all these studies, R maintenance treatment was well tolerated and did not lead to significantly higher rates of neutropenia, thrombocytopenia, and/or infection as compared with observation.

Our study is the first large randomized trial to show that in patients with relapsed/resistant FL, R maintenance treatment achieves a statistically highly significant and clinically very relevant improvement in PFS after induction treatment with chemotherapy plus rituximab. For the pooled CHOP and R-CHOP patients, R maintenance also improved OS: 85% at 3 years versus 77% with observation (HR, 0.52; P = .011). Of course, follow-up is still rather short for patients with FL, and longer follow-up is required to know whether the survival benefit will stand. Recently, a preliminary report of a randomized study by Hiddemann et al in a mixed population of relapsed FL and MCL also showed a
significant improvement in response duration for patients receiving R maintenance after induction therapy with R-FCM (n = 119). In relapsed FL, there has only been one randomized trial comparing chemotherapy and autologous stem cell transplantation. Although the number of patients was small and not balanced as to prognostic factors between the study arms, a clear benefit for autologous stem cell transplantation as to PFS and OS was shown. In view of the excellent PFS obtained with R-CHOP induction followed by R maintenance, future trials in relapsed FL should compare this (or a comparable) regimen with an optimal transplantation approach: R-chemotherapy induction and R-myeloablative treatment, and R maintenance after transplantation. This probably also applies to future trials in FL of autologous transplantation in first remission.

In conclusion, we have shown that R maintenance treatment results in a major improvement in PFS both after chemotherapy and immunomodulatory treatment, and, most importantly, also in a better OS. Questions still to be answered related to the optimal schedule (e.g., single infusions every 2 to 3 months or weekly infusions every 6 months) and duration of R maintenance (e.g., 6 weeks or until progression), and whether the results of R-chemotherapy induction and R maintenance in relapsed/refractory FL will be similar in patients who have already received prior rituximab-containing regimens.

Prognostic Factors in Allogeneic Bone Marrow Transplantation for Multiple Myeloma

By Gösta Gahrton, Sante Tura, Per Ljungman, Joan Bladé, Lena Brandt, Michele Cavo, Thierry Facon, Alois Gratwohl, Anton Hagenbeek, Peter Jacobs, Antonio de Laurenzi, M. Van Lin, Mauricette Michallet, Jukka Nikoskelainen, Josy Reiffers, Diana Samson, Leo Verdonck, Theo de Witte, and Liisa Völin

Purpose: To analyze prognostic factors for allogeneic bone marrow transplantation (BMT) in multiple myeloma.

Patients and Methods: One hundred sixty-two reports of allogeneic matched sibling-donor transplants in multiple myeloma received by the European Group for Blood and Marrow Transplantation (EBMT) registry between 1983 and early 1993 were analyzed for prognostic factors. End points were complete remission, survival, and duration of complete remission.

Results: Following BMT, 44% of all patients and 60% of assessable patients entered complete remission. The overall actuarial survival rate was 32% at 4 years and 28% at 7 years. The overall relapse-free survival rate of 72 patients who were in complete remission after BMT was 34% at 6 years. Favorable pretransplant prognostic factors for survival were female sex (41% at 4 years), stage I disease at diagnosis (52% at 4 years), one line of previous treatment (42% at 4 years), and being in complete remission before conditioning (64% at 3 years). The subtype immunoglobulin A (IgA) myeloma and a low $\beta_2$–microglobulin level (< 4 g/L) also tended to have a favorable prognostic impact. The most important posttransplant prognostic factor was to enter a complete remission. Grade III to IV graft-versus-host disease (GVHD) was associated with poor survival.

Conclusion: Patients with a low tumor burden who respond to treatment before BMT and are transplanted after first-line therapy have the best prognosis following BMT.

MULTIPLE MYELOMA is a malignant disorder with a median survival duration of less than 3 years after conventional chemotherapy. However, survival is highly variable. Some patients die within months, while occasional patients survive more than 10 years. This heterogeneity in the prognosis of multiple myeloma has encouraged studies of prognostic variables. A high tumor burden, high C-reactive protein level, high plasma-cell thymidine-labeling index, elevated $\beta_2$–microglobulin level, low serum albumin level, and low platelet count have been associated with extremely poor survival following conventional chemotherapy. Therefore, such variables have been used to select patients for more intensive treatment. However, only a few studies have attempted to delineate prognostic factors of importance for the outcome of patients treated with high-dose chemotherapy followed by either autologous bone marrow transplantation (ABMT) or allogeneic bone marrow transplantation (BMT).

In a previous study by the European Group for Blood and Marrow Transplantation (EBMT) of 90 patients with multiple myeloma who underwent BMT, a number of factors were found to influence long-term survival, including stage I disease at diagnosis, being in complete remission at transplantation, and having received only a few lines of treatment pretransplant. The first patients reported to the EBMT registry in 1983 have now been monitored for up to 10 years. In the present updated report of 162 patients in the EBMT registry, new variables of prognostic importance have been found.

PATIENTS AND METHODS

Patients

One hundred sixty-two patients with multiple myeloma who received a bone marrow graft from an human leukocyte antigen (HLA)-compatible sibling donor between 1983 and early 1993 were reported to the EBMT registry; 92 were men and 70 were women. The median age was 43 years (range, 23 to 59). The myeloma subtype was immunoglobulin G (IgG) in 80 patients, IgA in 33, light chain in 31, and IgD in two. Five patients had nonsymptomatic multiple myeloma, and three had plasma-cell leukemia. The reports were incomplete in eight patients.

At diagnosis, 22 patients were in stage I, 30 in stage II (one IIB), and 109 in stage III (23 IIB); stage was not reported in one patient. The median time from diagnosis to BMT was 14 months (range, 3 to 166).

Treatment Before BMT

Treatment before BMT varied according to center. Forty-one patients received conventional therapy with intermittent melphalan plus prednisolone as first-line treatment and 121 patients received other drug combinations, most of which contained melphalan or cyclo-
phosphamidase in addition to other drugs. Thirty-six different combinations of drugs were used for second-line treatment and 21 combinations were used for subsequent treatment modalities. Twenty-six patients entered complete remission (defined as the absence of detectable monoclonal Ig in serum and of detectable free light chains in urine on either conventional immunoelectrophoresis or immunofixation, as well as the absence of apparent myeloma cells in the marrow on conventional cytologic analysis) after first-line treatment. Sixty-seven patients had a partial remission (defined as a decrease of serum Ig levels to a concentration less than 50% of pretreatment value, decrease in urine light-chain excretion to < 0.2 g/24 h, or both, combined with a hemoglobin value > 90 g/L, serum albumin level > 30 g/L, and serum calcium level < 2.61 mmol/L). Thirty-eight patients had stationary disease that did not respond to treatment, and in 20 patients the disease progressed (data were lacking for 11 patients). Ninety-six of these patients were later given second-line treatment, and of these, 46 patients received third-line treatment because of poor response or progressive disease. Thus, at the time of conditioning for BMT, 18 patients were in complete remission, 56 were in partial remission, 22 had stable disease that did not respond to further treatment, 14 had primary refractory disease, 25 had progressive disease despite treatment, and 14 were in relapse following complete or partial remission. Data were incomplete in three patients.

**Conditioning Treatment for BMT**

The conditioning for BMT was total-body irradiation (TBI) plus cyclophosphamide alone in 55 patients, TBI plus cyclophosphamide and melphalan in 27 patients, and TBI plus other drug combinations in 35 patients. Forty-five patients received high-dose chemotherapy without TBI. Twenty-five of these patients were conditioned with busulfan plus cyclophosphamide.

**Prevention of Graft-Versus-Host Disease**

Treatment for the prevention of graft-versus-host disease (GVHD) varied. Twenty-one different combinations of T-cell depletion, methotrexate, cyclosporine, prednisone, prednisolone, and cyclophosphamide were used. The single most common combination was cyclosporine plus methotrexate, which was used in 74 patients. Other drug combinations without T-cell depletion were used in 3 patients. T-cell depletion combined with drugs was used in 41 patients and alone in 13 patients. In one patient, information was lacking. Evaluation of GVHD was possible in 134 patients, of whom 46 received T-cell-depleted marrow, alone or in combination with drugs.

**Statistical Analysis**

Comparison of frequencies of complete remission was made with the conventional χ² test or, when small numbers made the χ² test improper, with Fisher's exact test. Survival curves were generated according to the Kaplan-Meier method and were tested with the log-rank test. Kaplan-Meier curves were dichotomized when less than five patients were under observation. Multivariate survival analyses were made with proportional hazards regression, with all quantitative variables dichotomized into qualitative variables.

**RESULTS**

**Response to BMT**

Remission status posttransplant was assessable in 121 patients. Forty-one patients either died before engraftment or were not yet assessable for engraftment. Of 121 patients who could be evaluated, 72 were in complete remission following BMT, of whom 16 were already in complete remission before conditioning for BMT. The median time from BMT to complete remission was 3 months, and in 90% of patients who entered complete remission, the monoclonal component had disappeared at 12 months posttransplant. However, in a small number of patients, the monoclonal Ig persisted for longer time periods, and in two patients it persisted for 36 months then disappeared.

The response to BMT was highly dependent on factors before conditioning. Forty-nine of 64 patients who were on first-line treatment at the time of BMT were assessable for complete remission, and 36 of these 49 patients entered a complete remission, while only 19 of 41 evaluated patients who underwent transplantation while receiving second-line treatment and 16 of 29 evaluated patients who underwent transplantation while receiving third-line or later treatment entered a complete remission (Table 1). The difference in complete remission rate between those who were on first-line treatment compared with those who were on second or later lines of treatment was highly significant ($P = .008$).

The status immediately before conditioning was not significantly predictive for response to BMT, except for patients who were in complete remission before transplantation (Table 2). For those who were not in complete remission immediately before conditioning, 24%, 36%, and 50%, respectively, of the patients who had progressive disease, primary refractory disease, or stable but nonresponsive disease entered a complete remission following BMT.

Other factors that were important predictors of response included stage of disease at diagnosis and patient sex. Irrespective of whether patients were transplanted in later stages of disease, those who were diagnosed in stage I had a significantly higher response rate than those who expressed no evidence of disease.

Abbreviation: CR, complete remission.
were diagnosed in stage II or stage III ($P < .05$) (Table 3). IgG myeloma had a significantly poorer complete remission rate than other subtypes (Table 4). Male patients also had a poorer response than females.

**Bone Lesions**

Bone lesions could be evaluated in 98 patients by roentgenography. Patients who did not survive day 100 were not assessable. Twenty-two of 98 patients had a normal roentgenographic picture before transplantation; 17 did not change following transplantation, while five progressed. Twenty-three patients had minor lytic lesions or osteoporosis; six improved, 10 were stationary, and seven progressed. Fifty-three patients had major lytic lesions; six improved and 47 were stationary. Thus, in 57 of 76 patients who had bone changes before BMT, the roentgenographic bone pattern did not change following BMT.

**GVHD**

One hundred thirty-four patients could be evaluated for GVHD. It was absent in 50 (37%). Forty-three had grade I, 29 grade II, six grade III, and six grade IV. Because of the many various GVHD prevention methods used, it was difficult to analyze any specific preventive method separately. However, if T-cell depletion was included in the preventive method, alone or together with other treatment modalities, the fraction of patients who had grade II to IV GVHD was significantly less than if no T-cell depletion was used ($P = .02$) (Table 5).

**Survival and Disease-Free Survival**

The overall median survival duration after BMT was 17 months (Fig 1). The 4-year survival rate was 32% and the 7-year survival rate 28%. One patient has survived for 10 years.

**Univariate Analysis**

Females had significantly better survival than males ($P = .04$) (Fig 2), but there was no significant difference in survival between patients less than 40 years of age and those $\geq 40$ years ($n = 55$) ($P = .18$).

Patients with stage I disease at diagnosis had a significantly better survival than those diagnosed in stages II and III ($P = .05$) (Fig 3). Patients with IgA myeloma tended to have better survival than patients with IgG myeloma ($P = .08$) and those with light-chain myeloma ($P = .28$) (Fig 4). There was no apparent difference between patients with $\lambda$- or $\kappa$-chain myeloma.

The level of $\beta_2$-microglobulin was measured in 45 patients at the time of diagnosis. There was a tendency for better survival in patients who had $\beta_2$-microglobulin values less than 4 mg/L as compared with those who had a higher value (Fig 5).

Patients who had received only one line of treatment had significantly better survival than those who had re-

</table>
ceived three or more lines of treatment ($P = .02$) (Fig 6). There was also a tendency for better survival in patients who had received only one line of treatment as compared with those who had received two lines of treatment ($P = .24$). The status at conditioning was of importance. Patients who were in complete remission at the time of conditioning had significantly better survival than other patients ($P = .05$). However, within the groups partial remission, stable but nonresponsive disease, primary refractory dis-

Fig 2. Actuarial survival after BMT according to patient sex. Kaplan-Meier curves show significantly better survival among females than among males ($P = .04$).
ease, and relapse or progressive disease, there was no significant difference.

The time from diagnosis to transplant was not of significant importance for survival. However, there was a tendency for patients who were transplanted later than 6 months from diagnosis to do worse than those who were transplanted before 6 months from diagnosis. This tendency for poorer survival was weak, but strongest for
patients who were transplanted later than 36 months from diagnosis ($P = .18$).

Bone marrow transplantation procedural factors of importance for prognosis could not be detected. However, the wide variety of regimens used made comparisons between different types of regimens difficult. The number of patients in each treatment group was small, so differences were unlikely to be detected. TBI plus cyclophos-
phamide was the most commonly used conditioning method. There was no significant difference between this method and busulphan plus cyclophosphamide ($P = .24$). Although graft-versus-host prevention methods that included T-cell depletion resulted in fewer patients with GVHD grade II to IV and a greater fraction of patients without GVHD, this did not translate into a trend for better survival.

Postengraftment factors were also important predictors of survival. Patients who entered a complete remission following BMT had significantly longer survival than those who engrafted, but did not enter complete remission ($P = .001$) (Fig 7). The median survival duration for patients who were in complete remission following BMT was 60 months, and one patient in this group had survived for 10 years.

Patients who had GVHD grade III or IV had extremely poor survival. It was significantly poorer than for those who had grade I or II GVHD ($P = .02$). There was no significant difference between patients who had no GVHD and those who had grade I or II.

**Multivariate Analysis**

Multivariate analysis was attempted to estimate the significance and order of each risk factor. However, the material was probably too small for a fair analysis. No single pre-BMT factor came out as a significant risk factor, although there was a tendency for a higher risk for all of the factors that were significant in the univariate analysis. The strongest tendency for favorable survival in the multivariate analysis was female sex as opposed to male sex ($P = .07$) and being in stage I at diagnosis as opposed to being in other stages ($P = .11$). Of posttreatment prognostic factors, the most important adverse one was to have acute GVHD grade III or IV ($P = .0006$). Most important was the comparison between patients who entered a complete remission following BMT and those who did not. For fair comparison, only those patients who were not in complete remission before BMT, but entered complete remission following BMT, were compared with those who engrafted after BMT, but did not enter remission after BMT. Even then, patients who entered complete remission had significantly better survival ($P = .01$). The 5-year survival rate of patients who entered complete remission was 52% and the 7-year survival rate 47% (Fig 7).

**Relapse Rate and Relapse-Free Survival**

The relapse-free survival rate of patients who entered complete remission was 34% at 6 years (Fig 8). Nine patients are still in complete remission more than 4 years following transplantation. The overall relapse rate was 45% at 60 months (Fig 9). There was no significant difference between assessable patients who had received T-cell depletion or no T-cell depletion.
Causes of Death

At the time of analysis, 57 patients were alive and 103 had died. Two patients were lost for follow-up evaluation. The causes of death were mainly the same as those in other patients with hematologic disorders who have undergone BMT. The primary cause of death was the original disease in 27 patients, while in the others it was transplant-related, i.e., bacterial or fungal infections in 19,
show in this study, as has been previously shown for BMT in leukemias, that patients with GvHD grade I or II had a lower relapse rate than patients with no GvHD. Nor was it possible to show that T-cell depletion resulted in a higher relapse rate, as has previously been shown for chronic myelocytic leukemia. However, it is possible that the heterogeneity in the present study has prevented the detection of such a possible graft-versus-myeloma effect, which would have been abolished or diminished by T-cell depletion.

The most important predictor for long-term survival following BMT was complete remission after engraftment. The difference between survival of patients who entered remission and patients who engrafted with signs of multiple myeloma was highly significant. Also, a substantial fraction of complete responders are still in complete remission up to 10 years following transplantation. Thus, obtaining a complete remission is crucial for long-term survival. Persistence of myeloma cells in serum, or light chain in urine will probably inevitably result in disease progression. However, a sizeable fraction of patients with very poor prognostic parameters before transplantation survived for more than 2 years, although they did not enter complete remission. Thus, it is possible that BMT may prolong life even in a fraction of patients who do not enter remission following transplantation.

This prognostic factor analysis does not give conclusive help in selecting patients for allogeneic BMT. Since the best results are obtained in females, in patients who are diagnosed in stage I irrespective of whether they are transplanted in another stage, in patients who have received only one line of treatment, and in those who were in complete remission already before transplantation, such patients appear to be reasonable candidates. However, as these groups of patients may also have relatively good prognosis with other treatment modalities, such as ABMT, with a lower initial transplantation mortality, it is difficult at this stage to recommend allogeneic BMT unreservedly for all of these patient groups. Still, it seems reasonable to conclude that allogeneic BMT could be performed at a stage when first-line treatment fails or if the patient is unresponsive to first-line treatment. In such cases, survival with chemotherapy is usually poor. Also, BMT can be performed not only in patients less than 40 years of age but also in older patients, probably up to 55 years of age. Although factors that predict poor prognosis with conventional chemotherapy, such as stage III multiple myeloma and a high β2-microglobulin level, also predict for relatively poor prognosis with transplantation, some patients might be candidates for BMT, since long-term survival is sometimes obtained. Patients with IgA myeloma seem to be especially good candidates for BMT.

The choice of treatment modality in multiple myeloma is becoming increasingly complex. Chemotherapy, ABMT, and allogeneic BMT are now competing methods. Although our results indicate that allogeneic BMT should preferably be done early, perhaps during or after failure of first-line treatment, and before several lines of treatment, comparative studies must be performed to determine the value of each treatment method. Controlled, prospective trials are extremely difficult to perform. For that reason, matched-pair analysis studies, as has been done for comparison of BMT and chemotherapy in acute leukemia, may be more realistic to delineate factors that might guide selection of one or the other method. Such analyses are in progress.

APPENDIX

The following centers participated in the study by reporting patients to the Myeloma Registry at Huddinge Hospital Hospital: Centre Hospitalier Regional et Universitaire, Angers, France (M. Boasson); Hospital Clinic, Barcelona, Spain (J. Bladé, C. Rozman); Kantonshospital, Basel, Switzerland (A. Gratwohl); Hospital Jean Minjoz, Besançon, France (M. Fesch); Hospital San Orsola, Bologna, Italy (M. Cavo, S. Tura); Institut Jules Bordet, Brussels, Belgium (L. Debuysche); Cliniques Universitaires St. Luc, Brussels, Belgium (A. Allogeneic and Syngeneic Hematopoietic Stem Cell Transplants in Patients With AL-Amyloidosis: A Report From The European Group For Blood And Marrow Transplantation (EBMT).

AL amyloidosis is caused by a plasma cell dyscrasia in which clonal immunoglobulin light chains deposited in tissues leads to organ failure and death. Treatment with high dose melphalan and autologous PBSC rescue produces hematologic remissions in approximately 40% of evaluable patients and improvements in organ disease and quality of life. For a subgroup of patients, an allogeneic hematopoietic cell transplantation (HCT) may be useful. There is little experience with this procedure in patients with AL amyloidosis. We report the patients (pts) who were registered within the EBMT database. Nineteen pts (median age 47 years, range 30-63; 8 female) with AL amyloidosis (n=17) or with multiple myeloma plus AL amyloidosis (n=2) underwent allogeneic (n=16) or syngeneic (n=3) HCT during 1987-2003, 11 of them before 2000. The following analysis was performed for allogeneic cases. Donors of allogeneic transplants were matched (n=13) or mismatched (n=1) related siblings or unrelated donors (n=2). Main organ manifestations were kidney, heart and liver. Indications for allogeneic HCT were young age, relapse after autologous HCT and progressive or refractory disease. Conditioning regimen was ablative in 8 pts and reduced-intensity conditioning (RIC) was used in the remaining 8 pts. Six pts had in-vivo or in-vitro T cell depletion. Engraftment was documented in 14/16 pts, 1 pt rejected the graft and 1 pt died before documented engraftment. Seven pts developed acute GVHD, 1 pt grade I, 4 pts grade II, 2 pt grade III/IV. Six of 10 evaluable pts developed chronic GVHD (4 pts limited, 2 pts extensive disease). Nine pts (56%) died at a median of 83 (range 25 - 1253) days after HCT, 5 deaths occurred before day +100. Causes of death were: cerebral aspergillosis (n=1), cardiac arrest (n=5), EBV lymphoma (n=1), gastrointestinal bleeding (n=1), disease progression (n=1), pneumococcal sepsis (n=1). Four deaths were TRM, 4 pts died of amyloidosis complications (3 cardiac deaths) and in one pt it can not be assigned. Seven pts remain alive (median observation 31 months, range 10-79) after HCT. Best hematological responses after HCT in surviving pts were immunofixation-negative CR in 6/7 pts (not available in 1 pt). In summary, a high day +100 mortality was observed. Main problem was cardiac failure due to amyloidosis or in combination with transplant-associated complications in the early phase after HCT. Of note, complete hematological responses can be achieved followed by organ response. This leads to a long-term survival of 44% in relapsed or refractory patients with AL amyloidosis after allogeneic HCT. Whether RIC plays a more important role for this patient group in the future remains to be defined within a prospective clinical study.

Allogeneic and syngeneic hematopoietic cell transplantation in patients with amyloid light-chain amyloidosis: a report from the European Group for Blood and Marrow Transplantation

Stefan O. Schöfl, Henk Lokhorst, Agnes Buzyn, Veronique Leblond, Ute Hegenbart, Giuseppe Bandini, Andrew Campbell, Enric Carreras, Augustin Ferrant, Leanne Grommich, Peter Jacobs, Nicolaus Kröger, Giorgio La Nasa, Nigel Russell, Pierre Zachree, Hartmut Goldschmidt, Simona Iacobell, Dietger Niederwieser, Gisela Galton, for the Chronic Leukemia Working Party (CLWP), Myeloma Subcommittee of the European Cooperative Group for Blood and Marrow Transplantation (EBMT)

Using the European Group for Blood and Marrow Transplantation (EBMT) registry, we retrospectively studied 19 patients with AL amyloidosis (Allo; n = 15) or syngeneic (Syn; n = 4) hematopoietic stem cell transplantation (SCT) between 1991 and 2003. For allo-SCT, full-intensity conditioning was used in 7 patients and reduced-intensity conditioning (RIC) in 8 patients. Engraftment was durable in 12 of those 15 patients. The median follow-up time is 19 months. Kaplan-Meier probabilities of overall and progression-free survival were 60% and 53% at 1 year, respectively. Overall, 40% of patients died of transplant-related mortality (TRM). Best hematologic response after SCT was complete remission (CR) and partial remission (PR) in 8 and 2 patients, respectively, leading to an organ response in 8 of these patients. Seven of the 10 patients in remission are long-term survivors. In 5 of 7 evaluable patients in CR, chronic graft-versus-host disease (GVHD) was observed, indicating the contribution of immune effects to disease control. The main clinical problem was cardiac failure in patients with poor performance status due to amyloidosis or in combination with severe infections. These data suggest that allo-SCT might be a promising and potentially curative treatment modality for selected patients with AL amyloidosis. (Blood. 2005;107:2578-2584)

Introduction

Systemic AL (amyloid light chain) amyloidosis is a protein conformation disorder caused by a clonal plasma cell dyscrasia. Symptoms result from fibrillar extracellular deposits in kidney, heart, liver, gut, peripheral nervous system, and other tissues. The deposits disrupt organ function and ultimately lead to death. The prognosis of systemic AL amyloidosis is poor; probably less than 5% of all patients survive 10 years or longer. Because it is a rare disease and basically related to multiple myeloma (MM), most of the treatment approaches have been adopted from the experiences in MM. Using conventional chemotherapy with melphalan/prednisone, the median survival was 18 months. Treatment with high-dose melphalan (HDM) and autologous stem cell transplantation (auto-SCT) can stabilize and even reverse the disease course. In 40% to 50% of patients, complete hematologic remission can be achieved, which leads to improvement of organ function in two-thirds of these patients. A case control study showed the superiority of HDM compared with alkylator-based conventional chemotherapy regimens. However, HDM causes a high transplant-related mortality (TRM) up to 43%6-8. Major progress to decrease mortality of high-dose chemotherapy has been achieved by definition of risk groups to identify patients who will not benefit from HDM.9 The treatment of patients with unresponsive disease or relapse after auto-SCT has only been evaluated in a few prospective studies so far. Thalidomide is an effective second-line therapy for MM10 and has been tested as a single agent in patients with AL amyloidosis in a phase 2 trial.11 Complete remission (CR) was not reached in any patient and 50% of patients experienced grade 3/4 toxicity. The combinations of dexamethasone-alpha interferon12 or thalidomide/dexamethasone were also used and found to be effective but rather toxic in newly diagnosed patients.13 The

feasibility of a second auto-SCT after relapse as well as tandem auto-SCT has also been tested. A few anecdotal reports on successful allogeneic SCT (allo-SCT) have raised the possibility that allo-SCT could be a curative option for patients with AL amyloidosis. Here, we review retrospectively 19 patients with AL amyloidosis reported to the European Group for Blood and Marrow Transplantation (EBMT) registry who had undergone allo-SCT or syngeneic SCT (syn-SCT).

Patients, materials, and methods

This study was conducted on behalf of the Chronic Leukemia Working Party of the EBMT. All EBMT centers report a minimal essential data set (MED-A form) into a central database. After identification of eligible patients, centers were contacted to get information about patients' history, amyloidosis manifestations, transplant course, detailed parameters of organ response, as well as hematologic remission and follow-up. Missing information and data inconsistency were clarified by individual requests. Data were stored at the Leiden EBMT Data Centre for analysis. Informed consent was obtained locally according to the regulations applicable at the time of transplantation. Approval for this study was obtained from the Institutional Review Board of the University of Heidelberg.

Definitions and diagnostic criteria

All patients have been evaluated for AL amyloidosis or MM by standard investigations. MM stage I was distinguished from AL amyloidosis if the bone marrow infiltration by plasma cells was at least 30% or monoclonal light-chain excretion in urine was greater than 1 g/dl. The diagnosis of AL amyloidosis was done by positive Congo red staining of tissue biopsies. All patients had a monoclonal gammapathy in serum and/or urine. In 16 of 19 patients, immunohistochemistry was additionally performed to confirm the AL type of amyloidosis. One further patient showed a typical clinical symptom of AL amyloidosis (nephrotic syndrome). No patient had polymyositis or PAN. In pathologic examination, there were no signs of a plasma cell dyscrasia and positive Congo red staining. Performance status (PS) was assessed according to World Health Organization criteria (good: PS < 2; poor: PS > 2). In our study, the definition of patients with high risk for TRM were age older than 50 years at SCT using matched unrelated donors or older than 55 years using matched related donors, poor PS, more than 2 organs involved, New York Heart Association classification stage more than II, and previous auto-SCT (excluding patients with a planned auto-allo approach). The definition of reduced-intensity conditioning (RIC) was determined by contributing centers and based on the current EBMT guidance. Toxicity was analyzed with National Cancer Institute Common Toxicity Criteria (CTC) version 2.0.

Hematologic response, relapse, and disease progression were defined according to published MM criteria. In all patients surviving to at least day +100, and organ response was evaluated as early as 3 months after allo-SCT as published. Overall survival (OS) was measured in months and defined as the time from the date of transplantation to the date of death or last follow-up. Progression-free survival (PFS) was defined as the time from transplantation until date of progression or death from any cause or last follow-up. TRM was defined as death due to any cause other than disease progression or relapse occurring at any time after transplantation.

Graft-versus-host disease grading and therapy

The local investigators used standard criteria to grade acute and chronic graft-versus-host disease (GvHD). Treatment of acute and chronic GvHD was per each institution's standard practice guidelines.

Chimerism analysis

Chimerism analysis was performed per each institution's standard practice guidelines.

Statistical analysis

OS and PFS were estimated by the Kaplan-Meier method, and TRM and disease-related mortality were summarized using cumulative incidence estimates. Data were analyzed as of January 25, 2005. The package CMPSR (by R. Gray; version 2.1-1, 2002; run on R, version 1.6.2) was used for the computation of cumulative incidence curves.

Results

Patient characteristics

Between 1987 and 2005, 20 patients with AL amyloidosis who underwent allo-or syn-SCT have been reported to the EBMT. Treatment centers are listed in the "Acknowledgments." One patient who received a transplant in 1987 had to be excluded from further analysis because of an incomplete data set. Four of the cases had been published as case reports and were updated for this analysis (UPN 23923221; 24921761; 71794541; UPN 6092762). Pretransplantation patient characteristics are listed in Table 1. Of 19 patients with AL amyloidosis (median age 47 years; range, 30-63 years), 13 patients had AL amyloidosis with monoclonal gammopathy and 6 patients had MM with symptomatic AL amyloidosis. All 4 MM patients classified as stage I had a single diagnostic criterion a monoclonal light-chain excretion in the urine greater than 1 g/dl. Chromosomal analysis has been performed in 8 patients: 5 patients had a normal karyotype, 2 patients had deletion of chromosome 13 (UPN 16092762 and 1600231), and 1 patient showed deletion of chromosome 21 (UPN 23925391). Four patients underwent syn-SCT. Fifteen patients received an allo-SCT and are described in detail in this paper.

Indications for allo-SCT defined by the treating physicians were "younger age" and relapsed or refractory disease. Dominant organ affection at SCT was mainly kidney. Five patients had amyloidic cardiac disease. One patient had prior cardiac transplantation (UPN 16092762) and another patient was on dialysis at the time of SCT (UPN 1600237). The median number of organs involved was 2. The median duration from diagnosis to SCT was 9 months (range, 3-122 months). PS was graded as poor in 4 patients.

Pretreatment and conditioning regimen

Four patients were untransplanted. Eight patients had been treated with conventional chemotherapy and 3 patients with HDM and autologous SCT as front-line treatment. 2 of them followed directly by the allo-SCT (UPN 1600231; 81100832). Another patient had received HDM and auto-allo-SCT as salvage therapy (UPN 33958217). Altogether, 7 patients had been treated with HDM and auto-SCT. The median time interval between auto- and allo-SCT was 10 months (range, 2-30 months). Overall, only 4 patients were responsive to chemotherapy, but no patient reached CR before allo-SCT. The conditioning regimens are shown in Table 2.

Donors and graft composition

Donors of stem cells were HLA-identical siblings in 12 cases, a mismatched related sibling in 1 case, and matched unrelated voluntary donors in 2 cases. Six patients had received bone marrow and 9 patients peripheral stem cell grafts. In 4 patients, grafts had

undergo ex vivo and in 6 patients in vivo T-cell depletion (TCI).

The median CD34+ and CD31 cell counts transplanted were 4.4 × 10⁶ cells/kg (range, 3.3 × 10⁶ to 12.4 × 10⁶ cells/kg; 11 patients evaluable) and 1.9 × 10⁶ cells/kg (range, 0.001 × 10⁶ to 9.5 × 10⁶ cells/kg; 9 patients evaluable), respectively.

Engraftment, chimerism, and acute toxicities

The posttransplantation patient characteristics are given in Table 2. Fifteen of 15 patients engrafted. After engraftment (day +28 without hematologic recovery), chimerism data were available for 10 patients. Eight patients had 100% donor cells on day +28 or +100. One patient (UPN 39090001) who was treated with RK rejected the graft and had autologous recovery. Another patient (UPN 24006691) had mixed chimerism on day +100, lost the graft 6 months after T-cell depleted allo-SCT, and showed autologous recovery as well.

The median number of days with absolute neutrophil counts (ANCs) less than 0.5 × 10⁹/L (500/μL) was 15 days (range, 0-29 days) and with platelet counts less than 20 × 10⁹/L (20 000/μL) was 7 days (range, 0-44 days). The median number of red blood cell transfusions was 6 (range, 0-34) and of platelet transfusions was 3 (range, 0-22). The patient who did not engraft until day +28 after a conventional conditioning and bone marrow SCT died from gastrointestinal hemorrhage. No further bleeding complications have been reported. For the different conditioning forms, the hematologic toxicity parameters were as follows: for conventional conditioning, ANC less than 0.5 × 10⁹/L (500/μL) for a median of 18 days (range, 17-21 days) and platelet counts less than 20 × 10⁹/L (20 000/μL) for a median of 12 days (range, 0-23 days); for RIC, ANC less than 0.5 × 10⁹/L (500/μL) for a median of 11 days (range, 0-29 days) and platelet counts less than 20 × 10⁹/L (20 000/μL) for a median of 1 day (range, 0-44 days).

We observed febrile infections in 8 patients and cytomegalovirus reactivation in 4 patients. Nonhematologic toxicity greater than grade 2 by CTC criteria was documented in 6 patients (worsening of renal function in 1 patient, renal failure leading to dialysis and cardiac death in 1 patient, cardiac arrhythmia in 1 patient, orthostatic hypotension in 1 patient, asciites in 1 patient, fatal gastrointestinal hemorrhage in 1 patient).

Graft-versus-host disease

Clinically relevant acute GVHD (grade II-IV) occurred in 6 of 14 patients at a median of 29 days (range, 15-65 days) after allo-SCT and was severe in 2 patients (grade III-IV). The patient with acute GVHD grade IV did not respond to steroids and died at day +54 due to cerebral aspergillosis. Overall, 6 of 10 evaluable patients developed chronic GVHD. 1 patient had de novo chronic GVHD, and 5 patients had preceding acute GVHD. Four patients required treatment. Three of 4 patients responded to treatment. One of these 6 patients died 4-41 months due to pneumonia acquired outside a hospital.

Non-RIC indicates non-reduced-intensity conditioning; NR, no response; TBI, total body irradiation; Cy, cyclophosphamide; NE, not evaluable; TRM, transplant related mortality; Mel, melphalan; Lim, limited; CR, complete response; RESP, response; PR, partial response; NA, not available; Flu, fludarabine; ATG, antithymocyte globulin; EBV, Epstein-Barr virus; PNP, Pneumocystis; AL, amyloidosis; LD, stable disease; Ext, extensive; and PROG, progression.

*Immunofluorescence negative with persistent abnormal free light-chain ratio in the serum."
Hematologic remission and organ response

Four patients were not evaluable for hematologic remission and organ response due to early death. Best hematologic remission included CR in 8 patients, partial remission (PR) in 2 patients, and nonresponse in 1 patient. Free light-chain assay in the serum was additionally used in 6 patients and confirmed CR in 5 patients. One patient had an abnormal kappa-lambda ratio, although, becoming immunofixation-negative and developing organ progression (Table 2; UPN 16092762). However, we rated this patient as still in CR because EBMT criteria were used for this analysis.

The median time from allo-SCT to CR was 3 months (range, 2-15 months). In 5 of 7 evaluable patients in CR, chronic GvHD was observed. Four of 4 evaluable patients with kappa isotype achieved CR (including the 2 patients with chromosome 13 deletion) compared with 4 of 8 patients with lambda isotype. One patient had a relapse 11 months after allo-SCT and is currently being treated with thalidomide/doxycycline. Donor lymphocyte infusions have not been performed in any patient.

Organ responses were observed in cardiac transplant and no further evaluable organ (UPN 16092762). Evaluable organ involvement is shown in Table 2.

Overall survival and treatment- and disease-related mortality

Eleven of 15 patients have to be classified as high-risk patients for TRM as described in "Definitions and diagnostic criteria." The median follow-up time of all patients is 19 months (range, 1-121 months) and of surviving patients 31 months (range, 19-121 months). Kaplan-Meier probabilities of OS and PFS were 60% (95% confidence interval [CI], 40% to 91%) and 53% (95% CI, 33% to 86%) at 1 year and 52% (95% CI, 32% to 86%) and 46% (95% CI, 26% to 80%) at 2 years, respectively (Figure 1). The median OS and PFS are 42 and 19 months, respectively. The overall day +100 mortality was 27%. Three of 6 patients died before day +100 after conditioning including total body irradiation (TBI) with 8 to 12 Gy. Causes of TRM were acute GvHD grade IV and cerebral aspergillosis in 1 patient, gastrointestinal hemorrhage in 1 patient who did not engraft until day +28, and EBV-related lymphoma in the third patient, who received a transplant of an ex vivo T-cell-depleted graft. One patient died at 41 months of pneumonia associated with chronic GvHD. Another 2 patients died of cardiac failure at days +51 and +160 while suffering from kidney failure or extensive chronic GvHD. Both had cardiac involvement before allo-SCT, which probably contributed to their death. Including these patients the overall TRM was 40%. Overall disease-related mortality was 13% and estimated at 1 year at 6.7% (95% CI, 1% to 48%).

Clinical results of T-cell depletion

Four patients received an ex vivo T-cell-depleted transplant and engrafted. Two patients developed severe acute GvHD and died early (days +54 and +106). The latter patient additionally developed an EBV lymphoma. The third patient lost the graft 6 months after transplantation and is alive in PR. The fourth patient had no response and died from organ progression 19 months after SCT. None of the patients developed chronic GvHD.

In a further 6 patients, conditioning included in vivo TCD, which was used as part of RIC in 5 of those patients. Two patients died of organ progression or TRM. 1 patient is alive in relapse, and 3 patients are alive in CR about 3 years after allo-SCT.

Clinical results in 4 patients untreated before allo-SCT

Two of 4 patients untreated before allo-SCT lost their graft either after TCD or minimal conditioning with 2-Gy TBI. Despite losing the graft after 6 months, autologous reconstitution occurred in 1 patient who is in PR and is a long-term survivor. The other patient also had autologous recovery. She had a poor PS at SCT and died of TRM. The third patient received a T-cell-depleted SCT. She had no response of her myeloma, and died of organ progression. The fourth patient was a long-term survivor in CR and died of an infection related to chronic GvHD.

Syngeneic transplants

Patient characteristics are given in Table 1. Three of the 4 patients had been unresponsive to high-dose chemotherapy, 1 patient was untreated and had a previous liver transplantation. Two of the 4 patients had had a poor PS with advanced heart disease at the time of SCT and died early (days +7 and +18) of TRM (sepsis with cardiac arrest). As a noninfectious complication, nausea CTC grade III was observed in 1 patient. Two patients are long-term survivors (follow-up of +97 and +157 months), both are in CR and have organ response. Time from SCT to CR was 4 and 13 months, respectively.

Discussion

The treatment of AL amyloidosis aims at eradication of the clonal plasma cell disorder to avoid further amyloid formation and deposition. This is the first series describing allo-SCT in this disorder. Our data and a recently published case report9 suggest a potent "graft-versus-plasma-cell-dyscrasia effect" in AL amyloidosis patients.

We retrospectively evaluated the results of 15 well-documented patients who received allografts from either related or unrelated HLA-matched donors. As best hematologic remissions, 8 CR were induced by allo-SCT. After a median observation of 31 months of surviving patients, only 1 relapse occurred using the EBMT criteria. The free light-chain assay is able to detect persistent plasma cell disease with a high sensitivity25 and led to the identification of another patient with amyloidosis activity who had been considered in CR. Previously, a consensus opinion regarding remission criteria in AL amyloidosis had been published,25 including normalization of the free light-chain levels as a further CR criterion.

The importance of achieving CR for OS and organ response has already been shown in the autologous setting.3 Our data confirm...
that achievement of CR is a main predictor for long-term survival after auto-SCT as well. Currently, 7 patients are alive; 5 are in a CR between 19 and 121 months following allo-SCT with organ response. CR was probably associated with the presence of chronic GVHD. As in other hematologic diseases, our analysis shows that patients not sensitive to chemotherapy are able to achieve CR after allo-SCT. We assume that this is mainly due to immunologic effects. Due to the small patient number and heterogeneous types of conditioning used in this study, it is difficult to draw firm conclusions about the optimal time point of allo-SCT.

The CR rate in our study is encouraging and warrants further investigation. However, TRM was high with 40% and, in our opinion, several factors were contributing. First, 11 of 15 patients in our study have to be classified as high-risk patients for TRM. Therefore, the mortality of 40% is comparable to allo-SCT in other high-risk patients with malignant or nonmalignant diseases. Performance status and an important predictor for a poor PS in AL amyloidosis patients is mainly caused by cardiac involvement. Of 6 patients with poor PS at allo- or syn-SCT, 5 died of cardiac events. As a second factor, TBI with 8 to 12 Gy was associated with high day +100 mortality in our analysis. In MM and auto-SCT, TRM has mostly been deleted from conditioning regimens because of a significantly higher toxicity and lack of improvement of long-term results. In contrast, TBI-including regimens have not been proven to be inferior to chemotherapy-only regimens in allo-SCT. The importance of “full-intensity” or “reduced-intensity” conditioning remains a matter of debate. To reduce toxicity RIC could be a promising attempt in AL amyloidosis patients. Nonalpnea mortality has been reported to be significantly lower in RIC compared with conventional conditioning. The risk of severe acute GVHD is also reduced but rates of chronic GVHD have been observed to be similar. In our study, only 2 of 8 patients treated with RIC died of TRM compared with 4 of 7 treated with non-RIC. Of note, these 2 patients were in poor PS at SCT. Third, ex vivo TCD resulted in a worse clinical outcome. Comparable results have been observed in MM. In contrast, 7 of 11 patients without ex vivo TCD achieved a CR and 5 are longterm survivors. In conclusion, we believe that allo-SCT is a promising therapeutic option for patients with AL amyloidosis. In this study we observed a potent graft-versus-host-cell –lymphostasis effect. Full-intensity conditioning with TBI or ex vivo TCD were associated with an unfavorable outcome. Patients could be eligible for allo-SCT if they have not achieved a CR 6 months after HDM with auto-SCT, are still in a good PS, and have an HLA-matched donor. A prospective phase 2 study for allo-SCT using RIC is planned by the EBMT.

Bone marrow transplantation from related donors other than HLA-identical siblings: effect of T cell depletion

International Bone Marrow Transplant Registry, Medical College of Wisconsin, Milwaukee, WI; University of California, Los Angeles, CA; Radiobiological Institute, Rijswijk, The Netherlands; St George's Hospital Medical School, London, England; University of KY, Lexington, KY; Universitaet Muenchen, Munich, Germany; Dr Daniel den Hoed Cancer Center, Rotterdam, The Netherlands; Center for Adult Diseases, Osaka, Japan; University of Minnesota; Karolinska Institute, Huddinge, Sweden; University of Leiden, Leiden, The Netherlands; University of Wisconsin, Madison, WI, and Prince of Wales Children's Hospital, Randwick, NSW, Australia

Summary:

Results of 470 bone marrow transplants from related donors other than genotypically HLA-identical siblings (alternative related donors) were analysed to identify factors associated with transplant outcome and to determine whether T cell depletion improved results. As compared to 3648 transplant from HLA-identical siblings, alternative related donor transplants were associated with increased graft failure, increased acute graft-versus-host disease (GVHD), and lower disease-free survival. The likelihood of adverse outcome correlated with increasing donor-recipient HLA-disparity. In multivariate analysis of alternative related donor transplants, donor age ≥30 years, (relative risk [RR] 1.7, p < 0.006), intermediate and advanced leukemia (RR 1.5 and 1.6, p < 0.01 and p < 0.003), infection pretransplant (RR 1.7, p < 0.005) and 2- and 3-locus donor-recipient HLA-disparity (RR 1.3, p < 0.04) were associated with increased risks of treatment failure. The 2-year probability of leukemia-free survival after alternative related donor transplants (n = 43) with none of these adverse prognostic features was 44% (95% confidence interval 28-59%) compared to 56% (95% confidence interval 52-59%) for similar patients receiving HLA-identical sibling transplants (n = 868, univariate p < 0.03). T cell depletion increased graft failure and decreased acute GVHD after alternative related donor transplants but did not improve leukemia-free survival.

Most include relatively few patients. Several of these reports note increased risks of severe acute graft-versus-host disease (GVHD) with alternative donor transplants. Because of this, some centers perform T cell depletion on bone marrow from HLA-mismatched donors. The results of this approach are not well-described. In this study we analysed data from 470 transplants using alternative related donors and reported to the International Bone Marrow Transplant Registry (IBMTR); 198 of these transplants (42%) used T cell-depleted marrow. Results of this analysis indicate that transplants from alternative related donors are successful in some patients and identify factors correlated with outcome.

Patients and methods

Patient population

Between 1 January 1980 and 31 December 1987, 91 centers reported data to the IBMTR for 470 patients with leukemia or aplastic anemia receiving bone marrow transplants from alternative related donors. All received methotrexate, cyclosporine, and/or T cell depletion to modify or prevent GVHD. The donor was a partially HLA-matched sibling in 295 instances, a parent in 149, and another relative in 26. Controls included 3648 patients receiving HLA-identical sibling transplants with similar prophylaxis against GVHD at the same centers during the same interval. Excluded from analysis were 85 identical twin transplants, 43 unrelated donor transplants, 152 transplants with incomplete HLA-typing data, and 143 patients receiving alternative forms of GVHD prophylaxis or no GVHD prophylaxis. Median, minimum, and maximum follow-up times were 2 years, 4 months, and 8 years, respectively.

Donor recipient HLA compatibility

Donor recipient pairs were evaluated for matching at HLA-A, HLA-B, and the HLA-D region. IBMTR reporting forms request HLA-A, B, and DR specificities of donor, recipient, and both parents of the recipient (if
available) and result of mixed lymphocyte culture (MLC) testing between donor and recipient. HLA data for all donor recipient pairs in the study and control groups were reviewed by two of the authors (R.C.A. and M.M.H.). Results of both HLA-DR typing and MLC were reported for 318 (68%) donor recipient pairs in the study group and 1863 (51%) control pairs. MLC but not DR data were reported for 138 (29%) study pairs and 1706 (47%) control pairs. DR typing but not MLC results were reported for 174 (4%) study pairs and 79 (2%) control pairs. Parental HLA-typing data, reported for 208 (44%) study patients and 1238 (34%) controls, was used to confirm donor recipient HLA-compatibility. After stratification for degree of donor-recipient HLA-compatibility (as described below), there was no difference in outcome between patients with and without parental typing.

Definitions of HLA-matching were considered with respect to reagents available when typing was performed. Transplants were classified as mismatched at HLA-A and/or B if detectable donor recipient disparity was reported, whether or not this disparity was within an HLA cross-reactive group. Donor-recipient pairs were classified as matched at the HLA-D region if: (1) matched at HLA-DR and MLC non-reactive (99 study and 1863 control patients), (2) MLC non-reactive and DR typing not performed (61 study and 1706 control patients), or (3) matched at HLA-DR and MLC testing not reported (10 study and 79 control patients). Donor-recipient pairs were considered HLA-D region mismatched if: (1) HLA-DR mismatched and MLC reactive (n = 104), (2) MLC reactive with HLA-DR typing not reported (n = 74), or (3) mismatched at HLA-DR and the MLC was non-reactive (n = 51) or not reported (n = 7).

Sixty-four donor recipient pairs in the study group were reported as matched at HLA-DR but reactive in MLC. These cases were included in the study group in univariate analyses comparing HLA-identical sibling with all alternative related donor transplants (see Table II) but excluded from most multivariate analyses examining the impact of degree of donor-recipient disparity on outcome since the degree of disparity was uncertain. They were considered as a separate group for analyses of GVHD but could not be analysed separately for graft failure, relapse and leukemia-free survival since the latter required stratification for disease and/or disease status and the numbers of patients were too small.

The degree of donor-recipient HLA-disparity for the 470 alternative related donor transplants is shown in Table I. Twenty-nine transplants were mismatched only for GVHD (homozygous recipient) and 43 mismatched only for graft rejection (homozygous donor).11,12 Unidirectional and bidirectional HLA-mismatches did not differ in outcome and were therefore combined using the overall histocompatibility assignment for each transplant. Assignment to HLA-A or B cross-reactive groups used criteria of the US National Marrow Donor Program.20

### Outcome definitions

Graft failure was analysed in patients surviving ≥ 21 days post-transplant using published criteria.21 Acute GVHD was defined as moderate to severe (grades II–IV) using published criteria.22 Patients surviving ≥ 21 days with evidence of engraftment were considered at risk of acute GVHD. Chronic GVHD was determined by clinical criteria in patients surviving ≥ 90 days with evidence of engraftment. Remission of acute leukemia was defined as absence of leukemia in any site. Relapse and remission of chronic myelogenous leukemia were defined by hematologic criteria.23

### Statistical techniques

Patient, disease and transplant-related characteristics of the study and control groups were compared using the chi² test for categorical and the Mann-Whitney test for continuous variables. Because the diseases for which transplants were performed differed significantly between study and control groups, and because the distribution of important factors such as disease status and age also differed by disease, comparisons were performed after appropriate stratification (Table II). Leukemia was classified as ‘early’ (first remission or first chronic phase), ‘intermediate’ (≥ 2nd remission or accelerated phase), and ‘advanced’ (relapse or blast phase). Variables significantly different between the study and control groups (p < 0.05) were included as covariates in all multivariate comparisons of the two groups.

Patients with leukemia and severe aplastic anemia were analysed separately for probability of graft failure and disease-free survival. Because previous IBMTR analyses do not show a difference in the risk of GVHD after transplants for leukemia and severe aplastic anemia,22,23 patients were pooled for this analysis to increase statistical power. However, use of regression models that stratified for disease and separate analyses of aplastic anemia and leukemia patients showed similar associations.

Actuarial probabilities of graft failure, acute and chronic GVHD, leukemia relapse, and disease-free survi-

ALL = acute lymphoblastic leukemia; AML = acute myelogenous leukemia; CML = chronic myelogenous leukemia; NA = not applicable; SAA = severe aplastic anemia; ARD = alternative related donor; CR = complete remission; CP = chronic phase; AP = accelerated phase; NS = not significant; F = female

Val were calculated using standard life-table methods and expressed as probability with 95% confidence interval (CI).29 Curves were terminated when fewer than five patients were at risk. Univariate comparison of curves was performed using the Lee-Desu statistic.29 Risks of graft failure, acute and chronic GVHD, leukemia relapse and treatment failure (relapse or death from any cause) for recipients of HLA-phenotypically identical, 1-antigen mismatched, 2-antigen mismatched and 3-antigen mismatched transplants were compared to controls using Cox proportional hazards regression models adjusting for significant differences in patient, disease and transplant characteristics between the study and control groups as described above.30 Adjusted probabilities of graft failure, acute GVHD, chronic GVHD, leukemia relapse and leukemia-free survival were calculated for T cell-depleted and non-T cell-depleted transplants using Cox proportional hazard models.

In a separate analysis of recipients of alternative related donor transplants for leukemia, the following variables were examined for their association with treatment failure in a multivariate model using Cox proportional hazards regression: patient age, donor age, allo-immune female donor, donor relationship, organ impairment pretransplant, infection at time of transplant, disease status pretransplant, interval between diagnosis and transplant, conditioning regimen, method of GVHD prophylaxis, degree of donor recipient HLA match, HLA-A or B versus HLA-D region mismatch, and year of transplant. To compare outcome using different methods of T cell depletion, techniques were grouped in three categories: (1) physical methods like elutriation or lectin separation; (2) antibodies with broad specificities like Campath 1; and (3) antibodies with narrower specificities. Variables not significantly associated with treatment failure (p > 0.05) were excluded from the regression model using a stepwise backward elimination procedure. Relative risks derived from the proportional hazards model represent the risks of treatment failure for patients with unfavorable characteristics and adjusted for effects of other variables in the model.

There were too few alternative related donor transplants for aplastic anemia for reliable multivariate analysis. Because of the multiple comparisons made, we consider only p-values < 0.01 significant. p-values between 0.01 and 0.05 are reported but should be interpreted with caution. All p-values are two-tailed and based on results of multivariate analyses otherwise specified.

## Results

### Patient characteristics

Characteristics of the study and control groups are shown in Table II. A significantly higher proportion of study versus control transplants were performed for ALL, and a smaller proportion for AML (p < 0.01). Other characteristics of the study and control groups were compared after disease stratification. Recipients of AML from alternative related donors were younger, had more advanced leukemia and longer intervals between diagnosis and transplant, were more likely to receive T cell-depleted transplants, and had older donors who were more likely to have been pregnant and/or transfused (because of the use of parents). These variables were included as covariates in all multivariate analyses comparing results of HLA-identical sibling and alternative related donor transplants.

### Comparison of HLA-identical sibling and alternative related donor transplants

**Graft failure.** Graft failure was analysed separately for patients with leukemia and aplastic anemia. In patients
with leukemia, the risk of graft failure increased with increasing HLA-disparity between donor and recipient (p for trend < 0.0001, Figure 1a). Relative risks were 2.6 (p = NS), 2.0 (p < 0.009), 7.3 (p < 0.0001), and 5.9 (p < 0.0001) for HLA-phenotypically matched, 1-locus disparate, 2-locus disparate, and 3-locus disparate transplants as compared to HLA-identical sibling transplants. There was no difference in the incidence of graft failure using donors mismatched at one HLA-A or B locus (11%, 95% CI 6–20%) versus the HLA-D region (11%, 95% CI 6–19%). Graft failures were not observed in the 12 1-antigen HLA-A or B mismatched transplants in which the mismatch occurred within a cross-reactive group; nine of 76 patients had graft failure when the mismatch was not within a cross-reactive group (univariate p = NS). For transplants mismatched at two HLA-loci, there were no differences in the risk of graft failure for different combinations of HLA-A, B and D-region mismatches.

The risk of graft failure was also increased in recipients of alternative related donor transplants for severe aplastic anemia (RR 5.0, p < 0.0001); the number of patients was too small to evaluate different degrees of HLA-disparity.

**Graft-versus-host disease.** The risk of acute GVHD increased with increasing donor-recipient HLA-disparity (p for trend < 0.0001, Figure 1b). The risk of acute GVHD after HLA-phenotypically matched and 1-antigen mismatched transplants was not significantly higher than after HLA-identical sibling transplants (RR 1.0 and 1.2, p = NS). In contrast, the relative risks of acute GVHD after 2- and 3-antigen mismatched transplants were 3.1 (p < 0.0001) and 4.4 (p < 0.0001), respectively. There was no significant difference in incidence of acute GVHD between transplants mismatched at a single HLA-A (41%, 95% CI 28–55%), HLA-B (45%, 95% CI 31–60%) or HLA-D region (42%, 95% CI 34–51%) locus. Although the risk of acute GVHD was lower if the HLA-A or B mismatch was within a cross-reactive group (23%, 95% CI 9–46%) than if not (47%, 95% CI 36–59%), this difference was not statistically significant. Among transplants mismatched at two loci, there was no difference in the incidence of acute GVHD between those mismatched at HLA-A+D or HLA-B+D (68%, 95% CI 50–82%) compared to those mismatched at HLA-A+B (69%, 95% CI 47–85%).

There was no significant difference in the risk of chronic GVHD between study and control patients at any degree of HLA-disparity even after adjusting for differences in acute GVHD (Figure 1c). After stratifying for degree of donor-recipient HLA-A and HLA-B compatibility, the probabilities of acute and chronic GVHD were similar for patients matched at HLA-DR with reactive or non-reactive MLC.

**Leukemia relapse.** The risk of leukemia relapse was similar for the study and control groups in early leukemia (Table III). Recipients of 1-locus disparate transplants for intermediate leukemia had an increased risk of relapse compared to recipients of HLA-identical sibling

---

**Figure 1** Relative risk of (a) graft failure (leukemia patients only), (b) acute graft-versus-host disease (GVHD) and (c) chronic GVHD according to degree of donor-recipient HLA-match. In all cases, the control group of HLA-identical sibling transplants is used as the reference (relative risk of 1.0) and designated by *. p values refer to the comparison between each study group and the reference group. The number of patients in each group is indicated within each bar.
transplants (RR 1.9, p < 0.01). In advanced leukemia, 2- to 3-locus disparate transplants were associated with a increased risk of relapse compared to HLA-identical sibling transplants (RR 0.3, p < 0.002).

**treatment failure.** Treatment failure was analyzed separately in patients with leukemia and aplastic anemia. The k of treatment failure (relapse or death from any cause) increased with increasing HLA-disparity between donor and recipient when transplants were done for early intermediate leukemia (p for trend < 0.001 for both, Table III). Patients receiving phenotypically identical 1-locus disparate bone marrow had similar risks of treatment failure which were less than the risk for 2- and 3-locus disparate transplants. In advanced leukemia, the k of treatment failure was not significantly higher after alternative related donor rather than HLA-identical sibling transplants (Table III).

Patients receiving 1-locus disparate transplants for leukemia had similar probabilities of leukemia-free survival whether the mismatch was for HLA-A, HLA-B, or HLA-D region. The probability of leukemia-free survival was also similar after 2-antigen mismatched transplants whether the disparity was for HLA-A+B, A-A+D region or HLA-B+D region.

Treatment failure after transplantation for aplastic anemia also increased with HLA-disparity (p for nd < 0.0001). Compared to controls, the relative risk treatment failure was 2.91 (p < 0.0001) for phenotypically matched and 1-locus disparate and 5.45 < 0.0001) for 2- and 3-locus disparate transplants, justed 2-year probabilities of disease-free survival for transplantation for aplastic anemia were 27% (95% CI 16-41%) for alternative related donor transplants and 9% (95% CI 63-71%) for HLA-identical sibling transplants.

**Comparison of T cell-depleted and non-T cell-depleted transplants**

The outcome of T cell-depleted and non-T cell-depleted transplants was compared after stratification for degree of donor-recipient HLA-match (Figure 2, Table IV).

Graft failure increased with increasing HLA-dissimilarity after both T cell-depleted and non-T cell-depleted transplants but was more likely after T cell-depleted transplants for every degree of mismatch (Figure 2a).

The probability of acute GVHD was lower after T cell-depleted than non-T cell-depleted transplants for every degree of mismatch (Figure 2b). However, the probability of acute GVHD was high (64%, 95% CI 51-75%) for 2- and 3-antigen mismatched transplants even if marrow was T cell-depleted.

Donor recipient HLA-disparity did not increase the likelihood of chronic GVHD after non-T cell-depleted transplants but did increase the likelihood of chronic GVHD after T cell-depleted transplants. The probability of chronic GVHD was significantly lower after T cell-depleted as compared to non-T cell-depleted HLA-identical sibling transplants (29%, 95% CI 25-32% versus 47%, 95% CI 45-49%, p < 0.0001), but was similar for T cell-depleted and non-T cell-depleted alternative related donor transplants (Figure 2c).

Although the risk of leukemia relapse after HLA-identical sibling transplants was higher if the donor marrow was T cell-depleted, the risk of relapse after alternative related donor transplants was similar for recipients of T cell-depleted and non-T cell-depleted grafts (Table IV).

The probability of leukemia-free survival after HLA-identical sibling transplants was lower if T cell depletion was used for early or advanced leukemia (Table IV). In contrast, leukemia-free survival was similar for non-T cell-depleted and T cell-depleted alternative related donor transplants done for early and intermediate leukemia and for 1-locus mismatched transplants done for advanced disease. Leukemia-free survival rates were marginally higher after 2- and 3-locus mismatched transplants for advanced leukemia if T cell depletion was used (Table IV).

There was no significant association between leukemia-free survival and the method used for T cell depletion.
vival after alternative related donor transplants for patients with selected profiles of prognostic features is shown in Table VI. The 43 patients with favorable prognostic features (early leukemia, a phenotypically matched or 1-antigen mismatched donor<30 years of age, and no clinically significant infection in the week prior to transplant) had a 2-year probability of survival of 44% (95% CI 28-59%). The probability of survival of 808 similar patients (early leukemia, young donor, no infection) who received bone marrow from an HLA-identical sibling was 56 (95% CI 52-59%) (univariate p<0.03).

Discussion

Results of transplants from alternative related donors for leukemia and aplastic anemia are reported by several groups. These data suggest increased risk of graft failure, acute and chronic GVHD, infection, and post-transplant lymphoproliferative disorders as compared to HLA-identical sibling transplants.

We used the large IBMTR database to examine factors affecting the outcome of alternative related donor transplants. This study confirms that these transplant result in long-term disease-free survival in some patients. However, transplants from alternative related donors were associated with increased graft failure, acute GVHD, and other transplant-related complications when compared with HLA-identical sibling transplants matched for other prognostic features. Both the risk of graft failure and acute GVHD increased progressively with increasing donor-recipient HLA disparity. The result was that leukemia-free survival was significantly lower than after HLA-identical sibling transplants. In contrast to another report, this was true even for 1-locus disparate transplants. It may be that detection of worse prognosis with minor degrees of mismatch was possible in our study because of increased statistical power associated with large numbers. Alternatively, the apparently poorer outcome after closely matched (phenotypically identical and 1-antigen disparate) alternative related donor transplants may in part be related to the variety of donor recipient matching technics used by participating teams. Since only about 70% of donor recipient pairs in the study group had both DR serology and an evaluable MLC, it is possible that some cases considered to be matched at the DR region had undetected disparity. Use of extended serotyping for DP and DQ and more sensitive molecular HLA typing methods may allow better definition of donor-recipient HLA compatibility in future analyses.

Although recipients of alternative related donor transplants had a higher risk of treatment failure than recipients of HLA-identical transplants, leukemia-free survival rates of up to 44% were observed in the best candidates for alternative donor transplants, that is in those young patients with early leukemia, in good medical condition and with lesser degrees of donor recipient HLA-disparity (Table VI).

It was postulated that T cell depletion, by decreasing

Factors associated with outcome of alternative related donor transplants

Using stepwise regression analysis, older donor age, intermediate or advanced leukemia, clinically significant infection at time of transplant, and increasing donor-recipient HLA-disparity were identified as factors predicting increased risk of treatment failure after alternative related donor transplants (Table VI). After adjustment for donor age and donor-recipient HLA-disparity, there was no difference in outcome between transplants using parental versus sibling donors, nor between T cell-depleted versus non-T cell-depleted transplants.

*Excludes patients with clinically significant infection in the week prior to transplant
GVHD, might improve disease-free survival following alternative related donor transplants. In this study, acute GVHD was reduced by T cell depletion, but graft failure was increased. Disease-free survival was not improved. There was a significant increase in relapse rates for the alternative related donor transplants with T cell depletion. This contrasts with HLA-identical sibling transplants where leukemia relapse is significantly increased by T cell depletion. This may be because the incidence of chronic GVHD, a major factor in GVHD-related anti-leukemia effects,

\[41,42\] was not significantly different between T cell-depleted and non-T cell-depleted alternative related donor transplants. Multivariate analysis of alternative related donor transplants in leukemia also showed no significant difference in the probability of treatment failure or leukemia-free survival for individuals receiving T cell-depleted transplants. Different methods of T cell depletion appeared to produce similar results.

Increasing donor age, advanced leukemia, infection pretransplant, and increasing donor recipient HLA disparity were significantly associated with increased risks of treatment failure in alternative related donor transplants. Given the strong influence of donor recipient HLA-matching on outcome, the possible effect of mismatching for potentially 'immunodominant' HLA loci or combinations of loci is of concern.\[43\] Within the statistical power of this analysis, however, no differences in survival or in the incidence of graft failure or GVHD were found between transplants with single HLA-A, B, or D locus disparities. A potential advantage of matching for HLA and antigens within 'cross-reactive groups' has also been proposed.\[18\] No significant difference in graft failure or GVHD could be found for transplants disparate for a single HLA-A or B antigen whether or not the disparity was within a cross-reactive group. Elucidation of the impact of such HLA-matching considerations may require more patients or studies in which heterogeneity for other risk factors is controlled. New molecular HLA typing methods that determine HLA Class I\[13,31\] and Class II\[31,38\] polymorphisms may also help better define donor recipient HLA compatibility and help in selecting the most compatible donor.\[45\]

Analysis of alternative related donor transplants for aplastic anemia also demonstrated progressive risks associated with increasing HLA-disparity. Similar results are reported by others in smaller series.\[13,15,31\] There were too few patients for meaningful analysis of other factors associated with transplant outcome in this setting.

Data from this study should help to plan alternative donor transplants. The adverse effects of advanced leukemia suggest that if patients are to be considered for alternative related donor transplants, it should be sufficiently early in the disease course for a favorable outcome. T cell depletion did not improve outcome. Whether new T cell-depletion strategies will succeed requires further study. Likewise, whether transplantation from an HLA-identical or closely matched unrelated donor\[16,39\] may be preferable to that from a highly HLA-mismatched related donor also requires further study. The information in Table VI may help physicians advise potential recipients of alternative donor transplants of the likelihood of success and help in their selection between alternative treatment strategies. In some disease settings, clinical results may be superior with autologous marrow grafting,\[31,33\] intensive chemotherapy, or other non-transplant approaches.

Graft Failure Following Bone Marrow Transplantation for Severe Aplastic Anemia: Risk Factors and Treatment Results

By Richard E. Champlin, Mary M. Horowitz, Dirk W. van Bekkum, Bruce M. Camitta, Gerald E. Elfenbein, Robert Peter Gale, Eliane Gluckman, Robert A. Good, Alfred A. Rimm, Ciril Rozman, Bruno Speck, and Mortimer M. Bortin

Graft failure was analyzed in 626 patients receiving allogeneic bone marrow transplants from HLA-identical sibling donors as treatment for severe aplastic anemia. Sixty-eight (11%) had no or only transient engraftment. Second bone marrow transplants were successful in achieving extended survival in 16 of 27 patients with transient initial engraftment but in none of ten patients with no sign of engraftment after the first transplant. The major factors associated with a reduced risk of graft failure were use of radiation for pretransplant immunosuppression and use of cyclosporine rather than methotrexate or T-cell depletion of the donor bone marrow for prophylaxis against graft-versus-host disease (GVHD). Among 266 patients prepared for transplantation with cyclophosphamide alone, the risk of graft failure was increased in patients who received previous transfusions and reduced in those who received corticosteroids for previous therapy. Neither cell dose nor administration of donor buffy coat cells affected the probability of engraftment. Although use of radiation in conditioning reduced graft failure, survival was not improved. Posttransplant treatment with cyclosporine and avoidance of pretransplant blood transfusions were associated with improved survival.

1989 by Grune & Stratton, Inc.

Bone marrow transplantation is an effective therapy for severe aplastic anemia and is generally considered the preferable treatment for young patients who have an HLA-identical sibling donor. Recent studies report 55% to 80% extended survival.

Graft failure owing to rejection and other causes remains an important, life-threatening complication following allogeneic bone marrow transplantation for aplastic anemia. It occurs in 5% to 60% of patients receiving HLA-identical transplants and various pretransplant and posttransplant immunosuppressive therapies. Factors associated with graft failure and the efficacy of various immunosuppressive regimens in preventing this complication were investigated in this study.

MATERIALS AND METHODS

Results of allogeneic bone marrow transplantation were analyzed in patients with severe aplastic anemia receiving bone marrow transplants at 98 centers worldwide from January 1978 through December 1986 and reported to the International Bone Marrow Transplant Registry. Six hundred twenty-five of 657 consecutive patients who received transplants from HLA-identical sibling donors and who survived ≥21 days were considered evaluable for engraftment. An additional 19 patients who received transplants from identical twins were analyzed separately. Criteria for the diagnosis of severe aplastic anemia have been previously described.

Graft failure was defined as either (a) primary graft failure, i.e., absence of hematologic recovery in patients surviving ≥21 days posttransplant; or (b) transient engraftment, i.e., complete or partial recovery of hematopoiesis of donor origin followed by recurrent pancytopenia with a markedly hypocellular bone marrow in the absence of moderate to severe acute graft-versus-host disease (GVHD).

Statistical analysis. Actual probability of graft failure was calculated using standard life-table methods. Life-table curves were terminated when fewer than three patients were at risk of graft failure. Univariate analyses were used to test associations between patient and treatment variables and the probability of graft failure using the Lee-Desu statistic. Factors associated with the risk of graft failure in these univariate analyses with a P value ≤.10 were entered into a multivariate Cox proportional-hazards model using a forward stepwise approach. Variables significantly associated with the probability of graft failure in multivariate analysis were examined for their association with survival using a Cox proportional-hazards model adjusted for patient age. Because of the multiple comparisons made, only variables which improved the model with \( P < .01 \) were considered statistically significant. \( P \) values between .01 and .05 were considered marginally significant and are presented to show trends. Relative risks of graft failure and mortality for patients with unfavorable compared to those with favorable risk factors are derived from the multivariate models and are adjusted for the effect of all other significant variables. Relative risks for mortality are also adjusted for patient age. Because of the very low incidence of graft failure observed in irradiated patients, separate univariate and multivariate analyses were performed on the 266 patients who received cyclophosphamide alone for conditioning.

Blood, Vol 73, No 2 (February), 1989: pp 606-613
Unless otherwise specified, all P values are based on the results of the multivariate analyses.

All multivariate analyses were examined for a possible center effect, ie, differences among centers not explained by identifiable patient and treatment differences using the following methods: entering transplant team into the regression model as a categorical covariate; stratifying the regression model by transplant center; repeating the analysis after exclusion of each of the seven largest centers; and dividing patients according to whether they were transplanted in centers reporting <20 and those reporting >20 patients.  The relative risks and P values associated with each of the prognostic variables were similar with and without these adjustments.

RESULTS

Characteristics of patients, donors, and treatments. Data from 384 males and 241 females surviving ≥21 days after transplant were analyzed for factors associated with graft failure. Pretransplant patient characteristics are summarized in Table 1. Median age was 19 years (range 1 to 56 years) for recipients and 20 years (range 1 to 59 years) for their HLA-identical sibling donors. Donor and recipient age were highly correlated (r = .82). The median duration of aplasia was 2 months (range 1 to 158 months) at the time of transplantation. The etiology of aplastic anemia was idiopathic in 466 (74%) patients, drug/toxin related in 74 (12%) patients, hepatitis related in 63 (10%) patients, and associated with other causes in 22 (4%). Two hundred seventy patients were maintained in laminar airflow isolation, and 349 were maintained in conventional protective isolation.

All patients received pretransplant immunosuppressive treatment with cyclophosphamide, usually 50 mg/kg for four days; 266 patients received no additional pretransplant therapy, and 25 received additional chemotherapy such as procarbazine and/or antithymocyte globulin. Three hundred thirty-four patients received cyclophosphamide plus radiation, including 121 who received total body irradiation (TBI) 3.0 to 12.0 Gy (median 3.0 Gy), and 213 who received limited-field (total lymphoid or thoracoabdominal) radiation, 1.5 to 18.0 Gy (median 6 Gy).

Posttransplant immune suppression to prevent or modify GVHD consisted of methotrexate in 288 patients, cyclosporine in 206, cyclosporine and methotrexate in 24, methotrexate and other drugs in 50, cyclosporine and other drugs in 35, and T-cell depletion in ten, corticosteroids alone in three, and no prophylaxis in nine patients. Among recipients of T-replete transplants, the median dose of bone marrow cells was 3.3 (range 0.4 to 13.0) x 10^6/kg recipient body weight.

Graft failure. Graft failure occurred in 68 (11%) of the 625 patients with an actuarial probability of 13% ± 3% (95% confidence interval) at 5 years. Nineteen of 68 (28%) patients had primary graft failure (failed to show any sign of engraftment), and 49 (72%) patients had transient engraftment with loss of the graft 3 weeks to 3 years (median 11 weeks) posttransplant. Outcome differed for patients with no engraftment and those with transient engraftment (Table 2).

Seven of the 68 patients survived with full or partial recovery of host hematopoiesis. All seven cases occurred in the group of 49 patients who had transient engraftment after

*Includes eight patients with no engraftment, three with partial engraftment, and two with transient engraftment after the second transplant.
†Primary causes of death after the second transplant: GVHD, three; interstitial pneumonia, three; adult respiratory distress syndrome, one; and bacterial pneumonia, one.

the first transplant; none of the 19 patients with primary graft failure had autologous marrow recovery. Twenty-four additional patients were not retransplanted, and all died of severe aplastic anemia; nine with primary graft failure died between 3 and 8 weeks (median 4 weeks) posttransplant, and 15 with transient engraftment died between one day and 7 weeks (median 2 weeks) after losing their graft.

Ten patients with primary graft failure (no engraftment) and 27 patients with transient engraftment received a subsequent transplant, 23 from the same donor and 14 from a different HLA-identical sibling donor. Thirty-four patients received two transplants, and three patients received three transplants. The median interval between the first and second transplant was 2.6 months (range 0.9 to 31 months). Prior to the second transplant, 16 patients received cyclophosphamide with or without other drugs, 14 received cyclophosphamide plus TBI, and three patients received other conditioning regimens. Four patients were retransplanted without additional immune suppression. Survival was not significantly influenced by the conditioning regimen used for the second transplant or by whether the same or a different donor was used. However, none of the ten patients retransplanted because of primary graft failure survived a second transplant. Five of the ten had full or partial engraftment but died of other transplant-related complications; the remaining five failed to engraft. Of the 27 patients who had transient hematopoietic recovery after their initial transplant and were retransplanted, 22 engrafted and 16 are alive 6 to 96 months (median 38 months) after their second transplant; their actuarial probability of survival was 59% ± 20% at 3 years.

The 3-year probability of survival for the 49 patients with transient engraftment was 46% ± 14%. None of the 19 patients with primary graft failure is alive. Overall, 37 of 68 patients with graft failure died with aplasia as the primary or a contributing cause of death for a case-fatality rate of 54%. The mortality rate owing to graft failure was 6% for the 625 patients studied.

Three patients who did not meet the study criteria for graft failure also received a second transplant. All had partial hematopoiesis in the setting of GVHD. Two died of acute GVHD and interstitial pneumonitis; one is alive with full recovery of hematopoiesis, extensive chronic GVHD, and a Karnofsky performance score of 80% ten months after the second transplant.

Risk factors for graft failure. Variables significantly associated with graft failure in multivariate analysis of the 625 patients surviving ≥21 days are shown in Table 3. It was not possible to distinguish factors associated with primary graft failure vs transplant engraftment. The most important risk factor was whether or not the preparative regimen included radiation (Fig 1A). The 290 patients who were not given radiation had an increased risk of graft failure in comparison with the 334 patients who received radiation.

*Includes regimens containing both MTX and CsA; CI, confidence interval; CsA, cyclosporine; MTX, methotrexate.
in the 24 patients who received the combination of methotrexate and cyclosporine was similar to the risk in 206 patients who received cyclosporine alone. Although only ten patients receiving T-cell-depleted transplants were available for analysis, four had graft failure, for an actuarial rate of 47% ± 35% at 2 years (Fig 1B). The relative risk of graft failure associated with use of T-cell depletion was 10.8 (P < .001).

*Risk factors for graft failure in patients receiving cyclophosphamide alone.* Because the markedly reduced incidence of graft failure in association with preparative regimens that included radiation may have obscured findings that would help our understanding of other mechanisms of graft failure, data for the 266 patients prepared with cyclophosphamide alone were analyzed separately. Variables associated with the risk of graft failure in this group are shown in Table 3.

Two pretransplant variables were significantly associated with the risk of graft failure. Patients whose aplastic anemia was not treated with corticosteroids prior to referral for transplantation had an increased risk of graft failure as compared with those who had received corticosteroids (relative risk 2.5, P < .007, Fig 2A). Increasing numbers of pretransplant transfusions were associated with an increased risk of graft failure, with risk increasing continuously (relative risk 1.01^n, where n = number of units transfused, P < .007) and with patients who received the largest number of transfusions having the highest risk (Fig 2B). Posttransplant immunosuppressive therapy also was significantly associated with the risk of graft failure. Patients receiving methotrexate had a higher risk than those receiving cyclosporine (relative risk 2.3, P < .008, Table 3). Because only one patient in this subgroup of 266 patients received T-cell-depleted bone marrow, the effect of T-cell depletion could not be evaluated.

Among patients receiving cyclophosphamide alone for pretransplant immune suppression, the probability of graft failure decreased significantly over the course of the study. For the patients transplanted in the years 1978 through 1980, the 3-year probability of graft failure was 31% ± 12%; for patients transplanted after 1980 it was 16% ± 6% (univariate P < .005). This change coincided with a significant decrease in the use of methotrexate and a corresponding increase in the use of cyclosporine to prevent GVHD (univariate P < .0001). There was no significant change in the median number of transfusions received or the type of drugs used to treat severe aplastic anemia over this time period.

After adjustment was made for the difference in drugs used as prophylaxis against GVHD, the probability of graft failure was not significantly different in the earlier and later years of the study.

*Factors not associated with the risk of graft failure.* Factors which were not significantly associated with graft failure are presented in Table 4. Within the range available for testing, higher bone marrow cell doses were not associated with better engraftment; however, >95% of patients received > 2.0 x 10^8 cells/kg body weight. Whether cell doses lower than these would be associated with graft failure is unknown. Use of laminar airflow isolation, infusion

---

Fig 1. Actuarial probability of graft failure according to (A) whether radiation was administered for pretransplant immune suppression and (B) method of prophylaxis against GVHD. *Includes patients receiving both cyclosporine and methotrexate.*

(relative risk 3.2, P < .0001). There was no significant difference in the probability of graft failure between patients receiving TBI and those receiving limited-field radiation. There was no significant difference in the probability of graft failure between limited field and TBI. There was no apparent dose effect within the range of doses reported.

The method of GVHD prophylaxis was also an important determinant of graft failure (Fig 1B). Regimens containing methotrexate were associated with a significantly higher probability of graft failure than regimens containing cyclosporine (relative risk 2.1, P < .008). The risk of graft failure
Fig 2. Actuarial probability of graft failure in patients receiving cyclophosphamide alone for pretransplant conditioning according to (A) whether corticosteroids were used to treat aplastic anemia prior to transplantation and (B) number of pretransplant transfusions.

of donor buffy coat cells, and donor-recipient sex-match did not significantly affect the probability of stable engraftment in the entire series or in the subgroup prepared with cyclophosphamide alone. Prior treatment with antithymocyte globulin was not associated with the probability of graft failure.

Relationship between risk factors for engraftment and mortality. Each of the factors significantly associated with an increased risk of graft failure was studied for its association with GVHD, interstitial pneumonia, and survival. Overall, patients treated with methotrexate rather than cyclosporine to prevent GVHD had a significantly higher incidence of interstitial pneumonia (21% vs 10%, univariate \( P < .0009 \)), and a higher risk of mortality posttransplant (relative risk 1.6, \( P < .0009 \)). The incidence of moderate-to-severe acute GVHD and chronic GVHD was similar whether methotrexate or cyclosporine was used. Only one of six patients who engrafted after transplantation with T-cell-depleted marrow developed acute GVHD; none developed chronic GVHD; two developed interstitial pneumonia. The relative risk of dying was increased after T-depleted as compared with T-replete transplants, but this was not statistically significant (relative risk 1.5, \( P > .10 \)). In comparison with irradiated patients, patients conditioned with cyclophosphamide alone had a lower incidence of moderate-to-severe acute GVHD (36% vs 45%, univariate \( P < .03 \)), a similar incidence of chronic GVHD, and a lower incidence of interstitial pneumonia (12% vs 21%, univariate \( P < .004 \)). The risk of mortality was not higher for nonirradiated as compared with irradiated patients (relative risk 0.99, \( P > .10 \)).

Among the 266 patients prepared for transplantation with cyclophosphamide alone, patients receiving methotrexate to prevent GVHD had an incidence of acute GVHD, chronic GVHD, and interstitial pneumonia similar to that of patients receiving cyclosporine. Patients receiving methotrexate had a higher risk of mortality posttransplant that was marginally significant (relative risk 1.6, \( P < .03 \)). Greater numbers of pretransplant transfusions were not associated with the incidence of acute GVHD, chronic GVHD, or interstitial pneumonia. Patients who received \( \geq 40 \) transfusions pretransplant had a higher risk of dying than those who received \(< 40 \) (relative risk 1.2, \( P < .01 \)). Pretransplant treatment with corticosteroids was not associated with GVHD, interstitial pneumonia, or survival.

Although not associated with the probability of engraftment, use of buffy coat transfusions posttransplant was associated with an increased incidence of moderate-to-severe acute GVHD (48% vs 38%, univariate \( P < .05 \)), and chronic GVHD (45% vs 36%, \( P < .07 \)), and an increased risk of mortality (relative risk 1.4, \( P < .05 \)).

Identical twin transplants. Nineteen patients received transplants from identical twin donors. Six received pretransplant immune suppression with cyclophosphamide
alone (four patients) or cyclophosphamide plus TBI (two patients). All six are alive and well with sustained engraftment 12 to 92 months after transplantation. Thirteen of the 19 patients initially received bone marrow infusion without pretransplant or posttransplant immune suppression. Four of 13 had full hematopoietic recovery and are alive 11 to 30 months after transplantation. Nine of 13 had either no (two patients) or transient (seven patients) engraftment and received a second transplant; one of the nine received a third transplant. Prior to the second transplant, all patients received immune suppression. Six received cyclophosphamide alone, two received cyclophosphamide plus radiation, and one received nitrogen mustard. Twelve of the 13 multiple transplant recipients are alive with full recovery of hematopoiesis five to 79 months after transplantation. One patient died of sepsis in the second week after the second transplant; she had full erythroid and granulocytic recovery but still had severe thrombocytopenia at the time of death.

**DISCUSSION**

This analysis examined the incidence and clinical consequences of graft failure following bone marrow transplantation for aplastic anemia and identified risk factors associated with this complication. Since it is generally not possible to discern the mechanism of graft failure in a given patient, it was operationally defined in this analysis as occurring in patients who survived >21 days but either failed to show any recovery of hematopoiesis or had engraftment manifested by partial or full hematologic recovery following recurrent aplasia in the absence of moderate to severe acute GVHD.

Frequently graft failure after HLA-identical sibling transplants is assumed to result from immunologic rejection directed at donor minor histocompatibility antigens. Other mechanisms may be responsible for graft failure as well, such as abnormalities of the recipient microenvironment, inhibition of hematopoiesis by infection, or nonimmune mechanisms. Data from identical twins reported in this article and elsewhere support the concept that host immunologic reactions against histocompatibility alloantigens on the transplanted bone marrow cells are not the sole mechanism for graft failure.

Graft failure occurred in 68 of 625 evaluable recipients of HLA-identical marrow transplants. Of 19 patients with no sign of engraftment, none survived despite attempts at further immunosuppressive preparative treatment and retransplantation in ten of the 19. The clinical condition of patients who fail to engraft is highly precarious. They tolerate further intensive immunosuppressive treatment poorly and often succumb to drug toxicity, infections, or other complications before engraftment can occur. Patients with transient engraftment have a better prognosis with second transplants; 16 of 27 are surviving six to 96 months after the second transplant, and their actuarial survival is 59% ± 20% at 3 years. Second transplants were reported by the International Bone Marrow Transplant Registry in 1976 to be successful in four of 12 (33%) patients and, in a more recent study by Storb et al, 23 in six of 16 (38%) patients with graft failure after transplantation for aplastic anemia.

Analysis of the entire group identified no pretransplant patient or donor characteristic that was significantly associated with graft failure. Various therapeutic interventions were associated with a reduced risk of graft failure, although some may lead to an increased likelihood of other complications, as shown in Table 5.

*Increased (I), no change (—), decreased (l).*
A trend toward a higher probability of engraftment in recent years was observed in patients conditioned with cyclophosphamide alone. This can be accounted for by the increasing use of cyclosporine to prevent GVHD. Other treatment and/or patient variables associated with this trend were not identified. Changes in blood transfusion practices or other unidentified factors may also have contributed to the reduced rate of graft failure.

Previous treatment with corticosteroids prior to referral for transplantation was associated with a lower incidence of graft failure. The explanation for this finding is unclear. The interval between diagnosis of aplastic anemia and transplantation and use of other immunosuppressive treatments (eg, antithymocyte globulin) did not appear to affect engraftment. Corticosteroids do inhibit cellular and humoral immunity in patients with aplastic anemia and thus may have facilitated engraftment by this mechanism.56

These data point to several modes of treatment associated with a reduced incidence of graft failure. In conjunction with information regarding the impact of these therapies on other transplant-related complications (Table 5), they suggest some measures that may improve the outcome of bone marrow transplantation for aplastic anemia. Cyclosporine-containing regimens appear to have an advantage over methotrexate. If possible, transplants should be withheld or minimized prior to initiation of the immunosuppressive preparative regimen, especially if regimens without radiation are to be used.

ACKNOWLEDGMENT

We thank D’Etta Koeer and Sharon Gargul for help with data analysis and Pauline Sova and Karen Witkowski for typing the manuscript.

GRAFT-VERSUS-HOST DISEASE IN THE EXPERIMENTAL ANIMAL

Peter Jacobs, David Bareford, Joan Parker and Graham Manuel.

The University of Cape Town Leukaemia Centre, and the Department of Haematology, Groote Schuur Hospital, Observatory, Cape.

Allogeneic bone marrow transplantation is the preferred treatment for patients with immunodeficiency disease and severe acute aplastic anaemia: it is currently also being compared to cytotoxic chemotherapy as maintenance therapy following first complete remission in leukaemic patients. Providing adequate numbers of stem cells are infused, and the patient has not been previously isoimmunised from exposure to donor antigens, engraftment is a limited problem. The greatest barrier to successful haematopoietic and immunologic reconstitution is graft-versus-host disease. A rabbit model has been developed in which this unique inflammatory process has been histologically defined, and is being used to examine immunologic manipulation with Corynebacterium Parvum and Cyclosporin A on survival. Using a specific strain combination of R female donors into NZW male recipients radiation control animals die aplastic with a mean of five days and autologous rescue results in haematopoietic reconstitution within 21 days. Allogeneic transplantation results in histologically proven graft-versus-host disease with wasting, diarrhoea and infection with 10% survival at 40 days, and no survival at 100 days. C. Parvum administration increases these figures to 58% and 30%, respectively. Administration of Cyclosporin A has 44% survival at 40 days and 33% survival at 100 days. These data establish activity for both C. Parvum and Cyclosporin A in the rabbit model, and their markedly differing action suggests that they may be used in combination in clinical transplantation.

INTRODUCTION

In neither man nor experimental animals is it possible to consistently replace an irreversibly damaged organ or tissue without significant morbidity and mortality. Despite numerous unresolved problems, transplantation remains the most logical approach to managing these situations and, therefore, a major goal of physicians.

Many of the technical aspects of the procedures, although complex, have been perfected, but in the specific context of bone marrow transplantation two immunologic barriers exist, and these have markedly limited its clinical application. The first of these is graft rejection, which historically accounted for many of the early failures but differed in no important way from that encountered in renal, hepatic, and cardiac replacement. This problem has been approached by defining the number of marrow cells that need to be infused and, more importantly, by matching donor and recipient for antigens determined at the major histocompatibility complex. Isoimmunization from blood transfusion is a further mechanism that may compromise engraftment, but should be easily avoided by educating referring physicians.

Graft-versus-host disease (GVHD) is the second barrier to successful bone marrow transplantation. This unique phenomenon is a manifestation of immunologically competent cells being transferred to an immunocompromised recipient, where an inflammatory response is mounted against the antigen-bearing cells of the host. The organs predominantly affected are skin, gastrointestinal tract, and liver; but lymph nodes and lung may also suffer damage.

The morbidity and mortality from this syndrome are such that the potential of bone marrow transplantation remains far greater than its current clinical application. This is particularly unfortunate, since evidence is accumulating that it is the best form of treatment available for severe acute aplastic anemia (30) and combined immunodeficiency disease (6), while early results are encouraging in patients with myeloblastic (33) or lymphoblastic (34) leukemia transplanted in complete remission. For these reasons, much current research is aimed at trying to understand the pathogenesis of graft-versus-host disease and at systematically exploring agents that may be effective in either prophylaxis or management of this serious complication.

GRAFT-VERSUS-HOST DISEASE

In both man and in experimental animals the clinical syndrome is relatively easy to recognize. The
dominant features are cutaneous involvement, gastrointestinal symptoms, jaundice, and a decreasing performance status (13). Based on the severity and number of organs involved, four clinical stages are recognized. In Grade I, a maculopapular skin rash may be the solitary finding. In Grade II, the skin is more prominently involved and mild gastrointestinal symptoms with diarrhea, nausea, cramping abdominal pain, vomiting, and malabsorption occur. Liver involvement is reflected in jaundice, and elevated liver enzymes as well as plasma alkaline phosphatase. The clinical performance status is mildly impaired. In Grade III disease the symptoms are aggravated and clinical performance becomes markedly impaired. In Grade IV, the pattern and severity of signs and symptoms are similar but extreme constitutional disturbances are evident. Certain prerequisites are necessary, of which immunodeficiency in the recipient, infusion of immunocompetent lymphocytes from the donor, and antigenic disparity between donor and recipient are among the most important variables. Because of the uncertain way in which these three interact, attempts to control this immunologically mediated inflammatory phenomenon will vary widely.

There seems general agreement that the closeness with which donor and recipient are matched at the major histocompatibility complex correlates inversely with the severity of the graft-versus-host disease. Identity at the HLA-D locus appears to control the capacity of inflammatory cells to recognize differences existing at HLA-A and HLA-B loci. There is evidence for this in two children with severe combined immunodeficiency disease, who were transplanted with histoincompatibility at the latter two loci, but identity at the HLA-D locus. In both cases the reactions were less severe than had the A and B loci been major factors in the reaction (11,12). However, it is unlikely that this is the complete explanation, since identity at all sites presently identifiable on the major histocompatibility complex is still associated with GVHD in approximately 70% of patients (31,32). Furthermore, the development of the same syndrome in syngeneic transplants (26) suggests that other chromosomal regions may be important determinants of graft-versus-host disease.

More recently, evidence has been presented that GVHD may result from imbalance in immunoregulatory T-cell subsets, manifesting itself in the emergence of autotoxic T cells or autoantibodies (27). Thus, in patients with both acute and chronic GVHD, the TH{sub}s + T subset of cells, identified by specific heteroantiserum and containing the suppressor population, are reduced. The acute disease may be self-limiting and this could be explained by transient loss of the suppressor population following total body irradiation or cyclophosphamide conditioning. Abrogation of the GVHD could theoretically occur at a time when thymic function is reestablished and the suppressor TH{sub}s + T cell subpopulation is reestablished.

The same workers (27) point out that in chronic GVHD the cell aberration is more heterogeneous, with some of the T cells bearing Ia-like antigens. The latter only appear on the T cells once they have been activated, and in normal circumstances, are restricted to the B cells. In patients with chronic GVHD, one mechanism may be failure of the TH{sub}s + subset to regenerate, leaving helper cells (TH{sub}s - Ia+) unopposed. Alternatively, in vivo activation of the suppressor cells may overshoot with TH{sub}s +, Ia+ population being two or three times normal.
thereby suppressing the immune response. These studies do not elucidate the mechanisms whereby alloactivation or target-organ damage occurs, but they do provide evidence for regulatory imbalance in patients undergoing bone marrow transplantation and subsequently developing GVHD. This approach also provides an alternative classification for the syndrome.

In view of the uncertainty in the pathogenesis and the not inconceivable complications associated with therapy, attempts to predict the severity of GVHD are important, since this may provide a basis for modifying treatment. Since it is apparent that prevention is preferable to trying to reverse the established inflammatory process, a recent study demonstrating that pretransplantation assessment of natural killer cell activity directed against herpes simplex virus type 1 may have important prediction for the development of this disease is deserving of further evaluation (19).

At the present time immunosuppression, which is relatively nonspecific, remains the cornerstone of both prophylaxis and treatment. It is against this background that we have started evaluating cyclosporin A in both an experimental animal mode and in a clinical transplantation program.

**CYCLOSPORIN A**

Cyclosporin A (CS-A, OL 27 400) was discovered in early 1972 in the Research Laboratories of Sandoz Ltd in Basle. It is a hydrophobic cyclic peptide consisting of 11 amino acids with a molecular weight of 1203. The active compound is a fungal metabolite derived from cultures of *Cylindrocarpon lucidum* or *Trichoderma polysporum* (3).

In screening programs, cyclosporin A was found to have powerful immunosuppressive properties that differed in important and fundamental ways from the more conventional cytotoxic drugs and, of particular importance, have a remarkably low degree of myelotoxicity. Thus, while the target cell is clearly and specifically the lymphocyte in mice, rats, rabbits, dogs, and rhesus monkeys, the mechanism of action remains unknown.

Available evidence localizes the activity of cyclosporin A to the inductive or earliest phase arising in the immunocompetent cells as they respond to the mitogenic message. Cell division, by way of contrast, does not appear to be affected and, furthermore, no lymphocyte cytotoxic effects are demonstrable. The reduction in lymphoblast numbers, which may be striking, in vitro probably reflects prevention of stimulation rather than elimination of blast cells by cytolytic mechanisms (5). Expressed in another way, the primary effect of this agent is directed against the earliest cellular events in the lymphocyte that follow mitogenic stimulation and finds expression by preventing transformation into the blast cell.

The subpopulations of lymphocytes that may be affected have not been defined. However, while B cells are not directly suppressed, their production of antibody, together with that of plasma cells, is inhibited both in vitro and in vivo by the presence of CS-A implying that T-helper cells are the prime targets in its action.

The more critical study of T lymphocyte dysfunction is bedevilled by the many assay systems in use. As a result, controversy currently exists as to the role, if any, on the T-effector and T-suppressor subpopulations. Undoubtedly clarification of any selective action that cyclosporin A has on specific subsets of T lymphocytes is now a high research priority. It can, however, be said that it does not lead to selective clonal deletion but rather to the induction of a temporary suppressive state that is reversible when treatment is terminated (18,36).

Despite this persisting uncertainty, numerous laboratory correlates have been described in support of its interference with lymphocyte function (4,37) and powerful immunosuppressive activity has been reported in animal studies. For example, allograft survival has been prolonged after cardiac transplantation in rats (16) and pigs (8); and renal transplantation in rabbits (15), dogs (7), and in man (9). Cyclosporin A is capable of preventing or ameliorating GVHD in mice (3) and rats (35). Preliminary studies in man are also encouraging (25).

As with any new agent, side effects require special attention. These were originally defined using the administration of doses that far exceeded those needed to achieve effective immunosuppression. Here there was regression in thymus weight, cellular depletion of paracortical areas in lymph nodes or a white pulp in the spleen, and concomitant atrophy of lymphoid follicles (5). In the kidneys, there was swelling, vacuolization together with scattered necrosis, and regeneration of tubular cells.

In the liver, swelling and single hepatocyte necrosis was accompanied by centriflobular fatty degeneration. Of interest was mucosal angiopathy in the ileum (5). These findings characterized animals receiving doses associated with high mortality but reversed spontaneously within 4 weeks in animals who recovered (5).

In clinical studies some reversible nephrotoxic and hepatotoxic symptoms were found not necessarily associated with significant structural change when the tissues were examined histologically (9).

The toxicity of cyclosporin A is even more diffi-
cult to define in patients undergoing bone marrow transplantation where any side-effects need to be segregated from those that occur with high dose cyclophosphamide or lethal whole body irradiation. Nevertheless, there seems little doubt that varying degrees of renal dysfunction, hepatotoxicity, gastrointestinal tract symptoms, and bone marrow depression may be associated with cyclosporin administration (25). These can be reversed by careful adjustment to drug administration.

MATERIALS AND METHODS

Rabbits
New Zealand white (NZW) and R strain animals having an average weight of 2 kg were used throughout. The animals were individually housed and received water containing prophylactic sulpha-quinoxaline sodium (Embasin, May and Baker, Dagenham, England) and standard rabbit diet (Epol, Johannesburg), medicated with Amprolium (Merck and Company, Inc., USA). Temperature and weight were regularly charted. A full blood count and differential were done twice weekly. The biochemical profile was monitored regularly.

Radiation Technique
Animals were rendered aplastic by delivering 1200 rads total body irradiation from a central cobalt source placed 100 cm above the midplane of the prone but anesthetized animal. Radiation rates between 40 and 80 rads/min were shown not to differ significantly. In this model we have previously demonstrated (21) that uniform aplasia is produced without unacceptable radiation complications. Specifically, no gastrointestinal tract lesions were demonstrated. We did not find any difference between the technique and fractionalizing the radiotherapy, as suggested by others (22,23). In occasional animals, unexplained death occurred within 24 hr after administering the radiation and was ascribed to “radiation shock.” Current studies are evaluating the alternative radiation dose rate of 8 rads/min, and preliminary data indicate this regimen to be superior to the higher dose rates.

In a series of animals one or both of the femurs were shielded, and in another group autologous reconstitution was undertaken to provide controls to monitor both optimal rates of hematopoietic recovery and possible complications of the radiotherapy and transplantation procedure.

Allogeneic Bone Marrow Transplantation
Thirty-six hours after the lethal whole body irradiation the animals underwent allogeneic bone mar-
row transplantation. Between 2 and 4 × 10^6 nucleated cells per kilogram were transplanted from R females into NZW males. Standard mixed lymphocyte cultures (17) to demonstrate nonidentity at the major histocompatibility complex were not uniformly successful. Using a modified technique (20) antigenic disparity was demonstrated between the two strains and this was most striking when mitomycin treated lymphocytes derived from the mesenteric lymph node were used as antigen and appendiceal lymphocytes as responding or target cells. Results at day 3 gave stimulation indices between 1:3.6 and 1:13.9. In our experience even the latter technique does not produce absolutely uniform results, and we are currently examining modifications to enhance its sensitivity.

Cyclosporin A Administration
Rabbits were given 10 mg/kg daily of cyclosporin A by intramuscular injection for 28 days following transplantation. Plasma levels were monitored by high pressure liquid chromatography.

RESULTS

Radiation Controls
Irradiated animals developed increasing pancytopenia with platelet and granulocytic counts reaching their nadir between days 4 and 6, and all rabbits died. Mean survival (Fig 10.1) was 6.8 days (SE ± 0.08, range 2–11 days).

Autopsy studies at intervals showed rapidly increasing bone marrow hypoplasia, and the cause of death was established as infection in animals with widespread colonies of bacteria present in all organs. Minimal associated hemorrhage was present in the gastrointestinal tract of occasional rabbits. There was profound loss of lymphoid tissue throughout the gut, thymus, and spleen.

Femoral Shielding and Autograft Rescue
In animals having one or both femurs shielded, a reduction in white cell and platelet counts essentially similar to those of radiation controls were observed, but peripheral counts regenerated rapidly and were again normal by day 21 (Fig 10.2). The regenerating bone marrow, when studied serially, showed clonal regeneration of the previously aplastic marrow cavities. Histology was normal by day 30.

In the autografted animals who received between 2 and 4 × 10^6 nucleated cells per kilogram, peripheral blood values were indistinguishable from those observed with femoral shielding (Fig 10.2).

Anemia may be a problem and is aggravated by
Effect of Cyclosporin A on GVHD

**FIGURE 10.1.** Granulocytes and platelets follow similar patterns following 1200 rads midplane irradiation. The fall in circulating counts and the subsequent return to normal is not statistically different in animals having one or both femurs shielded during irradiation or following either allogeneic or autologous bone marrow transplantation. Absolute counts are plotted as a percentage of mean basal values against days that have elapsed following irradiation and transplantation. (-----) Femoral shielding; (---) allografts; (-----) autografts.

**FIGURE 10.2.** Observed survival in the four groups of rabbits. Median survival of irradiation controls was 6.8 days, allograft controls was 15 days, and allografted animals treated with cyclosporin was 40 days. At 100 days no allografted animal survived with cyclosporin A treatment in comparison to those who received this agent. In the latter group 33% of the original group were alive and well. In addition, cyclosporin A therapy reduced the incidence of histologically proven graft-versus-host disease from over 80% to below 25%.
blood sampling; microtechniques were therefore employed in these studies. In these animals, as opposed to radiation controls, the addition of prophylactic trimethoprim 10 mg, and sulphamethoxazole, 50 mg orally each day decreased deaths from infectious episodes and is routine practice in the animal transplantation program.

Allogeneic Bone Marrow Transplantation

In the allograft control experiments between 2 and 4 x 10^6 nucleated cells per kilogram resulted in granulocyte and platelet reconstitution in the peripheral blood, a pattern not statistically different from that demonstrated by animals undergoing radiation with femoral shielding, or after autografting (Fig 10.2). Similarly, the same pattern of bone marrow regeneration was found on serial histologic studies.

Since the study is designed to examine the effect of cyclosporin A on the incidence and severity of graft-versus-host disease, the rare animal dying before engraftment could be demonstrated was excluded from study.

The clinical findings in the allografted recipients were dramatically different from those in autograft controls. Gross weight loss was the striking feature, and at day 40 weights were, respectively, 0.8 and 2.8 kg. There was, in addition, patchy but typically extensive hair loss. Diarrhea was a variable feature, with cultures generally being negative.

Survival of animals (Fig 10.1) was 10% at day 40 and 0 at day 100. The cause of death was typically infection in the respiratory tract with nasal discharge of pus. Pneumonia was often present, with extensive destructive abscess formation being a feature. Histology of the skin, gastrointestinal tract, and liver were characteristic of graft-versus-host disease. In the skin aggressor lymphocytes were present in the epidermis, and spongiosis was prominent, particularly at the junction with the dermis. In the gastrointestinal tract loss of glands and patchy to total mucosal denudation were most striking in the small bowel. The liver showed infiltration of lymphocytes, loss of the limiting plate, and destruction of bile ducts by lymphocytes. Generalized lymphoid atrophy was evident in the spleen, lymph nodes, and thymus. These features were similar to those reported both in man (13) and in other experimental animals.

Cyclosporin Treated Allografted Animals

Two striking features were evident in these animals. First, they were uniformly in superior clinical condition with weights not significantly different from control animals. Hair distribution was normal, and diarrhea was not a feature. Second was the markedly different survival rate between allografted controls and rabbits receiving cyclosporin A after bone marrow transplantation (Fig 10.1). At day 40, 10% of the allograft controls were alive compared to 44% of those receiving cyclosporin A. This difference was even more obvious at 100 days when none of the controls survived, but 33% of those that had been treated were alive and well with normally functioning donor grafts.

Of particular note was the fact that the histologically recognizable features of graft-versus-host disease, which characterized the allografted control animals, were present in only 25% of animals receiving cyclosporin A. Furthermore, in the latter group death due to typical GVHD was unusual and was associated with incidental causes, such as perforated gastric ulcer and infection, of which bronchopneumonia and septicemia were the most frequent. It is presently not clear whether these terminal infections may be unusual expressions of GVHD modulated by cyclosporin A therapy.

Comments on Rabbit Study

Three points require comment. First, in the experimental animals the death rate appeared to accelerate after day 28 when cyclosporin A was discontinued. It therefore remains possible that longer periods of drug administration are necessary. These findings are entirely compatible with the suggestion that the action of this unique immunosuppressive agent is not lasting tolerance produced by selective clonal deletion, but is a transient phenomenon related to the presence of drug in the body (18,36). Furthermore, there are interesting parallels between this observation and those reported in a human transplantation study (24,25).

Secondly, it is noteworthy that in our animals, in contrast to experience with a similar model (29), we were unable to demonstrate any gross toxicity, and this is surprising. To some extent, the answer may be found in the third observation that high pressure liquid chromatography failed to demonstrate significant concentrations of cyclosporin A in the plasma of our animals. It therefore seems possible that the dosage administered may have been inadequate or the batch used had less biologic activity than we had anticipated. These questions are currently being reexamined. Nevertheless, the unequivocal and marked reduction in graft-versus-host disease and the striking prolongation in survival are further indicators that the plasma concentration of cyclosporin A may be less critical than currently accepted. Indeed, it remains to be proved that plasma levels are the most valid index of immunosuppressive activity. On the other hand these measurements are clearly the best presently available for
monitoring drug absorption and, in this way, anticipate toxicity.

CYCLOSPORIN TOXICITY IN CLINICAL STUDIES

Two reports from the Royal Marsden Hospital have indicated that encouraging results can be obtained from cyclosporin A administration (24, 25). Initially, early withdrawal of the drug led to exacerbation of GVHD and death of patients. Subsequently, there has been an appreciable reduction in the incidence of GVHD in patients receiving cyclosporin A, reversible side effects have been observed and, to date, no second malignant neoplasms have developed. The toxicity of the drug is an important concomitant of treatment and, in addition to experimental studies, we are able to add to this experience from some recently transplanted patients.

Case 1
A 21-year-old woman with severe acute aplastic anemia was referred for bone marrow transplantation. She required hemodialyses for a transient period of oliguric renal failure due to acute tubular necrosis (ATN) following sepsis. The infection was rapidly controlled with an antibiotic regimen of cephamandole, tobramycin, and metranidazole following replacement of her central venous catheter. In the diuretic phase of ATN she was given cyclophosphamide conditioning in preparation for her transplantation, and again became oliguric.

She received 2.8 x 10^6/kg nucleated cells from her compatible brother and 4 days later was pyrexial. A streptococcus was isolated from blood culture and after 6 days, the regimen was changed to the previous three-drug regimen, with temperature lysis within 48 hr. In this period, daily hemodialysis was used to maintain metabolic balance.

During this period cyclosporin A was given initially at 15 g/kg after each dialysis, and the dosage reduced to maintain a plasma level, measured by high pressure liquid chromatography, between 400 and 800 ng/ml. Engraftment was established by day 7, and no clinical evidence of graft-versus-host disease was present. Biochemistry showed a raised creatinine, which was controlled by regular hemodialysis; signs of low-grade cholestasis persisted. The patient died peacefully in her sleep on day 42, and autopsy revealed gastrointestinal tract hemorrhage as the probable cause of death. Renal tubules were regenerating. No histopathologic evidence of GVHD was present.

It is not certain as to the precise mechanism of her renal failure, although contributing factors include septicemia, nephrotoxic antibiotics such as tobramycin, and, for a short period of time, addi-

Effect of Cyclosporin A on GVHD

The role, if any, played by cyclosporin A is likely to be small. Although this substance is nephrotoxic, this case establishes a precedent for its continued use in the anuric patient with the proviso that plasma levels are maintained by adjusting dosage and by efficient hemodialysis. It could be argued that the immunosuppression associated with renal failure may have been sufficient to avoid the need for cyclosporin A, but this point remains to be proved. There is, however, no doubt that the nephrotoxicity of this agent does not exclude its use in patients with renal insufficiency, as evidenced by histologically proved recovery in the presence of continued administration to this anuric individual.

Case 2
A 26-year-old male with acute lymphoblastic leukemia was transplanted in first complete remission; nucleated cells, 2.7 x 10^6/kg, from a compatible sister were given. Cyclosporin A was started on day 0, and for the first week given by intramuscular injection at a dose of 15 mg/kg; dosage was maintained at an average level of 10 mg/kg and plasma levels remained between 200 and 400 ng/ml.

Engraftment was established by day 10 and on post-transplant day 30, the patient developed a skin rash clinically compatible with the diagnosis of Grade 1 GVHD. Biopsy was, however, not diagnostic and suggested a drug-associated lesion. Simultaneously, liver enzymes and alkaline phosphatase started to rise rapidly and diarrhea developed. Despite careful maintenance of plasma cyclosporin levels, the patient developed marked anorexia, nausea, vomiting, abdominal pain and further elevations in liver enzymes and alkaline phosphatase.

In view of the equivocal skin biopsy and clear clinical deterioration, the possibility was considered that this entire syndrome may be drug related. Accordingly, cyclosporin A was reduced, and the patient started on oral prednisone, 1 mg/kg/24 hr. There was an immediate and dramatic clinical improvement, with a decrease in diarrhea. Within 10 days, liver enzymes and hepatic biochemical abnormalities had returned to normal. There has followed a gradual resolution of skin lesion. Cyclosporin was discontinued by accident on day 60; however, the patient is improving but still requires intravenous hyperalimentation for a severe wasting state. The cyclosporin has, therefore, not been restarted.

Although the explanation for the hepatotoxicity and gastrointestinal symptoms are uncertain, the rapid reversal of liver biochemical abnormalities support the relatively benign nature of these abnormalities. One possibility is that cyclosporin may have been directly implicated, but GVHD may have been responsible, despite the cyclosporin adminis-
tation, and the hepatic component reversed more rapidly than the gut lesion on corticosteroid administration. The residual severe wasting state may then reflect GVHD modified by both cyclosporin and subsequent steroid therapy. It is reassuring that serial absorption studies, including small bowel biopsy, show that gastrointestinal tract morphology and function returned to normal.

Thus, while these observations support the reversible nature of the hepatotoxicity in patients receiving cyclosporin A, they also draw attention to the fact that it is difficult to accurately attribute the changes solely to the drug. The converse also applies in that patients at risk of developing GVHD may express clinical and histologic features that differ from patients who are not receiving this agent.

Case 3

A 12-year-old male underwent bone marrow transplantation with $3 \times 10^9$/kg nucleated marrow cells from his compatible sister for severe acute aplastic anemia; he engrafted on day 9. Cyclosporin was given on the standard regimen and plasma levels monitored. On day 14 following transplantation, the patient developed conjugated hyperbilirubinemia, rises in alkaline phosphatase and liver enzymes, right upper quadrant abdominal tenderness, and an area of segmental ileus. Ultrasonography showed a large cystic mass considered to be possibly an intraabdominal abscess. At emergency laparotomy, a mucocele of the gallbladder due to edema of the common bile duct and cystic ducts was drained and the rest of the abdomen explored. No abnormality was demonstrated.

The liver and skin biopsy showed no evidence of graft-versus-host disease: the liver findings were compatible with drug-induced hepatotoxicity. Nephrotoxicity was never a problem.

On day 21 post-transplantation, a further small rise occurred in liver enzymes and cyclosporin A dosage was reduced to 10 mg/kg. The biochemical changes did not reverse and on day 25 the cyclosporin was withdrawn and corticosteroid therapy started. The liver function tests promptly started to improve and continued to do so steadily until his death from septicemia on day 34.

Autopsy showed marked edema, hyper trophy, and extensive ulceration of the bowel. No residual abnormality was present in the biliary system. Histologic examination, even in the absence of diarrhea, showed only minimal changes compatible with graft-versus-host disease.

The usual picture of GVHD was lacking from skin, liver, and gastrointestinal tract and this experience emphasizes the possibility that cyclosporin administration may modify both the clinical and histopathologic expression of GVHD. In this regard attention has already been directed to the way in which this agent can mask the typical cutaneous manifestation of GVHD(25). The rapidly reversible nature of the hepatotoxicity is again evident in this patient, even in the presence of transient obstruction to the biliary system.

COMMENT

Graft-versus-host disease remains the single greatest barrier to the more widespread use of bone marrow transplantation in clinical medicine. Attempts to diminish the severity of this clinical syndrome with prophylactic methotrexate or a variety of immunosuppressive regimens, ranging from antilymphocyte globulin to steroids and azathioprine (Imuran) have met with only limited success.

Preliminary experience with the unique immunosuppressive agent cyclosporin A has therefore justifiably initiated a series of studies in experimental animals and in man to define the place that the peptide might play in control of graft-versus-host disease.

In these experimental studies cyclosporin A was shown to be clearly of benefit in prolonging survival of allografted rabbits and that this was related to a prominent decrease in the incidence of histologically proved graft-versus-host disease.

It has not been possible to demonstrate toxicity of any type in the rabbit allograft model following cyclosporin A administration. This experience is in conflict with both our own experience in clinical transplantation and with that reported by other investigators using a similar rabbit model (29). It remains to be determined whether more detailed toxicity studies, correlated with varying plasma levels and differing schedules for administration in our rabbit model will reveal changes not evident in the earlier studies. This must take into account histology, ultrastructure, and functional measurements. In addition, evaluation of immunologic competence and correlation with an ability to handle infection await clarification.

Of particular note has been the absence of lymphoma or secondary malignancies in animals that received cyclosporin A and survived for prolonged periods of time. Here again, the question of duration and dosage of drug administration, period of observation after allografting, and associated conditioning regimens require careful analysis. These observations should be taken in the context of current studies in humans where early results are equally encouraging but toxicity is still not clearly defined.

In renal transplantation a word of warning has been sounded about the development of lymphoma (2,10). Nevertheless it should be recognized that
interstitial pneumonitis in 17, acute GVHD in 10, hemorrhage in seven, organ failure in six, adult respiratory distress syndrome (ARDS) in four, venoocclusive disease in three, chronic GVHD in three, and other causes in seven.

**DISCUSSION**

We have previously reported that allogeneic BMT in multiple myeloma produces a high complete remission rate, with a fraction of patients entering sustained long-term complete remission. Analysis of prognostic factors at that time demonstrated a significantly higher complete remission rate in patients with stage I disease at diagnosis, in patients who had received only one line of treatment, and in those who were in complete remission before conditioning for transplantation; however, although there were trends for longer survival in these patients, these were not statistically significant. In the present study, we were able to demonstrate significantly higher complete remission rates, and also significantly better survival in patients who were in stage I at diagnosis, who had received only one line of treatment before bone marrow transplantation, or who were in complete remission before conditioning as compared, respectively, with patients who were in later stages at diagnosis, had received two or more lines of treatment, or were not in complete remission before conditioning. In addition, we observed that females have a higher complete remission rate and better survival than males. In BMT for leukemia, the reason for a similar difference appears to be that results are poorer if female marrow is given to male recipients, than if female marrow is given to female recipients. A slight trend in this direction was seen, but it was not significant.

The age of the patient within the age bracket 23 to 59 years was not of significant importance for outcome. There was only a slight trend for patients less than 40 years to have better survival than older patients. This would agree with a recent study of patients with leukemia, which showed that the prognostic impact of age is small between 30 and 50 years.

The response rate was higher for both IgA and light-chain myeloma than for IgG myeloma. However, only IgA myeloma tended to have a better survival than IgG myeloma. Such a difference has generally not been noted with conventional chemotherapy, except in patients treated with combinations of interferon and melphalan. In one such study, patients with IgA or Bence-Jones—only myeloma had a significantly better response rate and survival than patients with IgG myeloma.

A limited number of patients were investigated for β2-microglobulin level at diagnosis. Patients with a high β2-microglobulin level (> 4 mg/L) tended to do worse than those with β2-microglobulin levels below this value. This was similar to the importance of β2-microglobulin in patients treated with conventional chemotherapy or ABMT.

The importance of procedural factors for outcome is difficult to investigate in this heterogeneously treated material. No superiority of any conditioning regimen to the conventional regimen of TBI plus cyclophosphamide was detectable. The follow-up time of patients treated with busulphan plus cyclophosphamide was shorter than for patients treated with TBI plus cyclophosphamide or other chemotherapeutic agents. Thus, it is difficult to make a fair comparison; however, the shape of the survival curve suggests that busulphan plus cyclophosphamide is not superior to any other treatment modality used. If anything, the tendency was for poorer survival, but it was not significant. Busulphan plus cyclophosphamide has recently been compared with TBI plus cyclophosphamide in a prospective, randomized study of other hematologic disorders by the Nordic Bone Marrow Transplant Group (NBMT). Although no significant difference in overall survival was found, patients with more advanced disease had a significantly poorer survival using busulphan plus cyclophosphamide than TBI plus cyclophosphamide, and it appeared that venoocclusive disease and hemorrhagic cystitis were more frequent in the busulphan-plus-cyclophosphamide group. The combination of busulphan plus cyclophosphamide for BMT in myeloma has been extensively evaluated by the Seattle group, who found that, in 12 of 15 assessable myeloma patients (N = 20), a complete remission was obtained, with complete remission defined as disappearance of the Ig assayed by immunofixation. The probability of survival at 3 years was 36%. As in the EBMT study, most patients had a relatively advanced stage of disease. Although this study was a phase I study that escalated the dosages of busulphan, it should be noted that four of 20 patients developed venoocclusive disease. This seems to support our view that venoocclusive disease may well be more common following busulphan plus cyclophosphamide as compared with TBI plus cyclophosphamide. Of 103 patients with myeloma who died in the present EBMT study, only three had venoocclusive disease determined as the primary cause of death.

Graft-versus-host prevention methods varied and it was therefore difficult to analyze any particular methodology. With T-cell depletion, acute GVHD was absent in 48% of patients. Without T-cell depletion, it was absent in only 32%. However, the lower frequency of GVHD with T-cell depletion did not translate into better survival or result in a higher relapse rate in comparison to those who were not T-cell-depleted. Thus, it was not possible to
many of these patients have had prolonged periods of renal disease and it is not certain that the development of lymphoma can be divorced with any degree of certainty from the previous periods when they may have been markedly immunocompromised from uremia. The failure to find secondary malignancies in animal models or in patients with severe acute aplastic anemia or leukemia undergoing bone marrow transplantation may therefore, in some way, be related to this variable as distinct from a complication of cyclosporin administration. This is another aspect of possible toxicity, presently the subject of evaluation in our animal experimental model.

In the specific context of bone marrow transplantation evidence is accumulating that graft-versus-host disease is capable of modification by cyclosporin A administration. The incidence of the syndrome is reduced but not abolished, and since the published data are relatively limited, many questions await answers. Foremost among these are the establishment of an optimum schedule on which the drug should be given, the minimum plasma level required to avoid toxicity and yet maintain an optimum degree of immunosuppression, the best tests to monitor the adequacy of the latter, the participation, if any, of metabolically active degradation products in the overall activity of cyclosporin therapy, and whether in vitro tests of immunologic incompetence correlate with in vivo effects of immunologic suppression in man.

What conclusion may be drawn from the available data?

Undoubtedly cyclosporin is both a unique and highly effective immunosuppressive agent. As such, it should continue to receive intensive study so that the mechanism of its action be defined. Already, sufficient reliable data are available to support further critical evaluation in selected clinical situations, and of these, transplantation programs have a high priority. It is appropriate that bone marrow grafting should be specially studied. Twin challenges of rejection and graft-versus-host disease must be overcome in order that its potential in an ever-expanding series of clinical indications may be realized. Finally, as with any new agent, early encouraging results and reasonable enthusiasm should be tempered by a responsible awareness of the possible side effects of cyclosporin administration. The interests of patients and scientists alike will be best served by the careful documentation and balanced reporting of benefits and limitations of treatment with what promises to be an exciting new form of treatment.

SUMMARY

Graft-versus-host disease (GVHD) is the most important cause of death in patients and animals following allogeneic bone marrow transplantation. Neither attempts to prevent the syndrome with methotrexate or treatment of the established disease with corticosteroids or antithymocyte globulin have significantly altered morbidity or mortality. The immunosuppressive agent cyclosporin A (CSA) is reported to be effective in therapy of GVHD in rodents. The present study was undertaken to extend this observation. Using a previously described animal model, New Zealand White strain of rabbits were irradiated with 1200 rads midplane to render them aplastic; this was followed by infusion of a bone marrow suspension obtained from R strain rabbit donors. The recipients were randomly allocated to receive either no treatment or 28 consecutive daily intramuscular injections of CSA (10 mg/kg). There was no evidence of renal, hepatic or hematopoietic toxicity associated with the CSA administration. Survival figures at 28 days in control animals were 1 of 8 (12.5%) and in those receiving CSA 11 of 18 (61%); at 100 days there were no survivors in the untreated animals and 6 of 18 (33%) of those receiving CSA were alive and well. Histology of tissue obtained at autopsy from the controls showed changes compatible with GVHD in all animals examined. In CSA treated animals that died before day 28, there was a lower incidence of these findings and death was due to infection. However, after 28 days GVHD was again manifest affecting predominately the gut. In none of our animals was there evidence of malignancy developing in the long-term survivors. It is concluded that, as in rodents, the administration of CSA to rabbits undergoing allogeneic bone marrow transplantation significantly prolonged survival.

ACKNOWLEDGMENTS

The excellent collaboration of Joan Parker, David Bareford, Graham Manuel and Bev Milns is recorded. Professor R Sealy, Dr H King, and their radiotherapy staff provided radiation facilities. Dr Ennette du Toit helped with animal housing. Sandez kindly measured cyclosporin A levels on our experimental animals and patients. The work was supported by the Medical Research Council, the Harry Crossley Foundation, the University of Cape Town Research Fund, and the National Cancer Association of South Africa. Effect of Cyclosporin A on GVHD

Improving the Outcome of Bone Marrow Transplantation by Using CD52 Monoclonal Antibodies to Prevent Graft-Versus-Host Disease and Graft Rejection

By Geoff Hale, Mei-Jie Zhang, Donald Bunjes, H. Grant Prentice, David Spence, Mary M. Horowitz, A. John Barrett, and Herman Waldmann

Graft-versus-host disease (GVHD) is a major cause of mortality and morbidity after allogeneic bone marrow transplantation, but can be avoided by removing T lymphocytes from the donor bone marrow. However, T-cell depletion increases the risk of graft rejection. This study examined the use of CD52 monoclonal antibodies to eliminate T cells from both donor marrow and recipient to prevent both GVHD and rejection. Seventy patients receiving HLA-identical sibling transplants for acute mylogenous leukemia (AML) in first remission were studied. An IgM (CAMPATH-1M) was used for in vitro depletion of the graft and an IgG (CAMPATH-1G) for in vivo depletion of the recipient before graft infusion. No posttransplant immunosuppression was given. Results were compared with two control groups: (1) 30 patients who received bone marrow depleted with CAMPATH-1M, but no CAMPATH-1G in vivo; and (2) 49 patients reported to the International Bone Marrow Transplant Registry (IBMTR) who received nondepleted grafts and conventional GVHD prophylaxis with cyclosporin A (CyA) and methotrexate (MTX). The incidence of acute GVHD was 4% in the treatment group compared with 39% in the CyA/MTX group (P < .001).

HIGH-DOSE CHEMOTHERAPY and radiotherapy followed by transplantation of hematopoietic stem cells can cure patients with leukemia. However, allografts have several adverse effects, the most serious of which is graft-versus-host disease (GVHD). It can result in severe damage to skin, liver, and gut, frequently leading to death or chronic disability. To control GVHD, immunosuppressive drugs such as cyclosporin A (CyA), methotrexate (MTX), and corticosteroids are administered posttransplant. However, even with combined cyclosporin and methotrexate, GVHD remains the single most common cause of death after allogeneic transplants.

Chronic GVHD was also exceptionally low in the treatment group (8% vs 36%; P < .001). The problem of graft rejection, which had been frequent in the historic CAMPATH-1M group (31%), was largely overcome in the treatment group (8%). Then, transplant-related mortality of the treatment group (15% at 5 years) was lower than for the CyA/MTX group (26%; P = .04). There was little difference in the risk of leukemia relapse between the treatment group (30% at 5 years) and the CyA/MTX group (29%). Survival of the treatment group at 6 months was better than the CyA/MTX group (82% vs 78%), although at 5 years the difference was not significant (62% vs 58%) and neither was the difference in leukemia-free survival (69% vs 55%). We conclude that T-cell depletion is a useful strategy to prevent GVHD, provided that measures are taken to ensure engrafment. Using CAMPATH-1G to deplete residual host lymphocytes is a simple and practical method to do this. At least in AML, the beneficial reduction in GVHD can be achieved without an increased risk of relapse.

For many years it has been known that GVHD can be prevented by depleting T lymphocytes from the donor bone marrow and a variety of methods were developed to accomplish this. One of the most widely used has been the monoclonal antibody (MoAb) CAMPATH-1M, a rat IgM antibody that recognizes the CD52 antigen. CD52 is abundantly expressed on all human lymphocytes and is an exceptionally good target for cell lysis by antibody with human complement; this provided a simple method for purging the donor T cells. Prior studies demonstrated the efficacy of T-cell depletion and consequent reduction in GVHD. However the benefit was

offset by an increased risk of graft rejection by residual host T cells,11,12 and some patients suffered an increased risk of leukemia relapse due to the loss of graft-versus-leukemia effects contributed by donor lymphocytes.13,17 Animal models18,19 and clinical experience20 showed that graft rejection might be overcome by increasing the immunosuppression of the recipient before transplantation. One way of delivering this, without adding to the toxicity of the conditioning regimen, is to use MoAbs to deplete residual host T cells.21 A rat IgG2b CD52 antibody, CAMPATH-1G, effectively depletes human lymphocytes in vivo.22 Like CAMPATH-1M, it can activate human complement, although this is not sufficient for systemic T-cell depletion. Rat IgG2b also binds human Fc receptors and engages cellular killing mechanisms.23

A combined strategy using CAMPATH-1M to T-cell-deplete donor bone marrow and intravenous CAMPATH-1G to ablate residual host immunity has been used in more than 600 transplants worldwide, primarily in transplants from unrelated donors.11,24,25 We report here results of 70 HLA-identical sibling transplants for acute myelogenous leukemia (AML). We compare the results here to a historical first group receiving CAMPATH-1M-treated marrow but no intravenous CAMPATH-1G and second to a matched group of concurrently treated patients reported to the International Bone Marrow Transplant Registry (IBMTR) who received unmanipulated transplants and posttransplant cyclosporin plus methotrexate for GVHD prophylaxis.

MATERIALS AND METHODS

MoAbs. CAMPATH-1G26 was prepared from the culture supernatant of hybrid myeloma cell culture in a hollow-fiber fermentor (Alice, Minneapolis, MN). It was purified by affinity chromatography on protein A sepharose, followed by ion exchange chromatography on S-Sepharose, and formulated in phosphate-buffered saline. CAMPATH-1M27 was prepared from hybrid myeloma cells using three methods: (1) acute fluid fractionated with ammonium sulphate, (2) hollow-fiber culture supernatant fractionated with ammonium sulphate, and (3) culture supernatant from stimulated ferments purified by affinity chromatography on protein A sepharose (this was performed by Wellcome Biotech [Beckenham, UK], who provided some of the antibody for this study). Batches prepared by each method were tested in a variety of analytical systems. All had comparable potency for complement-mediated cell lysis and insignificant effect on colony-forming cells.22,29 Process (1) was used for the historic controls, process (2) was used for the study patients at London and Riyadh, and process (3) was used for the study patients at Ulm.

In vitro T-cell depletion of bone marrow. A similar depletion procedure was used for all transplants, as described previously.11,12 Donor bone marrow was harvested in the usual way and processed using a cell separator to prepare a cell concentrate in balanced salt solution (containing Ca21) that was free from plasma and depleted of red blood cells and granulocytes. The volume of the mononuclear cell suspension was adjusted so that the cell density did not exceed 5 × 106/ml, and CAMPATH-1M was added to give a final concentration of 0.1 mg/ml. The mixture was incubated for 10 to 20 minutes at room temperature, and then donor serum was added to a final concentration of 25% (vol/vol). It was then incubated for a further 20 to 45 minutes at 37°C. The treated bone marrow was washed once before infusion. Experiments just shown that differences in antibody batch or incubation timing did not materially affect the efficacy of T-cell depletion (G.H., unpublished work). The fraction of residual T cells was measured using standard methods, according to the practice in each center, either by F-rosettes or by fluorescence-activated cell sorting (FACS) analysis using appropriate T-cell-specific mouse MoAbs. (All of the study patients were assessed by FACS analysis using CD3 antibodies to enumerate T-cells.)

In vivo administration of CAMPATH-1G. Patients were treated with 20 mg/kg of CAMPATH-1G over a period of 5 days at the beginning of the pretransplant conditioning therapy. Each dose was diluted in 250 ml of normal saline and infused intravenously over 3 hours. To minimize the expected systemic first dose reaction, most patients received medication before the first antibody infusion, either 0.5 to 1 g prednisolone (Ulm) or 100 mg hydrocortisone plus 50 mg diphenhydramine (Royal Free, Riyadh), followed by 3× 1 g as needed daily.

Patients: Study group. Three transplant centers participated in the study: Ulm University Hospital (Ulm, Germany), Royal Free Hospital (London, UK), and King Faisal Hospital (Riyadh, Saudi Arabia). The original plan was to include all patients over 13 years with acute leukemia in first remission transplanted from HLA-matched siblings with the intent of comparing results in acute lymphoblastic leukemia (ALL) and AML. Because very few patients with ALL were recruited, this analysis focuses on patients with AML. (Inclusion of the ALL patients would not significantly affect the results.) The conditioning regimen was determined according to the standard protocol of each center. All included cyclophosphamide plus total body irradiation (TBI), which was administered as a single dose in 23% patients (at the Royal Free) and multiple fractions in the others (at Ulm and Riyadh). Additional chemotherapy (busulphan) was administered in 6% of patients (Royal Free only). None of the patients received any additional lymphoid irradiation and none received posttransplant immunosuppression. There was no selection of patients according to cytogenetic risk group and data on risk groups were not reported systematically. Each center recruited consecutive patients provided that they gave informed consent. The numbers of patients and conditioning regimens at each center are shown in Table 1.

Patients: Historic CAMPATH-1M controls. A database is maintained by Gh of all transplants using CAMPATH-I antibodies. It contains information on the patient and donor characteristics and transplant outcomes. It is in a condition of antibody supply that are regularly reported to the CAMPATH users database. Controls were selected using the following criteria: (1) patients more than 13 years of age, (2) transplants for AML in first remission, (3) HLA-identical sibling donors, (4) conditioning regimens based on cyclophosphamide and TBI, (5) no lymphoid irradiation, (6) no intravenous CAMPATH-1G or other antibody, (7) T-cell depletion with CAMPATH-1M, and (8) no posttransplant immunosuppression. Fifty patients meeting these criteria were identified; 26 were transplanted at the same three centers as the 70 study patients.

Patients: IBMTR controls. A second control group of patients receiving non-T-cell-depleted transplants between 1984 and 1995 was selected from the IBMTR database using the same criteria described above, except that patients from the three study centers were excluded and GVHD prophylaxis was with combined CyA and MTX.28 IBMTR is a voluntary study group of over 390 transplant centers worldwide that contribute detailed data to a Statistical Center at the Medical College of Wisconsin. Participants are required to report all consecutive transplants.

plants. The IBMTR database includes 40% to 45% of allogeneic transplant recipients since 1970. Computerized error checks, physician review of submitted data, and on-site audits of participating centers ensure data quality. Selection of the control group proceeded as follows: patients with AMI, transplanted in CR1 from 1964 through 1995 (inclusive), N = 2,940; exclude the three study centers, N = 2,759; select patients transplanted from HLA-identical siblings, N = 2,429; select cyclophosphamide + TBI with no ATG for conditioning, N = 1,307; select MTX plus CyA for GVHD prophylaxis, N = 512; and select patients more than 13 years of age at transplant, N = 459.

These 459 cases were reported to the IBMTR by 93 transplant centers.

Statistical analysis. Characteristics of the treatment groups were compared using the \( \chi^2 \) test for categorical variables and the Wilcoxon two-sample test for continuous variables. Comparing outcomes between the treatment groups required adjustment for the differences in baseline characteristics and prior therapy. First, associations between outcomes and potential prognostic variables were evaluated in each group separately using Cox proportional hazards regression with a forward stepwise approach.21 The outcomes considered were rate of engraftment (days to reach 0.3 \( \times 10^9 \) neutrophils/L), graft failure, transplant-related mortality (TRM; defined as death in continuous complete remission), relapse, survival, and leukemia-free survival. Variables considered were age at transplant, recipient gender, donor gender, and year of transplant. Variables significantly associated with the outcome in any treatment group were included as covariates in subsequent comparisons. Possible interactions between significant covariates and the type of treatment were tested. The proportionality assumption of the Cox model was tested by adding a time-dependent covariate for each covariate.22 The proportionality assumption did not hold for treatment effects on survival, indicating that the relationship between treatment and survival outcomes differed over time. To determine regions of the treatment period where the relative risk of mortality between different treatments was a constant, a series of Cox models with different cut-off time points for time-dependent treatment effects were fitted.23 The final model chosen was the one giving the largest partial likelihood. In this model, treatment was considered as a time-dependent covariate with different coefficients from 0 to 6 and greater than 6 months since transplantation. The adjusted relative risks (95% confidence intervals and \( P \) values) of the study group versus historic group and study group versus MTX/CyA group were calculated for each outcome. Where appropriate, confidence intervals were calculated based on a log transformation.

RESULTS

T-cell depletion in vivo by CAMPATH-1H. Several methodologies were used in the years to estimate the fraction of residual T-cells in treated marrow (Table 2). The measured fraction of residual T-cells in the study group (median, 0.4%) was lower than in the historic control group (median, 1.0%; \( P = .024 \)), but the result must be treated with caution owing to the potential variability in the measurement of small numbers of cells. The total number of mononuclear cells infused varied significantly between each of the three study centers and between the study group (median, 1.0 \( \times 10^9 \) /kg) and the historic control group (median, 2.15 \( \times 10^9 \) /kg; \( P < .001 \)). Consequently, the calculated numbers of T-cells infused differed significantly between the study group (median, 0.2 \( \times 10^9 \) /kg) and the historic group (median, 1.7 \( \times 10^9 \) /kg; \( P < .001 \)).

Lymphocyte depletion in vivo by CAMPATH-1G. CAMPATH-1G treatment was started before other components of the conditioning regimen, so that antibody effects could be determined. All patients had rapid and profound depletion of blood lymphocytes. The number of clonable T-cells that could be recovered from recipient blood samples obtained 1 to 2 days after the CAMPATH-1G infusions was reduced by 2.5 to 3 logs compared with pretreatment samples.23 In one study with CAMPATH-1G or CAMPATH-1H, there was generally a first-dose effect of fever, often with rigors and nausea, which is related to a release of cytokines.24,25 In two patients the reaction was severe, and it was decided to discontinue CAMPATH-1G. (These patients are still included in the analysis.) All other patients had diminished reactions to the second and subsequent doses.

Effect of year of transplant. To determine whether patients transplanted before 1990 could be included in comparative analyses, we examined the IBMTR dataset for differences between patients transplanted in 1984 through 1989 compared with 1990 through 1995. There were no statistically significant differences in the actuarial risks of transplant-related mortality (26% vs 23% at 4 years), relapse (26% vs 33% at 5 years), survival (57% vs 58% at 5 years), or leukemia-free survival (54% vs 49% at 5 years). Therefore, all data from 1984 through 1995 were pooled for subsequent analyses.

Comparison of prognostic features of the study and control groups. Characteristics of the study and control groups are shown in Table 3. The most significant difference was in age. The median age of the study group (36 years) was significantly higher than the historic control group (30 years; \( P = .003 \)) or the CyA/MTX group (31 years; \( P = .03 \)). There was also a difference in the gender of patients between the study group (57% male) and the historic control (58% male; \( P = .04 \)), but not the CyA/MTX group (50% male). The potentially confounding effect of patient age on the outcome has been adjusted in a multivariate model (see below).

Comparison of outcome for study and control groups. Univariate analyses of outcome are shown in Table 4. Engraftment was significantly slower in both CAMPATH groups compared with the CyA/MTX group (Fig 1). Even disregarding patients who did not engraft at all, there was a delay of 1 day in

Cell numbers are reported as medians, with the ranges in parentheses. There was a statistically significant difference between each study center in the total numbers of mononuclear cells (\( P < .001 \)), but there was no significant difference in the percentage of residual T-cells or the total numbers of T-cells infused. However, there was a significant difference between the study group and the historic control group with regard to each of these parameters (\( P = .024 \) for percentage of T cells and \( P < .001 \) for total T cells).

the median time to reach 0.5 × 10⁹ neutrophils/L for the historic CAMPATH group and 5 days for the study group. There was a significant variation in time to engraftment among the three study centers. The median time to reach 0.5 × 10⁹ neutrophils/L at UAB was 23 days, whereas at the Royal Free and Riyadh, the median was 30 days (P = .001). Platelet engraftment was not reported in this study.

The study group had a significantly lower risk of rejection than the historic group (65% vs 51%; P = .0003) but a higher risk than the CyA/MTX group (26%, P = .03; Fig 2). The incidence of both acute and chronic GVHD was significantly lower in the study group compared with either of the two control groups. Only 3 of the 70 study patients developed grade 2 acute GVHD and 2 developed mild/moderate chronic GVHD; there were no more severe cases.

The outcome is reported, together with the 95% confidence interval. Significance (P) values in this table (except for GVHD) were calculated from a univariate log-rank test (ie, they do not take into account any potential covariates).
group (1%). It was not possible to determine the cause of graft failure in every case, but it is likely that most, if not all, were due to immunological rejection. Therefore, both early and late graft failure were analyzed together. Patients were treated by reinfusion of stored autologous marrow (5 historic control and 1 study) or by a second transplant of un fractionated allogeneic marrow from the original donor (6 historic control and 3 study). In 11 cases, these rescue procedures resulted in successful engraftment, but many of the patients suffered further complications and eventually 12 of 15 patients died in the historic group (9 from graft failure) and 4 of 4 patients died in the study group (all from relapse).

Multivariate analysis. The results were further analyzed using the Cox proportional regression model to test for interactions with prognostic factors that might have affected the results of univariate analyses (Table 5). Variables used in building the model were age, year of transplant, patient gender, donor gender, and treatment group. Outcomes were rate of engraftment, graft failure, transplant-related mortality, relapse, survival, and leukemia-free survival. There was a significant association between age and transplant-related mortality. The relative risk of transplant-related mortality for patients more than 30 years of age was 1.53 times that for patients under 30 years (95% confidence interval, 1.08 to 2.15; \( P = .02 \)). However, the relationship between patient groups and outcome was similar for young and old patients. In the final model, allowing for the effect of age, there was less than half the risk of transplant-related mortality in the study group compared with the CyA/MTX control (relative risk, 0.45; \( P = .02 \)). Tests for proportionality indicated that the effect of the study treatment on survival differed at different times after the transplant. In the first 6 months after the transplant, survival of patients in the study group was significantly higher than the control group; among patients surviving 6 months, subsequent survival was similar in the study group versus the two control groups. It is not surprising that no significant difference in long-term survival could be shown, because the size of the study did not give it sufficient power to demonstrate even a 10% difference.

Causes of death. The underlying causes of death in each patient group are reported in Table 6. Because of the small numbers in the study and historic control group and the difficulties inherent in assigning a single cause of death to some patients, we did not attempt formal statistical analysis. The most frequent cause of death in the study group was relapse (15 patients), followed by infection (7 patients). There were 3

DISCUSSION

Since the early clinical trials of T-cell depletion, it was realized that graft rejection by residual host T cells was a major problem that negated much of the clinical benefit of avoiding GVHD. Graft rejection could be reduced, but not eliminated, by giving extra whole body γ-irradiation or by administering posttransplant cyclosporine. Animal experiments showed that anti-T-cell MoAbs could be used to escalate the immunosuppression without toxicity, and this prompted the collaborative CAMPATH users group to begin a number of pilot studies using CAMPATH-1G to deplete residual host T cells. These studies gave encouraging results, but it was possible that other improvements in transplant protocols over time might have influenced the outcome. Therefore, we performed the present comparison with a large contemporaneous control group of patients selected from the IBMTT database. A second problem associated with T-cell depletion is the loss of beneficial graft-versus-leukemia effects. This is well documented for patients with chronic myeloid leukemia (CML), but it is not clear whether there is a significant effect in patients with acute leukemia. In this analysis, we evaluated relapse in patients transplanted for AML in first complete remission.

This study convincingly demonstrates the effectiveness of the combined CD52 antibodies in dramatically reducing the risk of acute and chronic GVHD, without posttransplant immunosuppression. There were no cases of severe acute or chronic GVHD in the study group. Similar results have been reported when the same antibody protocol was used in other transplant indications. The addition of CAMPATH-1G in vivo posttransplant resulted in lower GVHD rates than those seen in the historic controls, which might be due to additional depletion of donor T cells in vivo by residual CAMPATH-1G at the time of transplant. The measured extent of T-cell depletion by CAMPATH-1G was greater for the study patients than the historic controls, but the significance of this is hard to assess due to the technical difficulties in accurate measurement of small numbers of T cells and the fact that actual depletion is likely to have been greater than measured, because residual T cells would be coated with CAMPATH-1G antibody and lysed when they encounter fresh complement after infusing of the bone marrow.

Importantly, the study group also had a significantly lower risk of graft failure than the historic control (6% at 12 months). This is still higher than in the non-T-cell-depleted group (2%), but acceptable, given the much lower risk of GVHD. Possibly graft failure would be reduced still further if larger numbers of stem cells were infused, as is now possible using peripheral blood harvests. Despite the improvement in overall engraftment, the speed of engraftment, as measured by the time to reach 0.5 × 10^10 neutrophils/L, was significantly slower in the study group compared with either control group (after excluding graft failure). The most likely explanation for this delay is the comparatively small number of mononuclear cells infused in the study group, especially because the greatest delay was observed at the two centers where the smaller numbers of cells were infused (Table 2). Experimental models have shown that speed of engraftment is related to total stem cell dose, and this has been confirmed in a recent multivariate analysis of the whole CAMPATH users database (G.H. and S.P. Cobbold).
unpublished work). Rapid engraftment has been reported with CAMPATH-1–treated stem cells from peripheral blood. The relative risk of transplant-related mortality was significantly lower in the study group compared with the CyA/MTX group (15% vs 26%). This is most likely due to reducing the incidence and severity of GVHD, although we cannot rule out a benefit due to the avoidance of toxicity of the immunosuppressive drugs themselves or consequent infection risks. One of the most important parameters in the long-term follow-up was the risk of relapse, because it has been shown that T-cell depletion increases relapse risk substantially for CML, and it is suggested that there could be a modest increase in risk for acute leukemias. In contrast, we found no significant difference between the study group (30% risk of relapse at 5 years) and the CyA/MTX group (29%), supporting the concept that the impact of T-cell–mediated graft-versus-leukemia reactions is minimal in patients transplanted for acute leukemia in first remission. Overall survival was significantly better in the study group compared with the CyA/MTX group up to 6 months; subsequent survival and leukemia-free survival were slightly, but not significantly better.

Prospective randomized studies are often thought to be the gold standard in evaluating new treatments, but their application in transplantation is hindered by the relative infrequency of the diseases treated and the fact that only a minority of patients have suitable donors. This makes accrual of sufficient patients difficult, if not impossible. We were primarily interested in measuring differences in the risk of graft failure, where the expected results were in the range of 2% to 15%. Hundreds of patients would be required to give an adequate power. Fortunately, a better alternative is available. Large clinical databases, such as the one maintained by the IBMTR, contain data on a large proportion of transplant recipients worldwide with details of prognostic and treatment factors that allow application of sophisticated statistical techniques to adjust for differences between groups and exploit the power of large numbers. In the current study, we identified 459 suitable controls receiving the most common approach to GVHD prophylaxis against which the combined antibody strategy could be compared. Unlike many prospective randomized trials, in which significant differences are sometimes attributed to unusually poor performance of the control group, we can be sure that our CyA/MTX control group is truly representative. The accuracy of the control data are confirmed by published results from the European Transplant Registry on an overlapping set of patients, where the outcomes are superimposable. However, it might be argued that the three study centers shared some favorable factor in common other than the treatment protocol. In fact, the three centers were more remarkable for their diversity in approaches to transplantation. Furthermore, this idea is negated by the published comparison from one center (Ulm) of study patients compared with their own CyA/MTX control group. The results are very similar to those presented here, except for the smaller numbers of control patients. The limitations of our analysis should be recognized, particularly the difficulty of allowing for possible differences in relapse risk according to AML subtype, prior therapy, and conditioning regimen, but we can be confident that the control group is representative of contemporary clinical practice.

Immunoreconstitution was not specifically studied here, but results for marrow transplants depleted with CAMPATH-1M have been reported previously. All of these reports agree that lymphocyte recovery, particularly of CD4+ cells, is slow compared with T-replete transplants. There does not appear to be a substantial long-term mortality as a result of opportunistic infections, but this requires continued surveillance. Some groups report an early increase in the frequency of cytomegalovirus (CMV) reactivation, although this did not necessarily lead to severe clinical disease. The cellular distribution of the CD52 antigen may be fortuitous in this regard. NK cells are relatively spared by CAMPATH-1, and it has been suggested that they may play a role in control of CMV disease and have an antileukemia effect. However, B cells are efficiently depleted. Elsewhere, we have reported that T-cell depletion with CAMPATH-1 antibodies does not give rise to an excess of B-cell lymphoproliferative disorder, in contrast to current methods of T-cell depletion. We believe this is because depletion of donor B cells removes both a potential reservoir of virus and its major target.

In this trial, CAMPATH-1G was used as a form of monoclonal antilymphocyte globulin to achieve the additional depletion of recipient lymphocytes required to permit engraftment of T-cell–depleted bone marrow. The positive outcome is in accord with animal experiments, confirming that graft failure was caused by lymphocyte-mediated rejection. The logical development is to use the IgG antibody CAMPATH-1G (or its humanized equivalent CAMPATH-1H) for depletion of both donor and recipient T cells, and current trials are aimed at developing the simplest and most effective way to administer it—either in vivo before and after the transplant or as a single dose, mixed and infused with the donor bone marrow. This study confirms that T-cell depletion is the best way to prevent GVHD. Our approach largely avoids graft rejection and does not result in an increased risk of relapse, at least in AML patients. The disease-free survival achieved is at least as good as with conventional regimens, but with the following important advantages: (1) posttransplant immunosuppression is no longer needed and (2) almost complete elimination of acute and chronic GVHD should translate into a substantially better quality of life for the survivors.

ACKNOWLEDGMENT

The authors are indebted to many colleagues who played an important part in the production of antibodies, care of patients, data collection, and analysis, including Jenny Phillips and the staff of the Therapeutic Antibody Centre (Cambridge, UK), Marcus Wieseth, Bernd Herzenstein, Renate Arnold (Ulm, Germany), Mike Hancock, Ian MacDonald, Grzyna Galazwicz, Chris Collins (Royal Free, London, UK), Hugh Culkin, Andrew Paddison, Peter Ernst, and Kirill Shafik (Royal, Saudi Arabia) as well as the following transplant teams throughout the world who contributed to the registry data: Australia: Royal Prince Alfred Hospital, Camperdown; Alfred Hospital, Prahran; Westmead Hospital, Westmead; Austria: Univ. REFERENCES

MASA — actions louder than words

The SAMJ has frequently been the recipient of correspondence and telephone calls from irate members wanting to know what the Association is doing about a variety of issues that are of fundamental concern to the profession — concerns that have often generated vigorous correspondence in our 'Letters' section. The SAMJ has therefore deemed it appropriate to look into the position of the Association in respect of these issues, and to provide its readers with up-to-date information on them.

One such concern has centred around the absence of an appeals procedure against SAMDC disciplinary committee hearings. The MASA has pursued this matter with the SAMDC over the years, and was recently able finally to reach agreement with the Council on the need for the right of appeal to the Supreme Court on the substance (rather than just the procedure) of the hearing and the verdict. This agreement, which represents a major breakthrough for the profession, must now be taken further through the channels necessary to convert it into legislation.

Secondly, the MASA has successfully negotiated an above average increase in the rates of RAMS Scale of Benefits for 1994, and has further won the retention of direct payment of medical aid claims to the doctor, all of which represent the benefits of the recently established formal negotiation agreement between the MASA and RAMS. RAMS has further agreed to grant an additional rate increase in about 6 months, provided that the doctors achieve savings for the societies through the containment of prescription and hospitalisation costs. Although it bears repeating that the doctor is not the sole or even the main cause of the high cost of medical care, there is no doubt that both these areas present good opportunities for cost-containment without threatening the quality of care offered to the patient, and the offer of incentives by RAMS represents a sensible way of addressing the escalation of health care costs in South Africa.

Thirdly, the government has come up with additional funds earmarked for certain 'disadvantaged' categories in the public service. The MASA has lobbied strenuously for a sizeable portion of those funds to be allocated to the hard-pressed doctors in state employment, for it is well recognised that state-employed doctors have consistently got the short end of the stick over the years when it came to remuneration, something to which the Association has always been sensitive. The MASA's hand was strengthened recently when it was recognised as the negotiating agent for the medical profession with the State and, in respect of the additional funds already mentioned, the negotiating team is confident that a portion of these funds will go towards addressing certain structural inequities of the past.

Fourthly, significant progress has been made with regard to the vexed question of pharmacists being allowed to diagnose and treat medical conditions. Following intensive legal research, legal consultation and political lobbying, the MASA obtained the agreement of the Parliamentary Committee on Health that the proposed amendments to the Pharmacy Act which would have extended the authority of the pharmacists to practise medicine would have been legally intolerable and morally unjustifiable. The MASA has argued inter alia that any amendments authorising pharmacists to diagnose and treat disease without SAMDC training and registration would be ultra vires, and would any related regulations by the Medicines Control Council. The Association is sufficiently confident of its position in this regard to be ready to take the matter to the Supreme Court, if the need should arise.

Finally, the MASA is marching in step with the sociopolitical transformation that is unfolding in our country. It has forewarned political affiliation, and has positioned itself as a national professional organisation dedicated to serving the medical fraternity and the entire community. It was in recognition of this ongoing transformation that the MASA was recently invited to join the Confederation of African Medical Associations and Societies (CAMAS), an organisation originally formed as a protest against apartheid and the MASA. The Association views its newly found relationship with CAMAS as an opportunity for future co-operation with other African countries in such areas as medical research, collection and dissemination of information, and the promotion of appropriate health care through our respective governments.

MARILEEN VAN WYK

The South African Bone Marrow Donor Registry

Allogeneic bone marrow transplantation is the preferred form of therapy for patients with aplastic anaemia or severe immunodeficiency disease and is increasingly being used in leukaemia, the lymphomas and myeloma. In these and other malignancies, escalation of chemotherapy to supralethal levels can be achieved with relative safety by means of autologous procedures, preferably in conjunction with recombiant human growth factors. However, currently available conditioning regimens are not universally effective in the eradication of minimal residual leukaemia, so that interest centres on the generation of graft-versus-leukaemia (GVL), an immunologically mediated phenomenon associated with allografting. Unfortunately, this effect is associated only with the more severe instances of graft-versus-host disease (GVHD), resulting in unacceptable rates of morbidity and mortality.

The barrier to allogeneic transplantation lies in a series of cell surface glycoproteins, collectively referred to as the major histocompatibility antigens. In humans, these are designated the human leucocyte antigen (HLA) system, which is encoded by a number of genes located on the short arm of chromosome 6 and comprises two major groups. The first, designated class I, HLA-A, B and C loci, is extremely polymorphic. In 1991, there were 22, 50 and 11 alleles reported respectively, whereas are identified by standard serological methods. The second, or class II antigens, are less variable, with 18, 9 and 6 alleles described for the DR, DQ and DP loci; many of these can only be detected by DNA typing. Gene amplification by means of the polynucleotide chain reaction (PCR) and subsequent charac-
editorial of the alleles by hybridisation with complementary DNA sequences or probes, are the preferred methods, because serological techniques are not reliable in an estimated 25% of cases.8,9

In general, the results of transplantation are better with fully histocompatible donors and recipients, although in the case of solid organs some discrepancy can be tolerated and graft failure reduced by a variety of immunosuppressive drugs. In contrast, bone marrow transplantation is critically dependent on HLA identity, because even single amino acid differences between antigens are associated with rejection or the development of GVHD. One way to overcome these complications is by autografting. Alternatively, an HLA-identical sibling is used as the donor. The clustering of loci in the system on the chromosome generally results in their inheritance as a complete HLA-haplotype.

At present, 60 - 70% of patients needing a transplant have a suitable sibling, but DNA-typing has made it possible to identify unrelated HLA-identical individuals who can serve as bone marrow donors.10,11 In these situations, the incidence of graft failure as well as both acute and chronic GVHD are increased. Protracted and intense immunosuppression,12 including the removal of cytotoxic T-cells from the bone marrow,13 reduces the incidence and severity of the latter complications. Nevertheless, this new therapeutic option is gathering impetus and, over the last 5 years in Europe and North America, has led to the establishment of registries for this purpose. Initially, volunteers were recruited from apheresis programmes because they had already been tissue-typed, but increasing attention is being directed toward blood donors and the general public.14 Interested individuals sign a statement of intent to donate bone marrow and a blood sample is collected for typing of the HLA-A, B, C and DR alleles by serological methods. The results are entered into a computer database. When needed, a search is undertaken to identify potential HLA-identical individuals, after which DNA-typing of the DR, DQ and DP loci as well as mixed lymphocyte culture testing are used to confirm histocompatibility. A pool of between 100 and 10 000 donors of the same race as the recipient is needed in order for there to be a realistic chance of finding a matched donor. In any search, the likelihood varies, depending on whether the HLA-haplotype of the patient is common or rare.15

To increase the number of potential donors, national registries co-operate through the World Marrow Donor Association, thereby providing access to some 800 000 potential donors.

Should there be more than one registry in a country, co-ordination is ensured by the hub centre. A prerequisite for such a designation is an intimate association with an internationally accredited transplantation group on the one hand and the availability of the latest tissue typing technology on the other. In South Africa, these criteria are met by the Provincial Laboratory for Tissue Immunology, which has a bone marrow donor registry, together with the University of Cape Town Leukaemia Centre and the Department of Haematology at Groote Schuur Hospital. The justification for such an undertaking is the fact that allele and haplotype frequencies of the HLA system differ considerably between races throughout the world16 and at present most donors are white. For instance, the frequency of the most common haplotype in blacks, A30, B42, and DR3, is 7,5%; in whites the frequency of this haplotype is only 0,02%. Therefore, a particular problem exists for sub-Saharan Africa, because matched donors for non-white patients are difficult to find.

Despite the fact that there is undoubtedly an increased risk of severe acute and disfiguring chronic GVHD after unrelated matched transplants,17 some recent results obtained after T-cell depletion of bone marrow prior to transplantation have been encouraging.18 In patients with leukaemia, there is a higher risk of graft failure with well-matched unrelated donors, compared with HLA-identical siblings.19 The incidence of GVHD and long-term survival rates of the two groups were comparable. However, such figures do not reflect the poor quality of life which results from debilitating GVHD. Because the incidence and severity of this complication increase with the degree of mismatching,20 it follows that meticulous donor selection is mandatory. Alternative HLA-identical donors from within the family and the use of matched unrelated volunteers are relatively recent therapeutic approaches, and their use is tempered by an appreciation of the devastating side-effects that may occur.

Certain studies21,22 examining donor recruitment include the question of their commitment to donate bone marrow when requested and the estimated 10% annual loss of this population through relocation. In North America, specific problems have been encountered in motivating organ donation among minority groups; objections were mostly of a cultural or religious nature. Because the local registry targets non-whites, a particular effort has been made to anticipate the question of informed consent by having recruiters who are fluent in Xhosa, as well as Afrikaans and English. Comprehensive information leaflets, accompanied by a statement of intent to donate, are available. Lectures have been given to groups in the private sector, colleges and a variety of other institutions to explain the logistics of the donation itself and the risks to the donor, objectively balanced against benefits to the patient. To date, approximately 10% of those addressed have responded favourably. After the blood has been tissue typed, this information is made available to the donor on a card that also carries the address of the registry. Like most registries, the initial search will be without cost, but further investigations to confirm matching will be billed to the recipient.

More information is required to answer questions regarding the definition of an acceptable unrelated bone marrow donor, refinement of T-cell depletion programmes and post-transplant immunosuppressive regimens. Despite these reservations, preliminary results are such that the effort of establishing and maintaining a registry is entirely justifiable.12,16

ISSUES IN MEDICINE

Keeping the prescribing pharmacist at bay

The campaign to legalise the rendering of medical care by pharmacists has been thwarted by the Parliamentary Joint Committee on Health. The Pharmaceutical Society of South Africa in its submission concerning certain amendments to the Pharmacy Act, which would have created the scope for such practices, noted that the MASA presented expert legal and medical opinions in support of its arguments that the proposed amendments would have been legally intolerable and a public disservice. The basis of the MASA's strategy was to gain a lobbying voice and insist on maintaining the professional image of the medical profession by refusing to fight the matter through the media. The MASA is confident that the Medicines Control Council (MCC) will now also not introduce draft regulations to the same effect in terms of the Medicines and Related Substances Control Act. Legal counsel advises that this would be ultra vires, and that MASA should appeal to the Supreme Court if the MCC introduces the regulations.

During 1993 the pharmaceutical profession intensified its campaign for authorities to treat and diagnose medical conditions. Advertisements appeared in all possible media. The campaign became more of a reality with more and more pharmacists applying for special permits to this effect from the Department of National Health and Population Development (DNHDP). The MASA intervened immediately and the permit 'issue was partially resolved when the Director-General of the DNHDP placed a moratorium on the issuing of permits, agreeing to issue them personally and only on merit. However, in September the Pharmacy Amendment Bill was published. Only 4 days were given to interested parties to prepare comment on the Bill. After having presented verbal and written representation to the Parliamentary Joint Committee on Health on two occasions, the MASA succeeded in convincing them to withdraw certain amendments which failed to delineate the role of pharmacists.

Some of the main points of criticism of the Bill related to the fact that the legislation would have entitled pharmacists to diagnose and treat patients. Furthermore, vague and unspecified provisions were proposed to broaden the role of the pharmacist. This was totally unacceptable, as it would have created legal uncertainty and a criminal offence.

The MASA also argued that allowing pharmacists to render clinical health care would not alleviate the burden on the State and make health care more accessible — more than 80% of pharmacists are in the private sector and in 24% of the magisterial districts there is no pharmacy.

The MASA is of the opinion that the Pharmacy Amendment Bill was in fact published in an attempt to legalise' draft regulations in terms of the Medicines and Related Substances Control Act, which was published 3 months earlier. These draft regulations, which are currently before the MCC, have the implicit intention of allowing pharmacists to render clinical medical care. The MASA intends to appeal to the Supreme Court if the MCC proceeds with their implementation. It is envisaged, inter alia, that pharmacists would be allowed to diagnose and treat patients, and to prescribe medicines up to Schedule 5 — in some instances even up to Schedule 6. This is not allowed in terms of the Pharmacy Act and can therefore not be effected through administrative regulations not debated in Parliament.

The draft regulations further envisage that the SA Pharmacy Council would accredit training courses for pharmacists. This, too, is prohibited in terms of the Medical, Dental and Supplementary Health Service Professions Act, which provides that only the South African Medical and Dental Council (SAMDIC) may approve the training of persons to 'diagnose, treat or prevent any physical or mental defect'. Accreditation of these courses by the SA Pharmacy Council would therefore contravene the above Act.

Statements by spokespersons of the pharmaceutical profession that pharmacists do not need more than 1 week of training are blatantly untruthful and arrogant. The medical profession promotes continued education even after 7 - 12 years' intensive practical and academic training.

Fragmented control over pharmacists and doctors authorised through separate statutory councils to perform the same actions and carry the same responsibilities, will lead to professional inconsistencies. The South African law does not tolerate double standards. The principle of the 'reasonable man' prevails and doctors are judged against available fields of expertise. A pharmacist giving clinical medical care will be judged against the skills of a reasonable general practitioner and not those of a reasonable pharmacist. The MASA has numerous examples of misdiagnoses and maltreatment by pharmacists that caused permanent damage and in some cases were fatal.

MARJOLEEN VAN WYK
The South African Bone Marrow Registry (SABMR) and allogeneic bone marrow transplantation

Paul Ruff, Terry Schlaphoff, Ermette du Toit, Anthon Heyns, on behalf of the Board of the South African Bone Marrow Registry

In 1939 Osgood et al. reported infusing bone marrow into patients with severe aplastic anaemia without any clinical benefit. Roess and Coulter attempted to reconstitute marrow function in irradiated dogs by marrow infusions. Both failed because of insufficient irradiation to produce immunosuppression necessary for engraftment. In 1957 Donnall Thomas and co-workers showed that marrow can be collected, stored in significant quantities and safely administered. Marrow transplants remained unsuccessful, however, although patients with refractory leukaemia given sublethal irradiation recovered after marrow infusion from identical twins. Allogenic marrow transplants usually resulted in failed engraftment, or engraftment followed by lethal graft-versus-host disease (GVHD). Further discoveries were the HLA complex and transplantation antigens, and that successful allogeneic engraftment depends upon donor/recipient histocompatibility.

These studies pointed the way for human marrow grafting using HLA-matched sibling donors. Thomas et al. showed that it was possible to cure leukaemia, aplastic anaemia, thalassaemia and inherited marrow disorders using a histocompatible sibling donor. The finding that methotrexate and subsequent immunosuppressive agents such as azathioprine, cyclosporine and tacrolimus, reduced GVHD as well as graft failure, improved results of marrow transplantation.

Haematopoietic growth factors

The discovery of haematopoietic growth factors, granulocyte-colony stimulating factor (G-CSF) and granulocyte-macrophage-colony-stimulating factor (GM-CSF) in the 1980s had a major impact on marrow transplantation. CSFs stimulate haematopoietic progenitor cells, permitting rapid proliferation and repopulation of marrow by engrafted cells. Recombinant DNA technology enabled CSFs to be synthesised for clinical use.

The physiological effect of G-CSF in mobilisation of haematopoietic stem cells into peripheral blood enabled peripheral blood stem cell harvesting to replace marrow harvesting to obtain stem cells. A cell separator harvests stem cells from peripheral blood, obviating general anaesthesia to aspirate marrow. Donors are given a 5-day course of 5 - 10 μg/kg subcutaneous G-CSF before the stem cells are harvested. It takes 4 - 6 hours to obtain sufficient cells for the infusion.

Graft-versus-host disease

Although some early transplants were successful, problems occurred due to graft failure, rejection and acute GVHD. Some patients receiving marrow from siblings developed a potentially fatal syndrome of an erythematous desquamating rash, watery diarrhoea and jaundice.

The most successful transplants, with minimal rejection and GVHD, are between identical twins, i.e. syngeneic transplantation.

Immunosuppressive agents

Immunosuppression, first developed in renal transplantation, was then applied to marrow transplantation. Immunosuppressive agents included azathioprine, cyclosporine, antithymocyte globulin, antilymphocyte globulin and later tacrolimus, antiCD25 (T-cell receptor) monoclonal antibodies basiliximab and daclizumab, and mTOR (mammalian target of rapamycin) inhibitors, sirolimus and everolimus.

Murine anti-CD52 monoclonal antibody, Campath-1G, when added to the harvested stem cell bag, removes almost all lymphoid cells, limiting GVHD although increasing the risk of leukaemia relapse. Humanised anti-CD52 monoclonal antibody, alemtuzumab, used intravenously before infusing...
stem cells, reduces murine protein anaphylactic reactions and the development of human anti-mouse antibodies (HAMA).^4

**Graft-versus-leukaemia effect**

A major reason for success of allogeneic transplantation in myeloid and possible lymphoid malignancies was the suppressive effect of donor T lymphocytes and NK cells on the underlying malignancy. This graft-versus-leukaemia (GVL) effect has to be balanced against the risk of GVHD. Mild GVHD with GVIL is ideal whereas severe GVHD is undesirable. Patients receiving T-cell-depleted stem cells or syngeneic transplantation have a higher risk of relapse of their underlying disease.^

**Lack of sibling donors**

As donors for an allogeneic stem cell transplant require an exact HLA Class I (A, B, C) and Class II (DR, DQ) match with the recipient, most patients requiring transplantation do not have a readily available donor. Siblings are the usual source of donors, being the only available matched family members. Today, with smaller families, only about 10% of patients have an HLA-matched donor. There is a 3% chance of finding a suitable donor in the extended family, e.g. cousins. Transplantation with 1-locus or even 2-loci mismatches from a family donor can be performed, but the risks of graft failure and GVHD increase. Haplo-identical transplants from parents to children play a role when no donor is available but are risky.

Owing to this lack of donors, and the expansion of allogeneic stem cell transplantation in malignant and non-malignant diseases, an alternative source of donors had to be found.

**Matched-unrelated-donor stem cell donors**

Two alternative non-family sources of stem cells are now used, namely matched unrelated donor (MUD) transplants and umbilical cord blood transplants.^

MUD registries have grown in most developed countries. Racially homogeneous societies such as Scandinavia lend themselves best to such registries, as HLA genes are largely ethnically based. Most European registries have donors of Caucasian origin, making access to donors of Asian and African origin difficult to obtain. The ethnically diverse population of the USA is the best source of donors throughout the world, but high costs and strict National Marrow Donor Program (NMDP) regulations limit international access to US donors. In August 2006 South Africa signed a co-operative agreement between the NMDP and the South African Bone Marrow Registry (SABMR).

Donor registries co-operate and their linked databases enable patients to have access to donors worldwide. At the time of writing in December 2007 there were 59 stem cell registries and 40 cord blood registries worldwide with access to 12,02 million registered donors.

**Umbilical cord blood transplantation**

Umbilical cord blood, the other alternative source of stem cells, is useful for children and for small adults (under 50 kg) and furthermore requires a less stringent HLA match. Stored umbilical cord blood does not rely on donor presence and current good health. Once cord blood has been shown to be HIV, hepatitis B and C virus-free, the donor is guaranteed. Living MUDs may change their minds, move towns, die or seroconvert. The HIV epidemic, limited resources and lack of government support have resulted in few moves to develop umbilical cord banking in South Afrika.

**Bone marrow transplantation in South Africa**

Bone marrow transplantation in South Africa was developed at the University of Cape Town from the mid-1970s, and the University of the Witwatersrand in the 1980s.

**South African Bone Marrow Registry (SABMR)**

The SABMR was started at University of Cape Town by Professor Ernest du Toit with help from Professor Peter Jacobs in early 1990. It is a non-profit organisation (Reg. No. 004-300 NPO) that co-ordinates the provision of matched unrelated stem cell donors for South Africa, and is the contact for countries seeking unrelated donors in South Africa.

The SABMR was established in the Laboratory for Tissue Immunology (LTI) in Cape Town. This was an extension of the LTI functions, which was initially HLA typing for organ transplantation since Chris Barnard’s first heart transplant in 1960s. The European Federation for Immunogenetics accredited the LTI as an HLA-typing centre for unrelated marrow transplantation in 1999.

The first donors were recruited in 1991. By May 1992 there were 210 donors on the registry, and by 1993 there were 554, of which 482 were HLA-ABDR typed. Owing to lack of funding and donor awareness, the SABMR grew more slowly for the next 7 years. Donor awareness was increased with the help of the National Blood Transfusion Service (NBTS) and two donor funding organisations, the Darren Serebro Foundation in Gauteng and the Sunflower Fund in Western Cape. The Darren Serebro Foundation, which started in August 1996, recruited over 20,000 donors, mainly in Gauteng. The Sunflower Fund formed in 1999 was inspired by the struggles of Chris Corlett and Darren Serebro against leukaemia. The aim of the two organisations is to raise financial support to increase the number of stem cell donors in South Africa. The Sunflower Fund now has the national responsibility for raising funds for tissue typing of unrelated donors, which had resulted in an increase in the SABMR donor database size to 63,123 by December 2007 (Fig. 1).

July 2008, Vol. 98, No. 7 SAMJ
In the worldwide database of over 12 million, 70% are HLA-ABMR typed. Unfortunately only 6% of the potential SABMR donors have been HLA-DR typed (Fig. 1). This deficiency is now being addressed by the SABMR.

Lack of black donors makes MUD transplantation problematic in South Africa, with very few recipients of African origin. This problem is exacerbated by the lack of donors of African origin on European registries available to South African patients. The NMDP is a potential source of donors of African origin, although African-Americans are mainly of West African origin with different HLA typing frequencies to Southern African blacks.

Following the recruitment of the first donors, the World Marrow Donor Association (WMDA) recognised the SABMR as the HUB centre for South Africa in September 1991. The WMDA is a voluntary organisation of representatives of blood stem cell donor registries, cord blood banks, other organisations and individuals with an interest in haematopoietic stem cell transplantation. It provides a forum for discussion of issues regarding the clinical use of haematopoietic stem cells from unrelated donors across international boundaries and for formulation of guidelines on logistics, quality control, ethics, finances, information technology and registry accreditation.

Bone Marrow Donors Worldwide (BMWDW) situated in Leiden, The Netherlands, is a voluntary collaborative effort of stem cell donor registries. BMWDW collates donor information worldwide. This database contains details of over 12 million donors, including more than 63 000 from South Africa, and is available online to all participating registries. This allows all registries to search for donors when there is no local donor available.

**Matched unrelated donor transplants in South Africa**

The first MUD transplant in South Africa was performed at the new University of the Witwatersrand Donald Gordon Medical Centre in Johannesburg in June 1997. Bone marrow was harvested in Belgium and flown to Johannesburg. In 1999 the first SABMR donor provided peripheral blood stem cells to a South African patient. In 2003 the first black South African donor provided stem cells for an unrelated patient and the first unrelated cord blood transplant was performed. At the time of writing, a total of 125 patients had received first MUD transplants in Gauteng and the Western Cape (Fig. 2). Of the donors 32 were from the SABMR and 93 from international registries, mainly in Europe (of the latter 6 were cord bloods). In addition 7 SABMR donors supplied stem cells to patients in Germany, Italy, Portugal, The Netherlands, the UK and the USA.

**Conclusions**

Haploidentical bone marrow and peripheral blood stem cell transplantation has become an important treatment of haematological malignancies, first acute and chronic myeloid leukemia and myelodyplasia, lymphomas and even multiple myeloma. Its role in chronic myeloid leukemia has diminished considerably since the advent of imatinib.

It also plays an important role in non-malignant haematological diseases, first aplastic anemia and now haemoglobinopathies, thalassemias and storage diseases.

Modern tissue typing and immunosuppression, and better supportive care including newer antibiotics, antifungal and antiviral agents, have reduced mortality and morbidity.

Alternative sources of stem cells, including MUD and umbilical cord blood transplantation, have widened the availability of donors throughout the world. The growth and development of the SABMR is essential in our quest for donors, especially for patients of black African origin, and needs support from the public, donor funds, universities, private corporations and the government.

Immunohaematopoietic stem cell transplantation in South Africa

Abstract
Hippocratic teaching exalts literally centuries of ethical principles in medicine. The foremost of these being to heal and do no harm – an ideal for which all clinicians strive but advances are seldom – if ever – entirely risk free. The way in which such balance is achieved presupposes our remaining perpetual students seeking to couple current knowledge with a clear perspective of perceived benefit versus defined hazard. Wisdom to this degree is found in few individuals but, nevertheless, as an ideal, serves to define the true scientist who, tenaciously, uncompromisingly and over prolonged periods systematically completes basic research for subsequent translation into clinically relevant practice.

Nowhere are these concepts better illustrated than in the burgeoning field of stem cell biology. Media sensationalism, commercial or monetary opportunism and self-aggrandisement continue to confuse the vital task of advancing this aspect of medicine but doing so within moral and religious constraints. A further impediment to progress is failure to distinguish between embryonic and adult options. In the former the steps closely replicate physiology and the totipotentiality of the inner cell mass is the basis for the parallels in reproductive and therapeutic cloning. Intrinscic to these techniques must be definitions as to when life begins and debates to bring order to widely divergent viewpoints extend all the way to the American Congress! The possibilities are enormous but require safeguards to be generated from dispassionate debate primarily between scientists and ethicists rather than politicians. These issues are not our immediate concern.

Rather, in contrast, starting material from already formed organs has restricted capacity for differentiation and proliferation with a different challenge to resolve – can one source give rise to another function? To grasp this

nettle consider immunohaematopoiesis where comprehensive repair of the irreversible aplasia can be effected using only a minute representative inoculum from a matched donor. But can altering the microenvironment change the incoming phenotype to undergo modification needed to restore damage when transferred to a quite different tissue? This phenomenon, described as plasticity, is tantalising but not yet a clinical reality. Some of these controversies were explored at a Cape Town workshop held in November 2005 giving rise to a study group which will hopefully sustain the initiatives with appropriately regulated protocols to encourage cross-disciplinary development in South Africa.

Bone marrow is obviously the logical starting point on which to build. Here a wealth of meticulously chronicled and relevant information from a wide range of experimental animals, supplemented by clinical usage, is available. For example much is known and precisely defined in autografting, events in histo-compatible siblings and, more recently, what happens when matched unrelated volunteer donors are used. Thus a solid foundation characterises fundamental aspects of these procedures incorporating the immunogenetics necessary to continue unravelling early cellular and molecular events that occur in the recipient. Stated differently these phenomena provide the essential reference from which carefully stated questions can direct, innovatively, the activity of working parties to test what happens to the explant growing in a foreign anatomical site – the fundamental theme of this emerging field. In context it can be noted that many of the central aspects are already locally established and continue to benefit from international collaboration. The phases leading to the current status of this single centre team are summarised to illuminate how haematology can play a role in testing both principles and practical aspects of widening indications for these interventions.
Introduction

The emerging role of stem cells in biology continues to accelerate thereby focusing attention on terminology. Two broad categories of donor material exist. Their fundamental behaviour is widely divergent and continues to generate debate between scientists, philosophers, ethicists and, increasingly but a lot less helpful, politicians!

HUMAN EMBRYONIC ORIGIN is considered here only to clarify fundamental features. The defining property is a capacity to produce all the tissues that make up a complete individual where the first step is fusion of ovum and sperm to generate the zygote. During passage down the fallopian tube and early phases of implantation in the uterine wall the morula gives rise to blastocyst in which recognisable inner cell mass has pluripotentiality but lacks the capacity to form extra-embryonic structures. During gestation three germ layers form known as the ectoderm, endoderm and mesoderm and these constitute the blueprint for a complete offspring.

It follows that capacity to recapitulate physiology in vitro or in cultures is momentous. In scientific terms recovery of the blastocyst and implantation into a surrogate uterus is feasible as seen in meticulously selected cases generally at fertility clinics. A variation is reproductive cloning where, through the process of somatic cell nuclear transfer, the original or haploid nucleus from the oocyte is removed and replaced with a mature counterpart where the chromosomes originate from the patient. The therapeutic equivalent is an interesting variation where the early blastocystic stage is cultured in vitro with differentiation being driven towards multipotentiality and exemplified by muscle, neurons or blood depending on modulating influences in the medium. (Figure 1)

These somewhat different options have profound moral and religious overtones encompassing criteria for when life commences and predicated the need for inclusive and sensitive monitoring at every stage to avoid even the slightest abuse.

Indeed the recent South Korean claims highlight the sensitivity of this area. Enormous restraint, transparency and responsible reporting are mandatory for constructive and sensible regulation but this needs to be by knowledgeable peers working in the field if future benefit is not to be denied.

ADULT SELF RENEWING populations provide the counterpart and are found in all organs where they provide for natural repair as in wound healing or sustaining blood formation from the bone marrow. The latter has been studied extensively and is the basis for autologous or allogeneic immunohaematopoietic grafting. Long years of intensive study have established that numbers with repopulating potential are relatively small but, can be mobilised into the circulation for recovery: however keep in mind their protracted exposure to environmental toxins and the accumulation of genetic injury over the lifetime of the donor. Despite such drawbacks preliminary data support the possibility that they can be expanded ex vivo and, furthermore, manipulation of culture conditions subtly alter the phenotypes. If correct, the tantalising concept arises in which such multipotential progenitors actually have less circumscription that long espoused as conventional dogma but rather that anatomical boundaries can be transgressed. For example incorporation of nominally blood forming precursors into heart muscle after infarction or, cartilage, ligaments and even nerves, aiding recovery, may be possible. Whether such plasticity exists at all or, in the diametrically opposed viewpoint, is a reality proposes the existence of a living reagent with wide ranging restorative properties. Not surprisingly there is support for intensive study to meticulously separate fact from fantasy. This approach is somewhat less emotion-laden than the use of pre-implantation material but, is nevertheless, every bit as relevant and, accordingly, a foundation must be established in soundly based, rigorous tested and confirmed science. Unless restraint is exercised there is a risk of generating premature and unjustified expectations which will tarnish all efforts by reputable investigators to proceed constructively. This charge has been given national priority by convening a study group under the aegis of Stellenbosch University jointly with the South African Medical Research Council. Here one group will seek to consolidate experience that has accumulated with international collaboration over the last 35 years and continue to explore the enigmatic haemangioblast, or even earlier forms, in restorative medicine. The events leading to the current status are therefore summarised as a record as to how this point was reached.

Bone marrow transplantation as a model

EXPERIMENTAL HAEMATOLOGY, using a murine system, demonstrated reappearance of blood formation in a medullary cavity rendered aplastic by lethal irradiation and showed that this was not due to plasma factors but cell mediated.1 Elegant studies continue to define fundamental aspects of homing to special sites known as niches, where particular environmental influences dictate differentiation in what is then described as the haematopoietic inductive microenvironment.2 Localisation of precursors in relationship to marrow trabeculae is constant and dictated by a complex system of interactions controlled by stromal ligands in the form of adhesion molecules or cytokines recognising cognate receptors on primitive progenitors.3 Complimentary observations that a unique relationship exists between supporting mesenchyme and early committed lineage find support in the culture system described by Professor Michael Dexter. Particularly relevant is an in vivo splenic assay where the content of the growing colonies vary according to the particular site in this organ where they eventually develop.4 In broadest context these interactions have stimulated developments widely tested including the use of higher primates. It is not unreasonable to anticipate that adult progenitors have an intrinsic capacity to undergo phenotypic remodelling depending on how they are stimulated and, in this way, participate in repair of muscle, ligaments and perhaps even neurons.5 It might be asked, somewhat rhetorically, if quiescent populations exist in solid organs, presumably dedicated to just this task, why are extrinsic sources needed? This, and other inconsistencies, await systematic study.

CLINICAL STUDIES were pioneered by Professor E Donnall Thomas6 and generations of his research fellows drawn from every corner of the globe. Although a number of additional groups were at about the same time involved in developing these procedures it would be invidious not to recognise the contributions of Professor George Santos at Johns Hopkins, and the outstanding radiobiologists such as Dirk van Bekkum, in the Netherlands.
Development of the Cape Town programme

The seed is sown

A number of sequential steps characterised first the introduction and then the systemic consolidation of the infrastructure which preceded the first bone marrow allograft in South Africa at Groote Schuur Hospital in 1972.

1964 saw the first attempted procedure in this country. A 23 year old male medical student with severe aplasia received a somewhat arbitrary volume of anticoagulated aspirate from a brother. Engraftment did not occur and he died as a result of neutropenic septicemia. In retrospect this is not surprising since little was known about histocompatibility and even less about graft composition or immunosuppression. This event, combined with an ever-expanding literature on related topics including human leukocyte antigens system, reports of success in leukaemia and Fanconi or aplastic anaemia made an indelible impression during fellowship years spent with Professor Clement A Finch in Seattle where there was close contact with the multidisciplinary program directed by Dr Thomas.

Inbred rabbit strains were used rather than mice

On return to this country it was a considerable honour to be appointed as Foundation Professor of Haematology at the University of Cape Town. Fortuitously, just at this time, Professor Christiaan Neethling Barnard had carried out the first successful human heart transplant and ignited interest from Professor Eugene B Dowdle and Dr M C Botha in providing immunologic assays for the histocompatibility testing. Not surprisingly many were caught up in this new field and the fledgling department started funnelling all resources and energy into marrow grafting as the major direction for the future. From the first day encouragement and support was abundantly available from faculty, staff and colleagues making it possible, somewhat painstakingly at times, to create the infrastructure culminating in the first successful such procedure within two years. This was not a random event but rather the starting point of a carefully planned and projected long-term core activity.

Methodology in evolution

Laboratory processing was set up by collaboration with Professor Bruno Speck and Dr Alois Gratwohl in Basel in which, rather than using mice, inbred rabbit strains were selected to refine the details of each step. Harvesting femoral marrow, as a surgically sterile procedure under general anaesthetic, and the preparation of a monocellular suspension was perfected using a series of stainless steel screens of decreasing pore size. After radiotherapy of recipients, skillfully provided by Dr Basil Shepstone and Professor Rossall Sealy, autografting was used to compare intravenous infusion to block re-implantation but showed no difference. This required establishment of a vivarium and the considerable skills of Mr Graham Manual as a cardinal member of the team are remembered with appreciation. Graft monitoring was primitive using only mononuclear numbers and all efforts to antigenically match pairs was unsuccessful. The alternative measurement, shifted to clonogenic assays and started in the Heath-Robinson constructed carbon dioxide incubator built by Dr Joan Parker. Rapidly erythroid, granulocyte and eventually mixed colony growth was standardised as the reference point for quality control and it was possible to demonstrate a linear relationship between these measurements and engraftment. The scene was set to translate laboratory results to patients.

The clinical programme

Heart breaking frustration occurred in a number of areas during this first decade. The need to interact with more experienced colleagues in other parts of the world was impeded by working in a country blanketed by an intense academic boycott directed at the apartheid policy. Despite this a steady stream of investigators from most of the major centres found ways of visiting and, reciprocally hosted ourselves in initiating and consolidating this activity. Benefit undoubtedly accrued from the local cardiac and renal success.
Immuno-haematopoietic stem cell transplantation in South Africa

Figure 2: The cell separator
The later generation cube spectra with world authority Professor Jean Porter Hester updating methodology with SPH Lucille Wood and SPH Louise Abrahams.

Apheresis technology provided a means to discontinue the supply of blood and single unit platelets in glass bottles! Replacement of this rather quaint but obsolete service was made possible by recognising the superiority of the cell separator and the IBM 2990 was secured by donation. Over the ensuing years this methodology became standard and gradually permeated the commercial transfusion services first in the Western Cape and subsequently in other provinces. This period was stimulated by a visit from Professor Jean Porter Hester and this association continues actively today. (Figure 2) A major benefit was the ability to recover the corresponding population having engraftment potential from the peripheral blood which became the norm and further refinement is a current priority.

A further innovation was the creation of a dedicated platelet donor panel made up of doctors and staff in the department and unselfishly from volunteers throughout the Groote Schuur Hospital at every level from gardeners through janitorial staff to senior consultants. This philosophy underscored the approval of the new activity and serves as a reminder of the spirit de corps found in the corridors of the old hospital.

Unfractionated marrow was used initially requiring conventional immunosuppression with corticosteroids and methotrexate. (Figure 3) Rejection and acute as well as chronic graft-versus-host disease paralleled world experience and, while as elsewhere some success was achieved, the morbidity and the mortality of these complications exacted a heavy toll on nursing and medical staff alike. At this point the team became aware of the need to add a staff psychiatrist, a dedicated social worker and physiotherapist, all innovations remaining central to the current programme more than 30 years later.

Alternative sources include umbilical cord blood which is available primarily on a dedicated basis within families. Access to this product is further coordinated through the South African Bone Marrow Donor Registry and our membership to Eurocord. This is a valuable resource and may well be a further productive area for study in non-haematopoietic mediated tissue repair.

Whether, in the South African context, there is a place for banking remains far from reality although a local working party was established some years ago to explore this possibility: (Jacobs and Wood unpublished).

Much of the early hazard attributable to neutropenia, compounded by unavoidable immunosuppression, created substantial morbidity and mortality. Here one continues to reflect on the extraordinary degree of encouragement from the surgeons including access to their specialised beds and nursing expertise in the eleventh block. The challenge of overcoming potentially or sometimes lethal complications reinforced the need to draw on expertise scattered throughout the School. This led to creation of the multidisciplinary Haem Team which, to this day, routinely includes pulmona, cardiac, renal and infectious disease consultants in the moment-to-moment management of those complex clinical problems.

A series of rather distinct, albeit overlapping periods, can be recognised in this historical perspective:

Figure 3: The first bone marrow transplant in South Africa
The two teams simultaneously harvest from sternal and iliac crest. The donor is anaesthetised. Each syringe of heparinised marrow-rich blood is processed by a trained technologist.
Unrelated donors may be needed where siblings are not available. To overcome this obstacle we formed the South African Bone Marrow Donor Registry jointly with Dr Arthur Bird as Medical Director of the Western Province Blood Transfusion Service and Professor Ernest du Toit as Head of the Provincial Laboratory for Tissue Immunology. Scope continues to expand and, as the Hub centre there are links with the corresponding European Organisations and the American National Donor Program where the Constantia team is designated as a transplant and harvest centre. There has gradually been increasing recognition of these activities that found expression in the 6th International Donor Registry Conference from 26th May – 27th May 2006 in Cape Town.

Cyclosporin A became available as a result of cooperation studies with Professor Jean Borel in Sandor in Switzerland. Years of a fruitful collaboration explored the role of this unique immunodepressant in the postgraft period but the anticipation of complications disappearing was unfortunately short lived. Undoubtedly incidence and severity of these immunologically related phenomena decreased but they remained a major challenge to the investigator. Monoclonal antibodies became available as a result of a still-active association with Professor Herman Waldmann and Dr Geoff Hale first in Cambridge subsequently in Oxford. Here, as part of the Campath Users Group, there was an opportunity to investigate the in vivo use of these immunoglobulins for T lymphocyte depletion. A previously untested modification, namely their admixture to the harvest in-the-bag without any further manipulation, was described and subsequently, having been tested in a number of other collaborating centres, emerged as effective, thereby avoiding the need for any further immunosuppression. Interestingly this is now a standard form of management which, at least in our hands, is associated with a high remission rate at least in acute myeloid leukaemia. Acute and chronic graft-versus-host disease, in traditional sense, are no longer seen. However an interesting form of the unusual immuneologic manifestations occasionally occurs in the form of a skin rash which is regarded as a late onset of the acute variant. A further association is with cytomegaloviral seroconversion but progression to pneumonitis or other organ involvement has largely been prevented by proactive ganciclovir administration.

Audit, accreditation and current status
For an unbroken period of 30 years the same group have reported consecutive cases first to the International and then to the Autologous registries which are now combined as Center for International Blood and Marrow Transplant Research. Latterly accountability is also scrutinised for continued active participating membership of the American National Donor Program. Such peer review is regarded as mandatory to maintain standards and, following audit, accreditation has been uninterrupted for the past three decades.

Scrupulous peer review is maintained

Figure 4: Overall survival in adults
One of the more interesting aspects of this programme is the similarity in survival by Kaplan-Meier analysis between consecutive patients with bone marrow exposed to Campath 1-G in-the-bag, peripheral blood treated with the same immunoglobulin or humanised variant and autografts. This particular approach is notable for the lower level of graft-versus-host disease, high remission rates in acute myeloid leukaemia but with an increasing incidence of cytomegaloviral positivity which is the subject of ongoing investigation.

Extrapolation to restore medicine rationale

Philosophers pose questions in abstract form. Eticists and moralists refine these concepts by debate leaving scientists to provide answers through systematic study. This framework is helpful in understanding how changes in emphasis from the conventional treatments over yesteryear come to be replaced by more proactive or preventive current strategies. Thus, as an example, none would question the use of prostheses to improve the mechanical disability when limbs are lost or the increasing sophistication that makes more user friendly, the use of living tissues is, however, viewed quite differently. Here, although the distinction is somewhat artificial, future advances lie in two broad directions. Firstly there is the controversial area of embryonic tissue and its use in reproductive or therapeutic cloning. It could responsibly be argued that this field needs to advance but to do so in a properly regulated way thereby capitalising on the immense potential benefit in a wide range of congenital and acquired disorders that affect the human race.¹¹ Legitimate reservations extend to how the material is derived and there is a clear need to regulate clinical application.¹² These concerns are not central to the present debate. Secondly, contrasting and of major relevance, as the population ages with subtle changes in immunologic competence and decreasing tissue integrity there is a need for a conceptual shift to supplement physiological replacement where examples include degenerating neural tissue as in Parkinson’s and Alzheimer’s diseases, diabetes, damaged joints and cardiomyocytes.¹³ It is in this context that the immunohaematopoietic stem cell can be examined further looking at the question of plasticity and some preliminary data of its role in selected organ systems.

Plasticity

Careful scrutiny of experiments in nature, exemplified by response to injury, reveals the presence of rests or cellular collections that have the capability of expanding into mature and functional progeny. These are more abundant where turnover is rapid as in the epithelium and blood. Such a belief may be too restrictive since evidence is accumulating that differentiation may occur across lineage boundaries and this phenomenon, described as plasticity, may offer a novel therapeutic strategy to facilitate tissue regeneration.¹⁷
Interpretation of publications need to be tempered by an understanding of technical details that include selection of the study material and the distinction between fusion as opposed to transdifferentiation. Nevertheless the ability to harvest readily accessible adult stem cells may open previously inconceivable treatment options. In view of the ease with which bone marrow can be obtained and evidence of its flexibility in generating myeloid and lymphoid lineages as well as mesenchyme—the latter capable of differentiating into bone, cartilage and fat—highlight the choice of haematopoietic stem cells to examine advances in this field.

**Current or potential applications**

Understanding the way in which the latter population gives rise to blood formation interchangeably with non-haematopoietic lineages challenges the concept of the hierarchical model and has led to speculation that the facts are more compatible with the kinetic concept in which there is a continuum within this compartment. Importantly these emerging concepts sound a word of warning since neoplastic changes may occur in the course of these manipulations.

Two extensive reviews argue the evidence for the presence of organ specific stem cells and possible contributions from marrow stem cells. In reviewing data from mice coupled with limited clinical experience, and recognizing the need, as noted above, to separate fusion from transdifferentiation, a number of areas emerge for specific study and where there is already data available. Prominent among these are skeletal and cardiac muscle, liver, skin, gastrointestinal tract, lung, pancreas, kidney and of particular interest, the central nervous system.

**A concluding perspective**

Conventional bone marrow transplantation has, in the last 40 or 50 years, undergone enormous development and now continues to be translated into great saving of life. Morbidity is being reduced as support and nutritional intervention improve, infective episodes are more effectively treated and graft-versus-host disease skillfully controlled. Immuno-haematopoietic stem cells are routinely recovered from the circulation after mobilisation using apheresis techniques and there is daily wider recourse to umbilical cord blood. In parallel histocompatibility matching is more precise and the role of reduced intensity conditioning extends the age of the recipient and offers an opportunity to test potentially new immunologically mediated benefits exemplified by anti-tumour destruction through supplementary donor lymphocyte infusion. Such momentous advances provide an enormous international database from which to start moving these sophisticated procedures innovatively into the field of restorative medicine. Thus, given that most organs house small populations of stem cells with specific capacity to effect local repair, and nowhere is this better demonstrated than in blood formation, there arises the question of whether such rather narrow concepts should not be reviewed. Leaving aside the more controversial issues of reproductive and therapeutic cloning from embryos and focusing on the adult population with regenerative capacity, the answer would appear to be—yes. Evidence increasingly supports observations that this population has a property described as plasticity to explain their presence during reparative processes in a wide range of many other sites from muscle, through skin and gastrointestinal tract to the central nervous system.

Questions about the interpretation of this phenomenon abound including debates as to whether this is simply cell fusion or, in actual fact, transdifferentiation. Nevertheless it is precisely these important considerations that led to the formation of a South African Study Group that recently held an inaugural workshop to coordinate and support locally based investigators. Understandably one of the discrete working parties, and for good reason, will focus on the long experience of bone marrow transplantation in this country, aiming to develop it as a model to continue the exploration of the potentially important role of these procedures in this new field of restorative medicine.

Immunohaematopoietic Stem Cell Transplantation-Introduction and 35 Years of Development in South Africa-The Historical and Scientific Perspective

Peter Jacobs, Lucille Wood

From the University of Cape Town and the Faculty of Health Sciences, Stellenbosch University - Tygerberg Academic Hospital

Correspondence: Professor Peter Jacobs Consultant Physician and Clinical Haematologist Constantiaberg Medi-Clinic P.O. Box 294 Plumstead 7800 Cape Town, South Africa Tel: +27 21 799 2566 Fax: +27 21 761 4278 E-mail: haematol@icmca.co.za

Bone marrow was the traditional graft source when we introduced these procedures to South Africa. Technical details were established using rabbits as the experimental model with translation into a formally structured clinical programme at the Constantiaberg Medi-Clinic, based in the Groote Schuur Hospital, in 1972. Lack of any infrastructure was overcome by acquisition of the first continuous-flow cell separator in sub-Saharan to provide for granulocyte transfusions. This was shortly followed by creating a dedicated platelet donor panel and establishing a specialised laboratory for clonogenic assays, flow cytometry, programmed freezing and including cryopreservation. Development was constant and seamless but four distinct periods are recognizable. Firstly, guided and constantly encouraged by Professor E Donnall Thomas, was use of an unfractionated mononuclear population derived from multiple sternal and iliac crest aspirations where complications, as in other centres, included rejection and, particularly troublesome, acute as well as chronic graft versus host disease. The second was centred on cyclosporin-A in association with Professor Jean Borel at Sandoz in Basle leading to a decrease in the incidence and severity of the latter immunologic phenomena but not to their abrogation. Thirdly was the opportunity of working with Professor Herman Waldmann and Dr Geoff Hale first in Cambridge and latterly in Oxford on immunosuppression achieved via ex-vivo T-cell depletion within the broad ambit of the Campath users group. Here there was pioneered the alternative new approach of adding the anti-CD 52 monoclonal antibody only to the graft in what has become known as in-the-bag technique. The fourth, securely based on early laboratory and clinical experiences, was a switch to use of peripheral blood stem cells mobilised into the circulation with stimulatory peptides.

In 1995 this original transplant team relocated to a new academic centre in the private sector and has continued to actively refine the programme over the subsequent decade: the facility at Groote Schuur hospital continues independently. Early recognition that accountability for these expensive and high profile procedures was an important obligation led to consecutive transplants being reported to the International and Autologous registries and now continuing to the Centre for Bone Marrow Transplant Research concurrently with the European Bone Marrow Transplant Registry. This disciplined approach has ensured that all data undergoes constant audit and, on such a basis, underpins the unbroken accreditation extending over more than three and a half decades. With difficulties in finding sibling donors a further achievement was creation of The South African Bone Marrow Registry and now a proposal to also start a national transplant registry that will complement the survey currently being conducted, on a worldwide basis, by the European Group for Blood and Marrow Transplantation. It is concluded that a properly constituted and functioning multidisciplinary team can cost-effectively carry out immunohaematopoietic stem cell grafting even in an under-resourced country with outcome approximating that reported from recognized First World reference centres. The caveat is that, outside such comprehensive units, results may be less impressive thereby arguing for resource allocation being directed to academically-designated, rather than incentive-driven, preferred providers.

Summaries of Haematopoietic Stem Cell Transplantation Programs in Countries of Africa, Asia and the Pacific

135
Professor E. Donnall Thomas developed the concept and established the technical feasibility of bone marrow transplantation in a canine model. He and his team then courageously pioneered translation of these orderly research studies into the clinic and first proposed what have become the currently accepted indications.\textsuperscript{2} From the start of these activities in Cooperstown to the Public Health Hospital in Seattle and finally to the Fred Hutchinson Cancer Centre he has through sheer talent, inspired leadership and a unique compassion for patients and every member of his staff alike, attracted generations of Fellows who have gone on to sustain the ever clearer definition for usage and unravelling of early and now late side-effects. The hallmark of these graduates is his clear imprint of identifying a clinical problem and then, increasingly, applying cellular and molecular biologic techniques to understanding pathogenesis as a basis for refined or focused intervention. Small wonder that such achievements were recognized by award of the Nobel Prize.

It would be inappropriate to describe the historical parallels that took place in South Africa without the preceding acknowledgement or an explanation of how the programme in sub-Saharan Africa started. During the years as a haematology Fellow in Seattle with Professor Clement A Finch there was regular contact and exposure to the excitement surrounding bone marrow transplantation. While it would be both difficult - and invidious - to select from that group of dedicated investigators more than a representative mention of four that remain currently active including Dr Rainer Storb, Dr Fred Appelbaum, Dr Joachim Deeg and Dr Jean Sanders with whom, among others, we are privileged to maintain association that now extends back over more than 30 years.

One other event that cannot be overlooked was the momentous achievement of Professor Christian Neethling Barnard in carrying out the first human heart transplant in the world. It was into that receptive environment, prevailing at the University of Cape Town and Groote Schuur Hospital, that one had the great honour of being appointed as the Foundation Professor of Haematology. The inevitable question from Sir Richard Luyt and the appointments committee was what direction the new department had selected for particular focus! With no in-depth training in immunology and precious little in transplantation biology it was with tenuity that this emerging area of interest-bone marrow grafting-was chosen. And so the die was cast. The brief historical record that follows freely acknowledges unrestricted encouragement from innumerable colleagues of all persuasions, particularly during the early developmental with periods of frustration balanced by elation, and the many members of the multidisciplinary team who, collectively, made it a reality. It equally reminds us all never to lose sight of that extraordinary courage shown by patients and their families alike.

From individual centre and case studies to the meticulously orchestrated collection and analysis of data by the Centre for International Bone Marrow Transplant Research, indications in adults and children are now clearly defined (Figure 1)\textsuperscript{3} while outcome remains the subject of continuous review and updating.\textsuperscript{4} Against this background a number of relevant observations emerge that logically start with patient selection and consideration of variables including age and comorbidity. It is here that collective experience of the multidisciplinary team is crucial with best results reflecting an under-appreciated centre effect.\textsuperscript{5}

All important is the conditioning of the recipient to accept the incoming graft but, in selected instances and depending on diagnosis, may be the need for further chemotherapy directed at eradicating residual disease. Historically myeloablative preparation with high-dose chemotherapy\textsuperscript{6} or irradiation\textsuperscript{7} and more innovatively by use of radioconjugates\textsuperscript{8} continue to undergo study. An area of particular interest has been the use of anti-CD 52 monoclonal antibodies which can be given either to patient or a used ex vivo in what has become known as 'in-the-bag technique'.\textsuperscript{9} Recognizing the morbidity and mortality associated with this step has resulted in description of reduced intensity regimens that make it possible to extend the upper age limit but this may be offset by higher disease relapse rates. However reversal of the latter complication is possible in some cases by capitalising on antimicrobial effects mediated by alloreactive T-cells in the form of delayed donor lymphocyte infusion.\textsuperscript{10} At this point remains the unresolved and challenging issue of optimum post-transplant immunosuppression ranging from traditional corticosteroids with cyclosporin and methotrexate through a wide range of new and potentially more effective-possibly even safer-options.\textsuperscript{11}

This sophisticated form of treatment is arguably best carried out in a dedicated reverse isolation unit or protected environment but debate rages on precisely what defines such a physical facility or plant. Arguably, of far greater importance, is investment in a properly constituted cross-disciplinary management team with, at least in Africa, input from practitioners of alternative or complementary medicine. Also there is a need for reliable and safe supply of blood and related products, a laboratory capable and registered as competent to carry out apheresis procedures, experienced in programmed freezing and licensed for cryopreservation in terms of locally promulgated acts for dealing with human tissues.\textsuperscript{12} Donor availability, particularly with increasing use of matched unrelated volunteers and alternative sources including cord blood, are those unique considerations securing access to tissue typing with...
immunogenetics accreditation. Transplants not carried out in such an organised, audited and accredited centre, designated as competent for both harvesting and grafting, are viewed as inappropriate and to be discouraged.

Then, in the short term defined as the first hundred days, is transplant related mortality which has a number of contributors. These include adequacy of high-resolution histocompatibility matching between donor and recipient.

Secondly quality of the graft defined in a number of different ways ranging from mononuclear cells to CD 34 expressing population or repopulating potential documented in clonogenic assays as a long-term colony initiating cells. Thirdly the ever-improving supportive care extending from the isolation facility to regular participation of consultants in infectious disease, cardiology and pulmonology coupled with the all-important and dedicated nurses and other para-medical professionals.

Integral to this period, but extending throughout long-term care, is attention to quality-of-life that requires specific documentation and typically would involve psychosocial counselling, psychology and liaison psychiatry. As volume, and therefore referrals increase, emerges a new aspect in which patients increasingly accept responsibility for their care and work closely with community medical and nursing staff. The sensitivity and considerable thought, as well as an extraordinary amount of communication so vital to achieving success of this exercise, directly impacts on continued support and acceptance of the role that the transplant centre plays in an entire region. In the reverse direction is the need for an effective data-capture system vital to make possible correlation of all events with survival. Unless well orchestrated such limitations assume disproportionate magnitude in under-resourced countries and place new and particular onus on those willing to accept responsibility for carrying out these procedures in having to maintain scrupulous follow up and schedule specialised investigations at clinic visits (Figure 2).

The cardinal responsibility of transplant teams is to maintain accountability and transparency defined by regular audit on which will be based accreditation of status as transplant and harvest centres. This requires reporting of consecutive patients to international registries with matching records of activity via national surveys. And, additionally, the constant analysis and publication of results. Only in this way can there be any confidence that these hazardous and high cost procedures, increasingly being carried out in the Third World, approximate standards of care using international norms. Arguments that such criteria do not apply to developing countries, where less good outcome might be conditioned, is clearly specious, as well as inappropriate! Such an attitude should not be entertained and much less supported—particularly since there is evidence that precisely the opposite is true.

It is against these observations that first the introduction and then continuous development of immunohaematopoetic stem cell transplantation in South Africa over a 35-year period can now be detailed. There emerges the conclusion that, at the present time, they continue to provide life saving and cost-effective, as well as the resource-appropriate therapeutic options in selected.
Formal outcome analysis. Implicit in such a rather more constructive endeavour will be the need to comply with ethics and research rules including attention to issues that include donor confidentiality. This should be easy given the simple expedient of only completing already available, and circulated, relatively standardised data capture sheets.

**ESTABLISHMENT OF THE CAPE TOWN INFRASTRUCTURE**

When this programme was inaugurated in 1970 blood was provided in glass bottles and platelets available only as single unit concentrates. To ensure that adequate transfusion support would be available an IBM 2990 was secured by donation and this prompt action initiated a long and ongoing collaboration with Professor Jeane Porter Hester (Figure 5). Although initially used for granulocyte transfusion the apheresis technology rapidly became the anchor, together with creation of a dedicated volunteer panel for donors, as one of the crucial moves towards realising clinical transplantation. Physical facilities were limited and the start-up procedures were carried out with literally unlimited encouragement in the newly built block for cardiac transplantation through the courtesy of Professor Christian Neethling Barnard. As a result of his programme histocompatibility testing also became available having only recently been introduced into our country. It was therefore possible to get class I by serology and some idea of class II by mixed lymphocyte reaction. These shortcomings were relatively soon appreciated and, in close collaboration with Professor Emette du Toit, high-resolution typing became available with eventual immunogenetic testing approved in her laboratory. The activity of the South African Bone Marrow Registry is reflected in the latest statistics report (Figure 6). The technical procedures of marrow processing including characterisation of the recovered mononuclear product necessitated development of a rabbit model in association with Professor Bruno Speck and Professor Alois Gratwohl in Basle to refine the methods and almost immediate establishment of flow cytometry and clonogenic assays using these transplants between strains showed that acute and chronic graft-versus-host disease closely paralleled what was being seen in the clinical programme. These manifestations were used to document the effects of cyclosporine-A just made available by Professor Jean Borel at Sandoz in Switzerland. The same approach proved crucial in evaluating the administration of the Campath series of monoclonal antibodies to the recipient but subsequently showing that even more effective immunosuppression was possible by exposing the graft to the protein ex vivo in what has subsequently been described as in-the-bag technique. This method has emerged as surprisingly rugged in abrogating classical acute graft-versus-host disease.

**DEMOGRAPHIC CONSIDERATIONS AND CURRENT TRANSPLANT ACTIVITY**

South Africa has a surface area of 1 219, 08 km² (Figure 3) with a population of 47 849 800 and density (135/km²). Complete records are available from the time bone marrow transplantation was started by the originally designated team (Figure 4). Now, with the recent proposal that a national database be started, matching activities throughout the country can be collected hopefully via the existing Bone Marrow Registry. Such voluntary participation should, in future, make these activities a matter of general record. At the same time South Africa has been included in a survey by questionnaire circulated from the European Bone Marrow Transplant Registry gathering essentially the same figures. Clearly these two activities need to be complimentary. Logically this exercise is but an initiating step which can easily be extended to properly managed centres that enjoy international designation.

and so substantially diminishing, almost to the point of extinction, the subsequently occurring chronic variant.21

THE CLINICAL PROGRAMME

Constant development, in a structured and actively evolving series of experimental and clinical studies, fell into four convenient but artificially distinct periods that characterise these activities in sub-Saharan Africa and particularly as chronicled at the University of Cape Town and Groote Schuur Hospital.16

UNFRACTIONATED BONE MARROW ERA mirrored experience occurring elsewhere in the world. Engraftment was often successful but plagued by graft failure and substantial morbidity as well as significant mortality consequent upon the syndrome of acute graft versus host disease (Figure 7). Here often-profound injury to skin, biliary endothelium and enterocytes, compounded by severe infection, responded only partially to immunosuppression with corticosteroids and methotrexate24 with extension to a severe sclerosing chronic form that created intractable disability in adults and children alike (Figure 8).25 In addition to the severe disability caused to recipients with devastating disorganisation of family life there emerged a more profound and often underplayed psychological injury to medical and nursing staff alike. This caused high staff turnover and understandable criticism from detractors of transplantation in general and particularly to the use in haematology with the focus on the perceived worse side effects in children.

CYCLOSPORIN-A ERA started when this undecapeptide was isolated by Jean Borel in Sandoz and our involvement in some of the earliest investigations of this biological breakthrough that was again thoroughly explored in the rabbit26 (Figure 9). Here, as when the experimental studies were translated into the clinic, incidence and severity particularly of acute graft-versus-host disease, was decreased but the broad range of complications changed surprisingly little. Nevertheless this was a seminal step in
Figure 7. Acute graft-versus-host disease. The syndrome of extensive skin desquamation, jaundice and large volume diarrhoea had a sobering effect in the initiation phase of the programme.

Figure 8. Chronic graft-versus-host disease. While many recipients survived a percentage had severe sclerosing variant of this complication of allografting with unmanipulated bone marrow.

Figure 9. Rabbit as experimental model. The early technical development was carried out using inbred strains allowing controlled allograft dosing with variation in severity of acute and chronic graft-versus-host disease. This reference was the basis for introduction of cyclosporin and Campath monoclonal antibodies.
being able to reverse weakening confidence of the local medical community in the role of immunohaematopoietic stem cell transplantation and set the stage for the continued active exploration of new and more effective agents.26

MONOCLONAL ANTIBODY OR CAMPATH ERA was in many ways the single biggest advance with which we were directly involved. Thus the opportunity was afforded us of working with Professor Herman Waldmann and Dr Geoff Hale, initially in Cambridge and subsequently in Oxford, through participation in the scientific deliberations of the Campath users group. There was the innovative approach of employing selectively synthesised series of immunoglobulins for the alternative approach of effecting immunosuppression by means of relatively selective T-cell depletion. Experience in the animal transplant model initially, with the lytic IgM protein, showed graft-versus-host disease to be beneficially affected and this could be duplicated in human allograft recipients with improvement in outcome. These events were enhanced first by the use of the opsonic IgG and then, more recently, the humanised chimeric protein confirmed in other countries.27

At about the midpoint of these collaborative studies innovative experimental evidence in our laboratory demonstrated that addition of the immunoglobulin to the graft, prior to infusion alone and without any subsequent immunosuppression using antibody or drugs, impacted favourably on acute graft-versus-host disease. This syndrome virtually disappeared although a late-presenting mild acute variant was recognized limited to skin, being grade 1 and typically responding to topical steroids but seldom needing systemic administration. This was the birth of the in-vitro, ex-vivo or, as it has subsequently become known, Campath in-the-bag technique.28

Overlapping with these developments was the recognition that a stem cell population having many characteristics similar to those derived from the bone marrow could be obtained by the much simpler expedient of recovery from the peripheral circulation usingapheresis technology with enhancement resulting from donor receiving stimulatory peptides in the form of G-CSF.29 A new observation emerged in that cytomegaloviral infections, which had not been particularly prominent whilst using marrow, now increased requiring constant monitoring and prompt administration of gancyclovir to avoid progression from viraemia to the much more hazardous situation of clinical disease typically in lung or gastrointestinal tract.

THE CURRENT ERA, spanning the last 12 years, has been particularly illuminating in the context of an under-resourced area where state support for teaching hospitals continues to relentlessly erode so that commercial ventures have become more receptive to accepting tertiary-level

Figure 10. Overall survival in children. Kaplan-Meier analysis shows that at 6.8 years there is a stable plateau consistent with cure. It is notable that results are similar for idiopathic aplasia, Fanconi anaemia and acute myeloid leukaemia with non-significant differences for lymphoblastic leukaemia and the remaining cases. There is also no difference in outcome for graft source, but a slight benefit for the female gender, which did not attain statistical significance.

Figure 11. Overall survival in adults. One of the more interesting aspects of this programme is the similarity in survival by Kaplan-Meier analysis between consecutive patients with bone marrow exposed to Campath 1-G in-the-bag, peripheral blood treated with the same immunoglobulin or humanised variant and autograft. This particular approach is notable for the lower level of graft-versus-host disease, high remission rates in acute myeloid leukaemia but with an increasing incidence of cytomegaloviral positivity that is the subject of ongoing investigation.

responsibilities. Thus it has been possible to relocate, within a single Facility, most of the original team into a privately based Academic Department of Haematology and Bone Marrow Transplant Unit that incorporates the Searl Research Laboratory for Cellular and Molecular Biology. The experiment has been successful proving that it is realistic to maintain the consecutive patient reporting system first to the International and then Autologous registries that are currently combined into the Centre for Bone Marrow Transplant Research. This period demonstrates feasibility of meeting the audit criteria for continued accreditation both as a transplant and harvest centre now extending, for an unbroken period in excess of three decades, as well as accommodating the need for matched unrelated volunteer donors. The latter sparked the need to start a donor registry that has become a national entity providing tissue-typing services for other centres in the country, regularly interacting with corresponding facilities and participates in searches from elsewhere in the world with activity recently updated. The standard is such that endorsement is maintained from the American National Donor Programme as well as the European Bone Marrow Transplant Registry. In parallel outcome has been analysed and reported in both children and adults (Figure 11). While particular relevance of these procedures in patients with lymphoma continues to attract our ongoing and special attention.

An important consideration in the Third World is to balance the need for these high cost procedures against resources available in state hospitals having limited budget and a competing private sector where restraints are of a slightly different nature dedicated by the particular insurance plan available through managed health care. In order that some idea of national activity can be gauged it was recently proposed that a bone marrow transplant registry be established within the ambit of the existing national body being the South African Bone Marrow Registry. The argument in favour of such a base is that it would allow comprehensive or inclusive recording of autologous and all forms of allogeneic transplantation and include alternative sources such as cord blood and matched unrelated volunteer donors and do so in a non-partisan way. It would also permit government, through the Department of Health, access to reliable statistics as to activity of the teams whether they be in university hospitals or private sectors. Additionally it would anticipate future needs for appropriate regulation that may be promulgated in terms of the human tissues act. Here particular issues relate to harvesting, any form of processing or manipulation of grafts and subsequent cryopreservation whilst monitoring movement of these human products not only within the country but a cross-border between countries through the medium of collaborating international registries.

CONCLUSION

The basis for this national experience can be factually recorded in three phases of past achievement and pres-
ent status with a projection for the future. Historically the experimental haematology and subsequent systematic translation into the clinical programme documents the capability of an under-resourced country to provide advanced and life-saving interventions as dictated only by the genuine needs within the community, across the age spectrum and catered for by the state or private sector even where costs are a major consideration (Figure 12). It is equally clearly demonstrated that in those few facilities that have elected to meet the criteria for ongoing audit and accreditation from international peer designations is possible as donor and harvest centre leading to participation in a worldwide community linked through registries that share search and provision of matched unrelated volunteers when these are not available locally. Finally it is time to survey activity within our borders and to this end reporting of consecutive procedures by each practice has been proposed forming a registry to operate within the ambit of the nation’s nationally launched South African bone marrow Registry. The latter initiative is given sharp focus by a similar approach already launched by the European bone marrow transplant Registry and both should be mutually complimentary. Such a proactive move would have the capacity for expansion to document outcome although this would require appropriate ethics and research monitoring. A further attraction is creation of a reliable database providing comparison between different regions of the world and, in local context, a basis to guide and educate practices in terms of regulation for transfusion practices and handling human tissues. The natural end-point becomes academic recognition for properly accredited programmes to safeguard future scientific and training requirements whilst simultaneously reducing any need for commercial or incentive-driven providers.

Human T-Cell Leukemia Virus (HTLV-I) Antibodies in Africa

Human T-Cell Leukemia Virus (HTLV-I) Antibodies in Africa

Abstract. Antibodies specific for human T-cell leukemia-lymphoma virus type I (HTLV-I) were demonstrated in serum samples from various groups of people in South Africa, Uganda, Ghana, Nigeria, Tunisia, and Egypt. The samples had been collected for other purposes and were presumably selected without bias toward clinical conditions associated with HTLV infections. Regional differences in antibody positivity were observed, indicating widely distributed loci of occurrence of HTLV on the African continent in people of both black and white ancestry. Two patients with high titers of antibody to HTLV-I had some signs of adult T-cell leukemia-lymphoma. In several groups a high frequency of false positive serum reactions was indicated when specific confirmation steps were included in the assay. Further characterization of these sera revealed highly elevated immunoglobulin levels, possibly due to polyclonal activation of immunoglobulin synthesis in these subjects. The possibility that related cross-reactive human retroviruses coexist in the same groups was not eliminated.

The human T-cell leukemia-lymphoma viruses (HTLV) are a family of related retroviruses originally isolated in the United States from patients with T-cell lymphoma and cutaneous manifestations (1). A particular subgroup of the family, HTLV type I, is linked to the cause of these malignancies, which share clinical and epidemiologic features with the disease called adult T-cell leukemia-lymphoma (ATL) that occurs in certain regions of Japan (2, 3) and in persons of African ancestry in the Caribbean Basin (4) and in the southeastern United States (5). An atypical chronic lymphocytic leukemia in Nigeria is also suggestive of an association with HTLV (6), as is the high incidence of antibodies cross-reactive with ATL in Old World primates captured in Kenya and Ethiopia and housed in West Germany (7) and the United States and Russia (8). Although the mechanism of transmission of HTLV is currently unknown, horizontal transmission is clearly implicated by molecular and epidemiologic analyses (9, 10). HTLV seropositivity in regions endemic for ATL is elevated overall in the general population and further elevated among close family members of cases and in recipients of blood transfusions (11, 12).

The present study, which is mainly descriptive, was undertaken to investigate the occurrence of antibodies to HTLV-I in various groups of people in widely distributed areas of the African continent. We studied serum samples that had been collected for surveys of diseases with no known association with HTLV-I and samples from hospital-based clinic patients. We used a highly sensitive enzyme-linked immunosorbent assay (ELISA) to detect antibodies to HTLV-I (13) (see Table 1). Because of the diversity of the test groups, our data cannot be used to make strict epidemiological comparisons, but can be used as a means to compare the distribution of virus antibody positivity with previously reported studies of exposure to the virus (2, 12, 14) in similar or analogous groups.

The testing procedure was performed in two steps (legend to Table 1). In step 1, all samples were screened to determine quantitative levels of antibody binding to HTLV-I. In step 2, "candidate" positive sera were selected and tested for specificity in one or more confirmatory steps. The screen-test results are expressed as a ratio (R) to a standard reference normal serum to control daily variations in test results (13). The threshold level, R = 2, was not expected to exclude negative sera. The use of this cutoff for confirmation was based on prior experience with normal U.S. blood donors where samples with a screening ratio of <2 are negative in the confirmation assay. This reference normal serum level and the threshold for detection of sera confirmed as being positive for antibody to HTLV-I were derived from an analysis of 1210 U.S. blood donors (15).

Specificity was considered confirmed when sera passed either one of the confirmatory tests described in Table 1. The accuracy and precision of the antibody-blocking procedure was verified by measuring the fractional reduction of antibody binding for mixtures containing a predetermined ratio of HTLV-positive antibodies to the reference normal serum. The results plotted in Fig. 1 show excellent agreement with the predicted results at low levels of positive antibody and deviation within acceptable limits due to incomplete blockade at the higher levels of human antibody. Of those sera failing confirmation by antibody blocking, only three were confirmed by absorption with virus-positive cells.

The values for the numbers of sera from the groups exceeding the screen-test threshold and for the numbers of confirmed positive sera in each of these groups are presented in Table 1. The median values for screen ratio (R) within the groups were in most cases close to the median value of 1.77 found for U.S. donors (13). However, median values of R for samples from Tunisia and Ghana were two to three times higher. This reflected the absence of a simple correlation between the prevalence of confirmed positive sera and the proportion of sera exceeding the screen threshold level (R = 2); for example, the proportion of confirmed positive donors in the Ugandan group (21 percent, which was highest of all groups) was two times higher, while the proportion of samples exceeding R = 2 was only one-half that of the Ghanaian groups.

We investigated some of the reasons for this apparent high rate of false positivity. Among the Ghanaian samples, 28 out of 67 with high ratios (R = 6) were nonconfirmed. The mean and median immunoglobulin G (IgG) levels of these 28 samples were, respectively, 130 and 106 mg/ml compared to 9 mg/ml for the standard control serum (measured by ELISA with immunopurified goat antise-
Table 1. Distribution of HTLV-I antibody among African donors. An indirect ELISA microtest to detect serum antibodies was used (13). Briefly, HTLV-I was purified by rate-zonal ultracentrifugation, disrupted, and coated into the wells of microtiter plates. Portions (3 μl) of test sera, control sera, and normal human sera were incubated overnight at 4°C in wells containing 100 μl of 20 percent heat-inactivated normal goat serum and were washed with PBS. After reaction with peroxidase-labeled goat antiserum to human IgG, sera with absorbance values two times greater than the normal control level were considered positive by a colorimetric assay, which involved the addition of phenylmethylsulfonyl fluoride (40 μl) to each well, followed by incubation for 30 minutes at 37°C. The absorbance at 630 nm was measured with a microtiter plate reader. Positive sera were confirmed by retesting the same lot of sera at a 1:2 dilution and with a titer of 100,000 or more. The sheep antiserum used in these tests required absorption with one volume of serum to each serum to be tested and with three volumes of serum to each serum to be tested and with three volumes of serum to each serum to be tested and with three volumes of serum to each serum to be tested. The antibody was determined by a 1:20 dilution of the serum samples. The ratio of optical density (O.D.) of the sample to the negative control was compared with a standard curve.

* Sera from Egypt were obtained from infected disease patients, National Research Unit No. 3, Cairo, Egypt. † Sera from Tunisia were obtained from healthy patients with no apparent disease, Tunis, Tunisia. § Sera from Ghana were obtained from patients with adult T-cell lymphoma. § Sera from Uganda were obtained from patients with adult T-cell lymphoma. ¶ Sera from Nigeria were obtained from patients with adult T-cell lymphoma. # Sera from South Africa were obtained from patients with adult T-cell lymphoma.

The positive sera were further analyzed by a nested-PCR assay for the presence of the HTLV-I proviral DNA. The positive sera were then subjected to a confirmatory test, and the results were compared with the results of the initial test. The results of the confirmatory test were then compared with the results of the initial test to determine the accuracy of the initial test. The data were analyzed using the chi-square test, and the p-values were determined using a significance level of 0.05. The results showed that the initial test was highly accurate, with a sensitivity of 98% and a specificity of 90%. The data also showed that the confirmatory test was more accurate than the initial test, with a sensitivity of 100% and a specificity of 95%.
years) compared to endemic populations in Japan where the antibody positive rate for the equivalent age group is approximately 5 percent (14).

The highest rate of antibody positivity, 21 percent, was found in a serum collection from Uganda (Table 1). The sera had been collected from patients with Burkitt’s lymphoma and from normal comparison groups in the West Nile region of Uganda over the years 1970 to 1972 as described previously (18). Since we were unable to discern any difference in the positivity rates between these groups they are listed together in Tables 1 and 2.

In a survey of patients with T-cell leukemia/lymphoma diagnosed in Nigeria (19), two cases fitting the typical characteristics of HTLV-associated disease were identified. The first case, a 19-year-old male student from Lagos, had an aggressive T-cell lymphoma with a high count of white blood cells that included cells of pleomorphic morphology, cutaneous involvement, and hypercalcemia. The second, a 57-year-old woman, had a clinically aggressive leukemia/lymphoma with generalized adenopathy and visceral involvement. She died shortly after diagnosis. Sera from both patients contained a high titer of antibodies to HTLV-I (see Table 2). One additional patient with ATL with high HTLV antibody titer, a native of Zaire, has been observed in Paris (20).

In Cape Town, 5 to 10 percent of patients with various malignant diseases had HTLV antibody (Table 1). There were no reported cases of ATL, and the greatest number of HTLV-I antibody-positive cases occurred among the myeloid malignancies (10 percent), although one patient with T-cell leukemia was positive. In areas of southwestern Japan that are endemic for ATL, the frequency of HTLV among patients with myeloid leukemias was 16 percent (2). Our present results with regard to the distribution of HTLV-I antibody within disease categories agree very well with the pattern found in the Kanto district, a nonendemic area of Japan (12). In that district, two important factors contributed to the high rate of HTLV-I antibody positivity in patients with diseases not linked with this virus. One was that the patient population largely originated from an endemic area and the other was the frequent use of blood transfusions in the management of myeloid leukemias (12).

With one exception, serum samples positive for HTLV antibodies were found in groups from all of the African subcontinental regions tested: Tunisia; Ghana; Nigeria; Uganda; Cape Town, South Africa; and Egypt. The absence of HTLV-I antibody in sera from the Johannesburg group may be related only to sample size and probably indicates a lower prevalence than in the other African groups. Race did not appear to be a disposing factor since positive serum samples from Cape Town were mainly of white origin. Although antibody-positive samples were detected in the Tunisian (taken as a whole) and Egyptian groups, the combined factors of frequency and titer found (Tables 1 and 2) were not significantly higher than the baseline for normal donors in the United States (15, 21). Both of the positive samples from Tunisian patients with lymphomas had very low titers, that is, 30 and 37, and the lymphomas were of B-cell origin. For reference purposes, among normal blood donors determined by comparable techniques, the HTLV-I antibody positivity rates between nonendemic and endemic regions of Japan range from 2 to 12 percent (2) and in the United States, 0.9 to 2.8 percent (15, 21).

The typical HTLV-I-associated disease as it occurs endemically in Japan, the Caribbean Basin, and sporadically elsewhere (22) is characterized by the occurrence of malignant cells of varying size and pleomorphic morphology with deformed nuclei and mature T-cell surface marker phenotype. It is often characterized by its onset at a relatively young age; by its aggressive clinical course with poor prognosis; and by the enlargement of lymph nodes, spleen, or liver; elevation of white blood cell count; hypercalcemia; and occasional skin involvement. Our data reveal increased levels of HTLV-I-specific antibodies in diverse African groups (compare with (23)) and suggest that the antibody levels in regions of South Africa, Ghana, Nigeria, and Uganda equal or exceed those found in previously described areas where HTLV-I and ATL coexist. It

Fig. 1. Correlation between specific antibody binding and its susceptibility to competition by HTLV-specific antiserum. A dilution series containing varying ratios of serum positive for HTLV-I antibodies to serum negative for antibodies was constructed by diluting a positive serum (serum F4608; titer = 3000) with our standard negative serum (serum F4600). Each dilution and the negative control serum were tested for HTLV-binding in wells pretreated with unlabeled sheep antiserum to HTLV-I and normal sheep serum as described in Table 1. The ELISA absorbances at 490 nm were measured and expressed as the ratio to negative human serum treated with normal sheep serum (abscissa); and the relative reduction of each diluted positive human serum after incubation with sheep antiserum to HTLV-I (ordinate). Solid line: a theoretical curve was constructed on the basis of the expected relationship between the fractional content of specific antibodies (abscissa); broken line: the maximum achievable reduction (ordinate).

would be interesting to conduct systematic surveys of patients with adult non-Hodgkin's lymphoma in various regions of the African continent, with an emphasis on clinical, pathologic, and immunopathologic features of the disease. A study of sera from African patients with known or suspected T-cell malignancies, including the acquired immune deficiency syndrome (AIDS) (24), would help to clarify the distribution of the HTLV family and the diseases associated with it, especially in view of the high HTLV-I antibody level in the Ugandan group, the occurrence of AIDS in neighboring Zaire (25), and the occurrence of Kaposi's sarcoma along the equatorial region of Africa with its highest prevalence in eastern Zaire and western Uganda (26).

Abstract

The intermediate to high grade B-cell non-Hodgkin lymphomas are now one of three malignant AIDS defining conditions. The others being Kaposi’s sarcoma and cervical carcinoma. While co-infection with oncogenic agents including the human herpes 8 or Epstein-Barr virus offer targets in preventive treatment strategies for these AIDS defining lymphomas (ADL), administration of highly active antiretroviral therapy leading to immune reconstitution permits use of standard or even high-dose cytotoxic drug regimens with curative intent. It is not certain whether this should be done concomitantly or sequentially. Additional benefit may derive from infusional or high-dose chemotherapy regimens depending on the histological subtype while use of monoclonal antibodies such as rituximab or immunohaematopoietic stem cell transplantation needs to be further evaluated within controlled studies. Socio-economic considerations have an impact especially in resource limited settings while availability of tools for appropriate geno-phenotypic diagnosis and immunological monitoring such as the CD4 cell count will play an important role in the risk stratification as well as disease management. While it is generally accepted that the impact of HAART has an overall benefit both in incidence and treatment outcome in ADL, the expanded access to HAART programs are falling short of all targets in Africa. Accordingly focus is given to some of these controversies, including epidemiology, pathogenesis, clinical features, therapeutic options and ethical considerations.

1. Introduction

The acquired immunodeficiency syndrome has reached pandemic proportions where, in many parts of sub-Saharan Africa, shortened mean life expec-

tancy in adults between 10 and 15 years [1]. This excess mortality is attributable to opportunistic infections and neoplasms, where Kaposi’s sarcoma and primary central nervous system lymphoma emerged as defining conditions 20 years ago followed subsequently by non-Hodgkin lymphoma and carcinoma of the uterine cervix [2]. Retrovirally infected patients have an increased risk of developing Hodgkin variants, myeloma, leukaemia, invasive anal carcinoma and lung cancer but correlation with progressive immunosuppression remains to be established [3].
Kaposi's sarcoma is the subject of a separate report [4]. Of the non-Hodgkin lymphomas, the small non cleaved-cell or Burkitt's type, diffuse large B cell group including immunoblastic, primary central nervous system lymphoma, plasmablastic of the gastrointestinal tract and primary effusion lymphomas are the most common subtypes seen in HIV disease with recognised demographic variations [5].

2. Aids defining lymphomas (ADL)

2.1. Epidemiology, risk factors and impact of HAART

The clinical characteristics of these lymphoproliferative disorders is markedly altered in the presence of human immunodeficiency virus (HIV) infections by the more frequent occurrence of constitutional symptoms and extranodal disease in the bone marrow, body cavities, jaw or rectum [6]. Additionally is the frequent association with Epstein-Barr virus (EBV) or human herpes virus-8 (HHV-8) [7,8] where there is some correlation with the degree of immunosuppression and presence of the primary central nervous system lymphoma subtype. The relative risk of developing one or other of the ADL is between 100 and 600 fold higher than the general uninfected population in contrast to the much lower occurrence of Hodgkin lymphoma [3].

Since highly active antiretroviral therapy (HAART) became the standard-of-care the overall occurrence rate of lymphoma has consistently declined with the evidence that not all benefit equally from these agents. A meta-analysis of 23 prospective studies that included 47,937 positive persons and bracketed the introduction of HAART showed the incidence of Kaposi's sarcoma to drop from 15.2% to 4.9% and lymphomas in general from 6.2% to 3.6% [9]. The major impact was evident in cerebral and immunoblastic subtypes, no difference in Hodgkin lymphoma with the contrasting relative increase in the Burkitt category [9]. From Europe a report of 7300 patients documented a dramatic decline in all illnesses defining the acquired immunodeficiency syndrome in response to antiretroviral therapy but, paradoxically, a relative increase in lymphoma [10]. These inconsistencies suggest a modest impact on overall incidence in survival that is not uniform across the different histologies and may reflect the concurrence of varying aetiologic agents or oncogenic processes. Variables such as viral load, low CD4+ T-cell count, poor performance status or increased age are established as associated risk factors leading to poor virologic control and correlating with significantly higher incidence of tumour development and inferior outcome following therapy [10]. Some of the latter may respond more favourably to immune reconstitution thus arguing for earlier commencement of treatment prior to development of severe immunologic decline [11]. On the subcontinent of Africa, the best statistics show that less than 25% of persons living with AIDS are receiving HAART [1]. Most of those on HAART have had an AIDS defining illness that results in the commencement of the antiretrovirals, which also implies that patients are presenting late when profound immunosuppression has been established.

Based on these facts it is anticipated that the expanded care and treatment program is not going to have a significant impact on the demographics of ADL for the time being in Africa. In South Africa there are estimated to be 5.5 million people living with HIV and the national prevalence rate suggests that 1 in 4 of the sexually active age group are infected with HIV [12]. A study conducted in one of the high prevalence provinces of South Africa, showed the incidence of ADL has increased four fold in the last 10 years, and this excess is attributable to HIV infection [13].

3. Pathogenesis and clinical presentation

Clinical heterogeneity likely reflects differing pathogenetic mechanisms including chronic antigen stimulation, release of cytokines such as IL-6, IL-10, CD23, CD30 and CD44 or co-existence of viruses such as HHV-8 and EBV with the latter virtually always demonstrable in primary central nervous system, diffuse large B-cell and Burkitt lymphoma and both together in plasmablastic (PBL) and primary effusion (PEL) [14]. Three major aggressive forms exist. Firstly Burkitt or Burkitt-like tumours are typically widespread with central nervous system involvement, expand rapidly and are associated with fever, night sweats and unexplained weight loss. Also of B-lineage are the PBL category while T-cell lymphomas remain rare while in PEL variants there is often a paucity of membrane markers. Other pathologic subtypes include polymorphic disorders resembling posttransplant associated lymphoproliferative disorders. Each of these differ in their underlying genesis, presentation and response to therapy but as a generalisation older age, low CD4+ counts
and no prior antiviral therapy favour development of these malignancies.

Available evidence supports a modest benefit for drug treatment on overall incidence in survival but this is not uniform across the histological spectrum suggesting that the presence of other aetiologic agents or oncogenic processes operating concurrently may respond variably to immune reconstitution. This concept would be consistent with the observation that these lymphoreticular malignancies have a different relationship here with the infection and its treatment to that seen with the defining entities such as Kaposi sarcoma.

Micro ribonucleic acids (miRNA) are a recently described class of non-coding molecules present in humans and eukaryotic organisms capable of modifying intracellular signalling by regulating message through antisense complimentary binding. Several hundred of these have been identified as being involved, directly or indirectly, with transduction or inhibition of cells cycling or apoptotic pathways [15,16]. Their presence during latent infection may lead to involvement with candidate proteins and here similarities as with EBV infections. Clarification of their role in these pathways may shed new light on the molecular pathology of cancer.

The human immunodeficiency virus may have direct carcinogenic activity through in insertional mutagenesis [17]. Retroviruses infect cells by direct host genomic contamination of viral cDNA which is a product of the reverse transcription of foreign RNA. This process can arise randomly but recently found to occur within the transcriptional unit as opposed to downstream or upstream in any particular gene leading to activation all deactivation of genes that modulate cell cycle or cause apoptosis and thus candidates for promoting malignant transformation [18,19].

4. Treatment and the modifying effect of HAART

Prior to the availability of effective antiretroviral drugs tolerance was poor and infectious complications high with complete response rates between 50% and 60% and two years survival being only 10% irrespective of the regimen employed [20,21].

Clinical trials have shown that a CD4+ count <100 [22] and 50/mm<sup>3</sup> [23,24] to be predictive of lower complete response (CR) rates. CD4+ lymphopenia has been associated with increased risk of infection in the neutropenic HIV infected patient [23].

The nucleoside reverse transcriptase inhibitor Zidovudine (AZT), besides its antineoplastic activity, has shown myelosuppressive effects and has been studied in ADI patients in combination with methotrexate [25]. It is generally recommended that AZT should be avoided during chemotherapy. In general, Protease inhibitor (PI)-containing HAART is well tolerated when administered e.g. with standard CHOP-like regimens, and their concurrent use can be recommended despite the fact that certain PIs such as indinavir may interfere with the metabolism of cytotoxic drugs, leading to increased intracellular levels [26]. Stebbing et al. [27] analyzed the impact of various types of HAART on the development of ARL and found that PI-based HAART and non-nucleoside reverse transcriptase inhibitor (NNRTI)-based HAART were equally effective at preventing ARL. Whether coadministration of PIs with infusional regimens like cyclophosphamide, doxorubicin, and etoposide (CDE) or etoposide, doxorubicin, vincristine, cyclophosphamide, and prednisone (EPOCH) is associated with increased toxicity will have to be determined in ongoing and future trials. With the introduction of highly active antiretroviral combinations outcome has improved largely as a direct consequence of enhanced immunologic status and bone marrow function. One of the arguments speaking for the concomitant use is the fact that in the era of HAART, patients with profound immunodeficiency are clearly living longer, although not always with a reconstituted immune system [28,29]. Reasons for HAART omission include concerns of drug interactions with chemotherapy and inconsistent compliance with antiretrovirals resulting in increased resistance [30] which fuels the discussion whether antiretrovirals should be optimally administered concomitantly or immediately after completing the lymphoma therapy.

5. Subtypes

5.1. Diffuse large B-cell (DLBL) and Burkitt lymphoma (BL)

These two represent the majority of all AIDS-related lymphomas [6].

Ratner et al. [25] demonstrated the feasibility of combining CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) chemotherapy with concomitant HAART and reported CR to be 48% (full-dose CHOP) in comparison to 30% (reduced-dose
CHOP). Only one opportunistic infection was reported during chemotherapy administration.

Several groups have investigated the use of infusional chemotherapy regimens. When used in this way dose-adjusted regimen such as EPOCH [22] has been designed with the intention to correlate dose intensity with haematologic toxicity. Etoposide, doxorubicin and vincristine was given continuously as a 96-h infusion together with oral prednisone for 5 days. This was followed by an adapted dose of cyclophosphamide according to initial CD4 cell counts. CR was found to be 74% and overall survival (OS) after 53 months follow-up was 60%. Patients with an initial CD4 count >100 cells/mm³ had a better survival compared to patients with a CD4 count of <100 cells/mm³. Unfortunately the study was not designed for the concomitant use of HAART. Other infusional regimen such as CDE consisting of cyclophosphamide, doxorubicin, andetoposide emerged feasibly when given with HAART [31]. Infusional therapy was postulated to reduce the risk of multi-drug resistance by overcoming the drug efflux associated with multi-drug resistance-1 gene expression [32].

In Burkitt lymphoma remission and survival rates remain poor when treated with CHOP-like regimens whereas HyperCVAD, alternating with high-dose methotrexate and Ara-C, led to 92% CR in 13 individuals with BL with 31 months median duration of CR and survival of 12 months, respectively. Outcomes appeared to be better for those receiving HAART [33]. Interestingly no difference was found in HIV-positive and -negative patients receiving the PETHEMA LAL3/97 protocol (Prednisolone, Vincristine, Daunorubicin, Asparaginase, Cyclophosphamide and intrathecal therapy over 5 weeks). Complete remission in HIV-positive and -negative patients was achieved in 71% and 77%, respectively. The estimated 2-year OS was 51% and the only adverse prognostic factor was age of more than 60 [34].

As a general treatment recommendation for aggressive ARL infusional chemotherapy regimens are well tolerated and should be given preference to conventionally administered chemotherapy. Furthermore BL response rates and survival seem to be better when using intensive chemotherapy regimens and they are well tolerated especially when retroviral therapy is given concurrently.

5.2. Plasmablastic lymphoma

Plasmablastic lymphoma (PBL) is a subtype of large B-cell lymphoma more common in HIV-infected individuals often presenting extranodally in the oral cavity, jaw or rectum area [35] and has a rapidly progressive course. Characteristically large plasmablasts are found and there is close association with EBV [36] as well as HHV-8 [37]. In a study performed in the pre HAART era all patients followed up died within 34 months (median 7 months) [38]. This was contrasted by a post HAART era study [39] in which 8/12 patients were reported to be alive (median follow-up > 11 months) after treatment with cyclophosphamide, doxorubicin, high-dose methotrexate/ifosfamide, etoposide and high-dose cytarabine (CODOX-M/IVAC) – a treatment protocol originally designed for BL.

5.3. Primary effusion lymphoma (PEL)

This is a high grade, mature B-cell neoplasm that presents as a malignant serous effusion without solid tumour formation accounting for approximately 5% of all ADL and has been found to be associated with HHV-8 and EBV infection [5]. Outlook is poor despite the use of HAART with or without chemotherapy, attributable to presentation in very advanced stages of HIV disease and appears to be resistant to chemotherapy. Boulanger et al. [40] published results on 28 HIV-positive patients diagnosed between 1993 and 2003, (bracketing the time when HAART was introduced), with a CR rate of 50% and one year OS of 40%. It was concluded that performance status and use of HAART were the two most predictive prognostic factors.

In another small study 4 out of 5 patients were treated with chemotherapy and HAART while 1 out of 5 was treated with HAART alone achieving a CR in 3 patients [41]. Immune reconstitution is probably an important factor in the treatment of this disease.

5.4. Primary central nervous system lymphoma

This presentation is common in patients with severe immunosuppression defined as CD4 count less than 50/mm³ and a positive EBV status. Historically, prognosis is poor, with median survival rarely beyond several months duration but patients responding to HAART have demonstrated a prolonged median survival up to 1.5 years [42]. Among those receiving radiotherapy, completion of the prescribed antiretroviral course and treatment to at least 30 gray were both associated with better outcomes [43] but at the price of late complications
arising from irradiation such as leukoencephalopathy and radiation necrosis. Smaller reports in this subpopulation have also shown good responses to high-dose methotrexate-based regimens without the associated radiation related leukoencephalopathy [44]. The current available data favours treatment with high-dose methotrexate; radiotherapy should be reserved for relapse or chemoresistant disease. In both settings the addition of HAART is recommended.

6. The role of rituximab

This anti-CD20 monoclonal antibody has shown to improve response rates and OS in HIV-negative aggressive cases treated with CHOP without an increased risk of infectious complications [45]. In a phase III trial CHOP was compared to the same regimen and rituximab (R-CHOP) [24]. Rituximab at a dose of 375 mg/m² [2] was given with each cycle for a total of 6–8 cycles followed by maintenance in three monthly intervals. All patients received combination antiretroviral therapy and granulocyte-colony stimulating factor (G-CSF) support. Nonsignificant differences, marginally favouring the antibody containing arm were shown with CR rates of 58% versus 47%, progression-free survival 45 versus 28 weeks and OS 139 versus 110 weeks but with an increased risk in death from infection (14% versus 2%). In contrast, results from a trial using rituximab with infusional etoposide, vincristine, doxorubicin, and cyclophosphamide and prednisone (R-EPOCH) [46] have demonstrated a particular benefit for rituximab in patients with a CD4 cell count <100/mm³. Compared to historical controls, this agent improved survival from 16% to 57% at 19 months median follow-up. No additional benefit was seen for those with CD4 cell counts >100/mm³ but these patients already had cure rates of approximately 90%. Neutropenia was more frequently observed with R-EPOCH during and after chemotherapy but without any increased risk of death from infection.

More studies are needed until it can be suggested that rituximab will contribute to improved control in ADL but obviously also at a higher risk of severe infections and should be therefore used with greatest caution or only in controlled studies in patients with severe immunosuppression. It is possible that infectious complications may be reduced with routine fluoroquinolone prophylaxis during periods of severe neutropenia. The role of rituximab requires further clarification prior to routine use in patients with ADL.

7. High-dose chemotherapy and transplantation

Patients with relapsed or refractory ADL should be considered for high-dose chemotherapy followed by autologous stem cell transplantation (ASCT) [47] if appropriately selected. Even though all patients were started on HAART only the minority of the patients were able to continue antiretroviral treatment. With 32 months median follow-up OS was 85% and progression free survival 81%.

Infectious complications during ASCT were similar to those noted in the HIV-negative population but larger studies with longer follow-up are needed to better define the role of ASCT for the treatment of persistent or relapsed lymphoma. Krishnan et al. [48] reported that between 1998 and 2006, 28 HIV positive patients with high-risk ADL underwent ASCT with a median follow-up of 41 months, 2 year OS of 78% and PFS of 78%. All engrafted with median time of 11 days to absolute neutrophil count (ANC) > 0.5 × 10⁹/µL. Median HIV viral load (VL) at ASCT was 6113 copies/ml with 22 having an undetectable VL. At two years only 9 patients had an undetectable VL. Median CD4 count at ASCT was 164 cells/mm³, rising to 263 cells/mm³ at two years post ASCT. Despite the excellent outcome and ongoing antiretroviral therapy this demonstrates clearly, there is still progressive attrition of the immune system and reflects the natural history of HIV infection and limitations of current antiviral therapy.

8. Socio-economic impact of treating arl patients in africa

The approach in treating ADL patients is also dependent on the financial constraints under which a health system has to operate. It is therefore not feasible to drain the budget in a low resource setting just because certain treatment modalities exemplified by monoclonal antibodies such as rituximab or ASCT have been found to be superior over other but maybe more affordable therapies. As a consequence arising from these financial limitations patients with ADL would have to be firstly stratified with reference to their potential risk for developing opportunistic infections caused by pneumocystis carinii, cytomegalovirus, atypical mycobacterium species or others. Several authors have confirmed
that ADL patients were less commonly diagnosed with opportunistic infections in the HAART era as compared to pre HAART era patients [49,50].

Therefore we would suggest to design future studies or risk stratify treatment decisions in ADL patients with regards to their CD4 cell count. This would mean to treat patients with a higher risk for opportunistic infections defined by CD4 cell counts <100 cells/mm³ with infusional regimens such as dose-adjusted EPOCH or CDE under the concomitant protection of HAART. Patients with a low risk for developing opportunistic infections here with CD4 counts >100 cells/mm³ where toxicity or treatment-induced infections are less problematic could receive full or even high-dose chemotherapy determined by the subtype.

In addition, the threshold to prescribe prophylactic fluoroquinolones during periods of neutropenia should be low and ADL patients undergoing chemotherapy should receive prophylaxis for Pneumocystis carinii pneumonia regardless of their CD4 cell count.

9. Summary

Despite the historically poor prognosis in ADL, outcomes have been improving with the use of antiretroviral therapy and more intensive chemotherapy regimens, especially in aggressive subtypes. Particularly in patients with CD4 cell counts <100/mm³ relapse rates remain high and overall prognosis poor. Infusional chemotherapy regimens such as EPOCH or CDE have been designed especially for patients with aggressive subtypes and should be given preference especially in patients with a CD4 cell count <100/mm³. These regimens are generally well tolerated achieving complete response rates in aggressive lymphoma patients in 50–75% and 2–3 years overall survival in 40–60%. The use of either concomitant, or sequential administration of HAART, depending on absolute neutrophil and CD4 cell counts remains to be clarified in future studies even though there is a preference for concomitant HAART in patients with a CD4 count <100/mm³. Burkitt lymphoma should be treated with intensive regimens rather than standard CHOP-like chemotherapy. Independent from CD4 count the neutropenic patient should additionally receive prophylaxis against the most common bacterial and opportunistic infections.

The addition of rituximab to chemotherapy may have a role which needs to be further clarified in future studies although it seems that infectious complications appear to be higher, notably for those with severe immunosuppression. Once with refractory or relapsed disease, high-dose chemotherapy with autologous stem cell transplantation, where affordable, appears to be well tolerated and effective but should be considered for selected patients and remains an investigational approach.

Abstract
Retroviral infections have reached pandemic proportions in sub-Saharan Africa and are cutting across continents with rapid and devastating effects. The initial focus on immunologic defects and primarily infectious complications continue to be modified by highly active antiretroviral therapy. A greater understanding of the pathobiology of this formidable foe has opened many opportunities for interventions as the battle continues to contain and hopefully find a long lasting compromise between infectivity and mortality of this group of viruses and their human hosts. As acute becomes a more chronic disorder longer survival allows specific changes on target organs including blood and bone marrow function and the vascular tree. This relationship is given consideration in this review.

Key words:- HIV-1 geneology, CD-4 depletion, T-cells, cardiovascular complications.

Introduction
Since its discovery in 19831,2,3, Human Immunodeficiency Virus (HIV) has been responsible for approximately 25 million deaths worldwide. There are estimated to be 47 million people living with HIV worldwide, 25 million of which live in Sub-Saharan Africa4. A further 45 million are projected to become infected before the end of 2010 unless a drastic global prevention program is instituted5. Classified as a pandemic, current mathematical models are projecting an escalation that is likely to peak around the middle of this century with a shift in its current epicentre from Southern and West Africa to new foci in Asia and Russia. A staggering anticipated burden of disease in the range of 60 to 240 million infected people will be living in India and China by 20506. This represents
a devastating psychological impact on the regions that are and will be most affected by this phenomenon with escalating human suffering and profound economic retardation. Unspiring and transgressing all specialities of Medicine, it is incumbent on us to behave this unprecedented scourge with the compassion and professionalism it deserves. Never in the history of mankind has there been such an unrelenting multifaceted impact on human welfare, which threatens to transcend into posterity in all its ramifications. This review attempts to put in perspective the lessons learnt from the outset of this disease, and demonstrates succinctly how it transcends multidisciplinary fields by highlighting the understanding of the impact is has on the haematopoietic and vascular system. Without an effective prophylactic vaccine or some form of immunogenetic modulation, it is likely to exponentially progress and change dynamics around the world.

**HIV-1 Geneology**

HIV is a retrovirus belonging to the lentivirus group, capable of infecting susceptible human cells and incorporating reverse transcriptase derived complimentary DNA into the host cell genetic banks, thus starting of a process of self-replication using host machinery resulting in progressive immunological decay and ultimately, Acquired Immune Deficiency Syndrome or AIDS. There are 2 known main groups HIV-1 and HIV-2. The largest group HIV-1, is further subdivided into subgroups M, N and O. HIV-1 subgroup M is responsible for the demographic holocaust and global pandemic that humanity is facing currently. There are now numerous clades and hybrids of group M that have found unique niches in human populations around the world due to a complex interplay between viral characteristics, human genotypes and social demographics. HIV is closely related to other lentiviruses known as the Simian Immune Deficiency Viruses (SIV) found in African primates of which there are almost as many subtypes as there are species in Africa, thus demonstrating a high degree of evolutionary specificity. The Sooty Mangebey African monkey and Chimpanzees harbour alternative immunodeficiency viruses known as SIVsm for Sooty Mangabey and SIVcpz for Chimpanzee. These are the closest relatives of the HIV group. Within the HIV group of viruses, the HIV-1 group N and the HIV-2 groups C–G are the closest genetically to SIVcpz and SIVsm respectively (Figure 1).

![Phylogenetic tree of the SIV/HIV lineages](image)

Figure 1: Phylogenetic tree of the SIV/HIV lineages. SIVpz refers to the SIV virus found in chimpanzees and SIVsm to the SIV found in a specific African Green Monkey known as Sotty Mangabey. The phylogenetic tree shows the probable relationship between the SIV and HIV in terms of evolutionary similarity that these viruses have to one another and points of possible divergent ancestry.

Both of these groups are extremely rare in humans. Only six persons are known to have been infected with HIV-1 group N and only single individuals by HIV-2 groups C–G. This may however
represent the beginning of the historical evolutionary process of cross-species adaptation of SIV to HIV (7). SIV infection in African monkeys appears to be ancient and a well-adapted lineage specific process resulting in a state of non-pathogenic latency in most cases. This is not true for humans infected with HIV or Asian macaques infected with SIV. Both of these hosts are highly susceptible to these viruses and develop a pathogenic state slowly culminating in AIDS.

The First Established Cases of HIV-1 and the Timing and Location of its Origins

The first well recognized epidemic of HIV was in the early 80's among gay men living in San Francisco. However with the aid of retrospective insight, several conclusive public health scenarios confirmed that pockets of small epidemic cases of HIV infection and AIDS existed much earlier in Africa and Europe. Conclusive support for this is found in numerous reported cases such the Norwegian sailor who had travelled extensively in Europe and Africa in the late 1950's and early 60's, and subsequently developed the characteristics that are now known as HIV/AIDS in 1966, his wife was also affected as was their child born during this period. All of them died around 1976. Frozen serum from all three of them retrospectively tested positive for HIV-1. This suggests that the virus must have been in circulation and contracted by this sailor well before 1966. There are numerous similar accounts of patients and sera examined from people living or having contact with Central and East Africa before the outbreak of the American epidemic. Work done by Dr Ho and his team at the Aaron Diamond HIV centre in New York, identified conclusively the presence of HIV-1 in a sample of stored frozen serum from a man that lived in the Democratic Republic of Congo the former Belgian Congo in 1959. Thus making this the first ever-confirmed case of HIV-1 infection in Man. These facts demonstrate that HIV as a human infection has been around for a much longer time frame than we are accustomed to thinking about and Africa probably has the most mature epidemic to date, which would explain why the statistics are so alarming in this geographical location.

Immuno-Biology of HIV Infection

The Trojan Horse Phenomenon:

HIV infects susceptible human cells by mechanism that involves a combination of several receptors, co-receptors and surface antigens. Most importantly among these receptors are the CD4 and the chemokine receptors CCR5 and CXCR4 on a variety of host cell, and the glycoproteins gp120/gp41 complex on the HIV surface. The first cells to encounter the invading virus are usually the tissue macrophages or dendritic group of cells (DC). Majority of naturally occurring strains of HIV-1 use CCR5 as a co receptor for primary infection of both the tissue DC and macrophage cells. The HIV virus has been observed to preferentially target and infect fixed tissue or circulating DC precursors using the CCR5 receptor.

Infection of DC by the virus generates a cytokine induced intrinsic up-regulation of viral expression in and on the cell thereby increasing the transmission potential to other susceptible cells in the microenvironment by migration and chemo-attraction. By another mechanism, the DC will readily attach and bind to the virus gp120 envelope glycoprotein with several adhesion molecules. Among these is DC-SIGN (or CD209), a C-type (Ca-dependent) lectin that selectively recognizes high-mannose oligosaccharides of the virus gp120. DC-SIGN is expressed on some DC subsets, including those derived from blood monocytes and particularly those found in lymphoid tissues and beneath genital mucosal surfaces. DC-SIGN-expressing cells can internalise HIV virions via the CCR5 and CD4 receptor complex into a trypsin-resistant compartment, sequestered from the immune system and where viral infectivity can be retained and amplified for several days with the effect of potential enhanced onward transmission as it migrates through tissue boundaries. The virus is therefore transported to the central lymphatic tissues by the DC either internalised in an intact and infective form, on the surface or digested within the context of the MHC molecules for cell mediated response.

Conjugates between DC and T helper cells are easily formed, a process which is designed to provide cross talk between innate and adaptive compartment of the immune system in the antigen presenting process. HIV with the help of the DC uses this functional liaison with extreme prejudice serving to facilitate transmission by locally concentrating whole virions in the proximity of its main target cells during this physiological interaction of the infectious synapse. The DC thus acts to
bring the intact and infective enemy into direct contact with the most strategic cells of the immune system. But as fate would have it, these cells are the precise victims of the virus. The DC can thus be described as the Trojan horse of the invading enemy and inadvertently facilitating the rapid dissemination of a highly destructive virus, which has a crippling effect on the immune system\textsuperscript{18}. HIV infected DC, cell macrophages and monocytes by virtue of their mobility and migratory capacity will act as the transferring medium of the virus to sites remote from the point of initial infection. By this same modality transmission also occurs into highly susceptible lymphoid rich tissue spaces and other organ spaces such as the bone marrow and sanctuaries like the brain\textsuperscript{15,16,17,18}.

**CD4 Depletion and Factors Fuelling the Flames of Immunological Attrition:**

T-lymphocytes are divided into two broad categories which are the newly thymic released naïve cells and antigen experienced also known as memory cells. Within this compartment two further subtypes are recognised. These are the central memory (CM) T cells characterised by a CCR7 positive and CCR5 negative surface phenotype which circulate between the peripheral blood and the lymph nodes (LN) and the effector memory (EM) T cells that migrate out into the extralymphatic sites like the gastro intestinal (GI), genital lamina propria and the skin.

![Diagram](image)

**Figure 2:** T helper cell genealogy and homeostasis. Thymic derived cells replenish the naïve compartment, which in turn is cytokine driven to retore the central memory compartment confined to the lymph nodes and blood. This compartment is somewhat resistant to HIV infection by virtue of their chemokine receptor profile and important in replenishing the effector memory compartment, which resides predominantly in the mucosal surfaces of the gut and respiratory systems. This compartment is highly susceptible to HIV infection and undergoes dramatic depletion in the early and chronic stages of HIV infection.

These subsets are CCR7 negative and CCR5 positive which confines them to the periphery where they will remain and die. The EM cells are believed to constitute about 50% of the T population and are exquisitely vulnerable targets of HIV by virtue of their CCR5 coreceptor surface phenotype. Infection of these cells via the CCR5 receptor is designated R5 viral tropism\textsuperscript{19}. The EM pools are rapidly and almost completely depleted in the acute infective phase and attempts to replenished them from the CM compartment occurs which in turn is dependent on the thymic naïve population output\textsuperscript{19} (Figure 2).
There is convincing evidence now that this process of replenishing of EM cells from the CM compartment is cytokine driven and the rate at which this occurs has clinical implication for the progression state and natural history of the disease. Evidence suggests that rapid progressors have a deficient capacity to replenish the EM T cell compartment because of a physiological cytokine deficiency of IL-2. Resting CM and naïve T cells do not express CCR5 and are thus spared the devastation in the acute phase infection. If one then just defines the effect of the virus on T lymphocytes by examining the peripheral blood (PB) alone, a false impression emerges of the state of T helper destruction going on in the peripheral sites. However later in chronic phase when there is an exhaustion of CCR5 susceptible cells and replenishment is less efficient, HIV is able to mutate into an R4 tropic virus, which has an increased propensity to utilise the CXCR4 chemokine coreceptor as the main means of transfecting cells. CXCR4 is found most readily in resting CM and naïve cells resulting in depletion of the CM pool. R4 tropic viruses therefore become the predominant quasi-specie towards the end of the infection consuming what is left of the host T cell repertoire leading rapidly to AIDS. All T memory cells can undergo activation with upregulation of the chemokine receptor CCR5 at any time in their life span and can then be identified by characteristic additional immunophenotypically markers CD45RO and high CD26 expression. In this activated state the cell become even more susceptible to HIV infection. The upregulated mRNA expression of several chemokine receptors on activated memory T cells has been described as a phenomenon that appears to be dependent on exogenous cytokines. This heightened state of persistent activation can occur as a direct consequence of the HIV infection itself or independent of HIV by virtue of the environment or life style of the individual. Such a scenario would be found in tropical environments where parasitic, bacterial and viral infections are endemic and populations have become long term chronic carriers of these infection, or suffer repeated multiple infections over time, exacerbated in locations where instability is precipitated by periods of seasonal malnutrition or political upheaval. A similar situation would be found in intravenous drug abusers and men who have sex with men. Activated EM T cells represent the lymphocyte subset showing a higher transendothelial chemotactic potential, rapidly migrating to a site of inflammation and with the highest susceptibility to HIV infection. This setting only results in a ready and sizeable pool of activated competent CD4 EM cells meeting a formidable fee, which will lead directly and indirectly in their demise. Attempts to minimize the destructive effect of what appears to be a rapidly cascading immune and cytokine storm occurs through the amplification of regulatory pathways such as the CD4+ CD25+ T regulatory cells particularly at the mucosal surface where the destruction of the EM cells is so pronounced. This could have a beneficial effect by dampening down the activation state, which is the environment in which the virus flourishes. Now that it is apparent how much of the early and chronic phase damage to the T helper population takes place in the peripheral tissues of the mucosal surfaces of structures like the GI and lungs it is easier to appreciate why examination of the PB and the LN does not reveal much attrition at these stages.

The majority of GI tract CD4 EM cells expresses CCR5 and comprises a higher frequency of activated T cells than in the PB or LN in HIV-uninfected and infected individuals, thus representing the ideal targets for sustained HIV replication. Direct infection of this population results in an irreversible and profound depletion during the acute and chronic phase of HIV disease. However what is not yet fully understood are the direct or indirect mechanisms that the virus uses to drive a state of persistent activation of the immune system. This defines the chronic phase of the infection, a phenomenon resulting in far reaching consequences culminating in sustained attrition and aberrations of lymphoid tissue architecture that in turn impacts upon the ability of lymphoid tissue to support normal lymphocyte homeostasis and antigen presentation.

A similar phenomenon is seen in the primate macaques pathogenic model where primary simian immunodeficiency virus (SIV) infections result also in the dramatic depletion of both CD4 CCR5 EM T cells as well as a state of chronic unquenched cytokine storm. Eventually, persistent SIV replication results in chronic-phase immunological collapse or macaque AIDS. Again the main catalyst for this phenomenon appears to be persistent activation of the immune system. Data suggest that although CD4 EM T cell depletion is largely determined by viral and immunological mechanisms, it is exacerbated by failing production from a chronically progressive decline of CD4
CM T cell pool\(^2\). In the acute infection, GI CD4 EM T cells harbour on average, 13-fold higher HIV-1 viral DNA levels and 10-fold higher HIV-1 RNA levels than PB CD4 T cells. HIV-1 RNA is detectable in both "activated" and "non-activated" mucosal CD4 T cells of the GI although a significantly higher number of infected activated and proliferating T cells were detected in the GI tract compared to the PB.

A robust HIV specific cytotoxic response is detected in the GI tract as early as 18 days into the acute infection. Mucosal pan CD4 T-cell depletion is therefore probably multi factorial resulting from direct acute and chronic viral assault of susceptible activated CD4 T cells, which is compounded by activation-induced apoptotic cellular death and an initial robust host cytotoxic cellular response targeted against any infected cells\(^3\).

Interestingly this pattern and kinetics of early, severe and persistent dramatic loss of CD4 EM T cells in the GI tract has been found to occur in both pathogenic and non-pathogenic lentivirus infections. The African monkeys being the natural host, exhibit a chronic latent infection with insignificant consequences, while humans and the Asian macaques develop progressive immunological decay and AIDS. Although the non pathogenic SIV infections in African monkeys induces an almost similar pattern of mucosal target cell depletion observed during pathogenic HIV infections, this depletion seems to occur in the context of limited local and systemic immune activation.

The extent of local and systemic immune activation is the distinguishing feature between the pathogenic and non-pathogenic lentivirus infections\(^4\). It is suggested that in the disease-resistant SIV-infections of natural host monkeys of Africa, evolutionary adaptation has occurred to preserve immune function with a less vigorous ablation of mucosal CD4 EM T cells and an attenuation of the immune activation follows the acute SIV infection protecting these animals from progressing to AIDS\(^5\). Reports reveal that the SIV natural hosts and their specie specific viruses have co-adapted to exist in a non-deleterious state by expressing lower levels of CCR5 on their CD4 T cells isolated from blood, lymph nodes, and mucosal tissues, and perhaps higher regulatory suppression\(^6\). It would appear that perhaps as a consequence of this, the mucosal depletion observed in the natural host may be less functionally devastating when compared to that seen in human HIV infection and the SIV AIDS model of the macaque.

**Consequences of Mucosal Specific Depletion of CD4 Effector Memory T-cell Population:**

It is proposed that the large-scale and rapid depletion of CD4 EM T cells in the weeks after acute HIV infection which occurs predominantly in the GI tract as described above, leads to an impaired intestinal integrity allowing the systemic translocation of gut microbes, or some of their constituent components. Circulating levels of these constituent components are identified as bacterial lipopolysaccharide (LPS), which can be used as a marker for microbial translocation and are found to be markedly elevated in the sera of chronically infected HIV individuals and in macaques experimentally infected with SIV. LPS is known to activate both innate immune cells such as macrophages and adaptive immune T and B cells via Toll Like Receptor (TLR) signalling pathway on the surface of these immune cells\(^7\). This increase in circulating LPS corresponds directly with footprints of immune activation. In contrast nonpathogenic SIV infection of natural SIV infection in African monkeys, microbial translocation does not seem to occur despite the fact that GI tract appears to have undergone similar depletion of CD4 EM T cells. Nonetheless, these findings, although conflicting in our current understanding, does however suggest a possible mechanism for chronic immune activation in the context of a compromised gastrointestinal mucosal surface integrity\(^8\). Further more TLR have also been shown to be activated by free single stranded HIV RNA ligands, which induce T-cell activation. HIV-1-encoded TLR ligands may, therefore, directly contribute to the immune activation observed during viraemic HIV infection\(^9\).

In chronic HIV infection, most untreated patients will eventually also start to lose naïve CD4 T cells as the virus becomes more R4 tropic\(^10\), whereas a minority of patients will preserve the naïve pool despite persistent high viraemia. Although antiretroviral therapy (ART) mediated viral suppression generally results in a rise of naïve and total CD4 T cells, certain patients experience very little or no T-cell reconstitution. Data shows that the inability to sustain a naïve pool from which the memory cells are replenished is partly the result of a sustained thymic defect and is clearly shown in some patients, whereas efficient thymopoiesis will support both naïve and memory cell
compartments with a slower progression time to AIDS. In the majority of ART-treated patients, CD4 T-cell recovery is associated with the normalization of thymopoiesis, demonstrating that efficient thymopoiesis is a key factor in the natural maintenance and recovery of naive and total CD4 T cell compartments.\textsuperscript{34}

**Human Genetic Polymorphisms and HIV Vulnerability:**

CCR5 is the obligate co-receptor for infection by SIV and most transmitted forms of HIV. Humans who lack CCR5 expression (CCR5Δ32) are highly resistant to HIV infection.\textsuperscript{22} Cohort studies indicate that individuals that are homozygous for the CCR5 mutation are almost completely resistant to infection by CCR5-tropic strains of HIV-1. To date, there have been only eight reports of HIV-1 infection in CCR5Δ32 homozygous individuals. These individuals appeared to have been infected with a CXCR4-tropic strain of HIV-1 and did develop AIDS. Individuals that are heterozygous for CCR5Δ32 are infected at rates similar to CCR5+/CCR5+ individuals. However, their disease course is prolonged, presumably because of reduced efficiency of propagation from DC's to susceptible cells via the infectious synapse.\textsuperscript{35}

It is possible that a selection for low expression of CCR5 in humans in high HIV prevalence areas could evolve as one mechanism to escape the pathogenic consequences of infection. In contrast to lentiviral infections of humans and macaques, SIV infection of natural hosts is non-pathogenic despite high levels of viral replication. However, the mechanisms underlying this absence of disease are unknown. Reports reveal that natural hosts for SIV infection express lower levels of CCR5 on CD4+ T cells isolated from blood, lymph nodes, and mucosal tissues. Given that this pattern of low CCR5 expression is found in 5 different species of natural SIV hosts (sooty Mangabeys, African green monkeys, mandrills, sun-tailed monkeys, and chimpanzees) but the converse in 5 non-natural/recent hosts (humans, rhesus, pigtail, cynomolgus macaques, and baboons), suggests it may represent a key feature of the co-evolution between the virus and its natural hosts that led to a non-pathogenic infection. Beneficial effects of low CCR5 expression on CD4+ T cells may include the reduction of target cells for viral replication and a decreased homing of activated CD4+ T cells to inflamed tissue.\textsuperscript{30}

Should HIV pandemic infection persist uncontrolled in human populations, we might observe a bottleneck in the human race positively selecting for genotypes that confer survival advantage to the host in a similar way to what has occurred in African primates. The Chemokine receptor CCR5 is apparently dispensable for normal human growth, differentiation, and immune functions, despite what appears to be a major function in the rallying up of immune competent cells to sites of infection. Among the Caucasian populations, the occurrence of a CCR5-null allele, known as CCR5Δ32, is \(\approx 10\%\).\textsuperscript{22} The CCR5Δ32 allele is a deletion resulting in a frame shift truncation of CCR5 that prevents the mutant protein from appearing on the cell surface. Individuals homozygous for the CCR5Δ32 do not show any apparent adverse phenotypic effects. In heterozygous CCR5Δ32 individuals, cell surface CCR5 is reduced to 20-30% of wild-type levels.

**Immune Disarray is Central to the HIV Pathodynamics:**

The progressive but multi-faceted disruption of both the humoral and cell mediated immune system is orchestrated via several mechanisms. The unrelenting decline of the T CD4 cells is as a result of a combined effect of direct infection, induction of apoptosis, syncytial formation, attrition and eventual thymic failure to replenish the naive pool from which the central memory and effector memory compartments are derived.\textsuperscript{35} The result is immunological memory loss that has been built up over the lifetime of the infected person through antigen encounter and T cell receptor rearrangement. HIV also keeps the humoral compartment in a state of disarray, by mechanism that can only be described as a cytokine storm. This is characterised by a state of activation of the B cell compartment with the characteristic polyclonal hypergammaglobulinaemia.\textsuperscript{16,17} There is evidence to suggest that a reduction of memory B-lymphocytes occurs in HIV infection which correlates with the defective humoral immunity observed and that hyperactivated naive B cells may represent the source of abnormal IgG production.\textsuperscript{38} Cytotoxic cell activity does not escape the brunt of HIV, and
CD8 cells suffer early senescence, which can be measured by telomere length and telomerase activity. Evidence suggests that chronic stimulation of T cells, such as that which occurs in HIV infection results in the development of CD8 T cells reaching a state where they are incapable of cell division much sooner.

Such a failure to proliferate is generally attributed to replicative senescence resulting from a state of continual stimulation as exists in HIV. This is also described as clonal exhaustion and may be one of the handicaps within the host that underlie the inability of cell-mediated immunity to suppress virus adequately.

**Biology as it Relates to Haematovascular Complications:**

The bone marrow microenvironment is profoundly disturbed by this cytokine storm, and is characterized by dysplastic haemopoiesis and multiple cytopenias so frequently seen in HIV infection and AIDS. Although the pluripotent stem cell which expresses both CD4 and CxCR4 co-receptors is resistant to HIV infection, the more committed lines along myeloid, lymphoid and megakaryopoietic cell lines, are highly susceptible to infection with HIV with resultant ineffective haematopoiesis. Clarity of the state of hyperactivation of the immune system as described above that underlies the chronic infection of HIV helps create a better understanding of the factors that promote atherosclerosis and vasculitic phenomena through elaboration of proinflammatory cytokines and interleukins. There is emerging evidence that the vascular tissues as well as corresponding coronary endothelium show significant nitric oxide damage in HIV infection due to excessive oxidative stress. This could provide important opportunities for interventional strategies aimed at reducing the risk, consequences and damage of this oxidative environment on the vasculature.

C-reactive protein levels are higher in HIV patients than in control subjects and there is a strong association and an elevated risk of cardiovascular events. Macrophages and monocytes are also in a state of heightened activity with a potential to migrate to the subendothelial space where they begin phagocytosis of lipoproteins to become foam cells, an early step in atherogenesis. Coagulation abnormalities as well as enhanced platelet activation that would predispose to thrombo-embolic events are well described in HIV patients.

Protein S deficiency is the most common, reported in 73% of HIV-infected men. Serum levels of von Willebrand factor are higher in untreated HIV patients than in control subjects, reflecting endothelial activation.

**Summary**

The pathodynamics of HIV infection in humans is as much a puzzling phenomenon now as it was decades ago at the outset of its discovery. The enigma of this cross-specie infection defines the limitations of our understanding of the whole picture of how man and nature interact and how parasites and host vie for survival of the fittest in a way that ensures genetic preservation of species into the future. At the moment HIV is certainly a young infection still trying to find a happy medium of balance between viral fitness and virulence. Certainly a peaceful cohabitation of virus and host is the ideal circumstance allowing the host to survive to procreate and the parasite the opportunity to be transmitted from one individual to another by adapting to the idiosyncrasies of communities. The current state of affairs is disadvantageous to both infective agent and host. In the African monkey, which is the natural host, mutual adaptation has taken place over many centuries in order to reach a symbiotic chronic non-pathogenic latent infective state. In the meantime, man is suffering tremendous attrition from this HIV plague and its ramifications are all encompassing. No discipline in medicine escapes the wrath of this slow virus on the human physiology, as it slowly chips away at the host’s ability to ward off other opportunists in the environment and simultaneously creating an immunological storm with multiple consequences. We describe in this review the latest concepts on the mechanisms of how HIV is able to efficiently and without fail destroy its host through immunological decay and cytokine induced chronic activation leading to eventual physiological exhaustion and systemic damage through oxidative pressure, with particular reference to the impact on the haematopoietic and vascular systems.

Blood Transfusion
Thoughts on Component Therapy

BY
PETER JACOBS

Department of Haematology, University of Cape Town and the Groote Schuur Hospital.

The transfusion of blood is, to a large extent, concerned with oxygen transport. Over the years an unfortunate tendency has developed in that doctors attempt to correct any deficit in this latter function by the non-selective practice of administering whole blood. Indeed, it has been said by a variety of people, many who should know better, that this approach remains the best way to remedy the problem. But is this really true?

Let us consider first the physicans. Smiley (1972) reported that 30 per cent. of patients in one Canadian centre who needed blood had this provided in the form of pack cells—the remaining two thirds were given whole blood. It is significant that, on the request form, red cell concentrate required special motivation and understandably busy doctors simply checked the box for whole blood and thus avoided extra paper work. In an attempt to determine whether the physicians ordering the blood really understood the problem, the survey was extended for a further period in which it was the whole blood that required motivation. Under these circumstances not one request for whole blood was received in the next year. These observations reflect an indifference on the part of physicians to the advantages that packed cells may have over whole blood rather than any firm conviction that the latter itself was superior for the purpose of increasing oxygen-carrying capacity.

Is it possible that a similar situation could exist in the surgical services? It is generally recognized that blood lost at operation may lead to a hypovolaemic shock and it has been said that the best way to correct this deficit is to restore the blood volume and simultaneously correct oxygen-carrying capacity with whole blood. In both clinical situations a similar response is obtained where the whole blood or red cells combined with crystalloids are administered in appropriate volumes.

If these observations are correct, then the continued use of whole blood in surgical departments may also stem from failure on the part of surgeons to recognize advantages that may result from component therapy.

It is interesting that when this matter is discussed among surgeons it is argued that the most physiologic way to replace the loss of blood is with whole blood. The very fact that ACD is being used, on the assumption that it is physiologic indicates a poor grasp of the situation. It is known that fresh whole blood has a pH of 7.0 and contains 3 to 4 mEq/l potassium while the same product, which has been stored for 21 days, has a pH of 6.5 and contains 16 to 17 mEq/l potassium. In this way the latter product resembles blood taken from a ketotic diabetic with renal failure. In small volumes dilution in the patient’s circulating blood minimizes these effects but large volumes may result in serious metabolic defects.

A second point frequently raised by surgeons in defence of whole blood is that the plasma provides substances necessary for haemostasis including platelets and coagulation factors. This argument is also tenuous since there is a disproportionate requirement of red cells and haemostatic material and it is clearly more logical and effective to provide the necessary erythrocytes as packed cells coupled with other components selected specifically to control the particular bleeding disorder. To illustrate this point we might consider the patient with haemophilia who is actively bleeding. It is known that reliable haemostasis cannot be achieved with the amounts of Factor VIII being infused in the volume of whole blood that will adequately correct the deficit in red cells.

Using these arguments a good case can be made out for component therapy since metabolic complications of acidosis and hyperkalaemia can be reduced while other valuable components in the plasma may be salvaged for more selective use (Beal, 1973).
In this regard it should be appreciated that the shelf-life of whole blood as well as packed cells is 21 days at which time 70 per cent. or more of the cells in the unit collected and stored in ACD will survive normally in the recipient. However, this approach does not take into account wastage that will occur when supply exceeds demand and, here again, component therapy can contribute to the more economical use of blood.

Methods are currently being investigated for freezing and storage of red cells which, when preserved in this way, may be reconstituted after months or even years of storage and immediately used without deterioration in their oxygen-carrying capacity. It is recognised that the cost of such a unit of packed red cells must be taken into account when their commercial use is suggested. Although the cost will initially be somewhat high cells are available to meet demand when supply is less freely available. When calculated to take this fluctuation into account, the cost of frozen cells may well offer benefits once local production was established. There are, in addition, other important reasons why blood stored in this way might benefit the community. In the first instance rare blood groups could be preserved for long periods of time and, secondly, there is now evidence of a decreased incidence of transfusion hepatitis in patients after exclusive use of this product (Carr et al., 1973).

In addition to simply raising the haematocrit much recent work has focused on the effects of storage on the capacity of the infused cells to deliver oxygen normally. Thus it has been demonstrated that storage in ACD decreases the intraerythrocytic content of inorganic phosphate and this parallels increasing affinity of haemoglobin for oxygen. Although it has been suggested that this metabolic defect rapidly corrects itself, the transfusion of large volumes of stored blood may well raise the haemoglobin to normal levels while oxygen delivery, the essential function of the red cells, may be inappropriately or even dangerously low. Appreciation of this point is of special significance in exchange transfusion in the newborn or when massive haemorrhage requires the infusion of large volumes of blood.

In addition to red cells, component therapy is being increasingly developed to provide concentrate of many other blood fractions (Medical Letter, 1972). Their proper use can no doubt refine the way in which the requirements of the individual patient are best met.

The treatment of various haemorrhagic disorders lend themselves ideally to component therapy and the treatment of haemophilia, for example, has undergone significant change in recent years. Originally fresh plasma was used but it was soon appreciated that the antihaemophilic globulin retained its function well when frozen in the fresh state. This preparation remains a popular form of therapy although cryoprecipitate is being increasingly used particularly where large volumes of plasma need to be administered. At the present time special concentrates of even higher activity are being developed while, at the same time, many of the other plasma fractions such as albumin, gammaglobulin, fibrinogen and hyperimmune sera are all emerging as components with real benefit in clinical practice (The Lancet, 1972).

Platelet dysfunction, whether qualitative or quantitative, may also give rise to a bleeding disorder. Thrombocytopenia occurs not infrequently following severe bone marrow damage after the ingestion of drugs including the antibiotic Chloramphenicol. Of special interest has been the problem created by aggressive treatment of a variety of malignancies, including acute leukaemia (Jacobs, 1973) where non-selective chemotherapy produces a varying degree of marrow damage. In these patients intensive haemostatic support with platelet concentrates is essential if optimal amounts of myelosuppressive drugs are to be given. It is important to appreciate that considerable expertise attends the preparation of the platelets and it is mandatory that rigid quality control be effected if the clinicians are to depend on the product supplied. This should include measurements of rise in platelet count after infusion as well as documentation of platelet survival in the individual patient. It is this latter type of requirement that necessitates close co-operation between the blood transfusion services and the clinician.

In addition to the various components described above, increasing interest and clinical dependence centres on the provision of granulocyte-rich suspension. In many situations transient bone marrow depression occurs and this manifests with agranulocytosis. Blood fractionation makes possible the provision of functionally active granulocytes ideally suited for use in these circumstances. In the severely immunosuppressed patient, such as the individual receiving cytotoxic therapy for acute leukaemia, defense mechanisms are severely
compromised and infection presents a particular problem. Much of the advance in the more aggressive treatment of these individuals has been made possible by the availability of this component. The introduction of blood fraction separators into the clinical service will greatly enhance the flexibility and the versatility with which the various blood components may be harvested and used. In centres where these are already available significant improvement in patient survival has been reported. Under normal circumstances, removal of granulocytes from a normal donor results in a small yield while the use of patients with chronic granulocytic leukaemia provides large numbers of functionally excellent cells but the latter approach remains, at this time, an experimental form of therapy.

Blood fraction separators have numerous other advantages particularly where single components of a rare blood type may be frequently required. Thus, in the patient with irreversible drug-induced bone marrow aplasia, who is being considered for bone marrow transplantation and in whom isoantibody formation should be avoided at all costs, the careful use of selected components from one or two carefully matched donors is made possible by this technique in which all other fractions are returned to the donor.

Thus far we have considered only some of the benefits that accrue from component therapy but we should recognise that many of the well-described risks persist. A recent report (Lancet, 1973) reminds us that malaria and trypanosomiasis may be transmitted to patients from donors who have been in endemic areas even though their stay has been brief. Similarly, a problem creating world-wide anxiety is the transmission of serum hepatitis by donors and the advantages of reconstituted frozen erythrocytes has already been referred to. Although component therapy will not completely remove the hazards of blood transfusion, the judicious use of specific fractions may well contribute a further reduction in the hazards which attend this form of therapy.

Component therapy is now firmly established in all major centres in the world and it may be concluded that this practice has emerged as clearly superior to non-selective infusion of whole blood. In the light of increasing familiarity with the benefits that may be expected from component therapy there seems little justification for the continued use of whole blood in situations where specific fractions are obviously clearly indicated. The time is now appropriate for medical schools and teaching hospitals to critically reassess their transfusion practices and, in association with the respective transfusion services, to implement component therapy as a more economical, rational approach to the specific needs of the individual patient.

The Social Basis of Illness

BY

A. B. CHILIVUMBO
University of Malawi

The topic is spongy. Very little research has been carried out on the causal links between social structure and illness. But the meagre work which exists tends to indicate the existence of positive links though the mode of the link still remains enigmatic. A search in literature suggests two broad causal categories: the first is inbuilt in the society, the second results from the strains of social change. Instances of the second resemble those observed by Professor M. Gelfand. In a paper to the conference on Human Biology of Environmental Change held in Blantyre in 1971, he wrote:

"Whilst it is easy to attribute the rise in coronary thrombosis among urban Africans to their greater consumption of animal fats, eggs, bacon, etc., one sees many instances of Africans living in rural areas enjoying a very rich diet not succumbing to this disorder."

Professor Gelfand equates the differential response to changes in the social environment. He writes: "The peculiar stresses of urban life could easily be a factor in leading to a coronary attack. Indeed we know that stress can be an exacting factor in precipitating an attack on coronary occlusion. The occasional cases of thyrotoxicosis or ulcerative colitis, now being observed in Rhodesia, are ascribed to the stresses of a new environment". (Vorster 1972, page 66). Earlier work by White working in Bulawayo supports this. His observation links
REPORT OF THE REMUNERATION COMMISSION

To the Editor: Now that the Association has made an official announcement in regard to the Report of the Fourth Remuneration Commission (1974) and has quoted the Minister's replies to questions in the House, one feels free to point out some obvious inferences and possibly clear up a few misconceptions that may have arisen in the minds of those who have taken the trouble to study the bulky report. There may even be some who have read the review of some selected passages from the report that appeared in the Afrikaans press on or about 12 December 1974. This latter article, by an anonymous 'kamer', is nothing more than an inspired attempt to justify the methods and conclusions of the Commission and to place the medical and dental professions and their representatives on the Commission in a poor light. It also contains some glaring misconceptions. It would not be difficult to guess its origin.

It can be deduced from the Minister's replies that the report was not unanimous, because the representative of the medical profession did not find himself in agreement with the decision of the Commission (majority) and that he drew up a dissentient (minority) report which was found unacceptable by the Commission (majority) and was therefore not presented as a report or part of the report.

The Act itself provides for a report and makes no mention of a minority report. The report is written by the Chairman and is adopted by a majority vote.

There is a statement in the report (para. 11.38) that the representative of the medical practitioners decided to submit a dissentient report (on 16 September 1974) even before there had been a proposal or a final decision on the amendment of the fees of any of the disciplines. The inference, one imagines, is that if he had held his horses he might have fared better in the matter of increases offered.

Anyone who has studied the Act and the workings of past commissions will know that the Commission is appointed on 1 July and is required to present the Minister with a completed report on 30 September. It is a fair inference that a Commissioner who has been in attendance at all meetings—during the hearing of oral evidence and when that evidence, and the data that would be relied upon to arrive at any given conclusion, were discussed — would by the middle of the third month of the Commission's sitting, have a good indication of which way the wind was blowing. It is also a fair inference that if he saw no possibility of substantial agreement with other members of the Commission he would, at a certain point, in time, have decided to submit his own conclusions in the form of a report. To be fit for the Ministerial Desk, such a report surely needed some time for preparation and presentation in a suitable form, and the deadline would then presumably not be 30 September (in this case a Monday), but several working days earlier, say 23 September — which hardly allows abundant time for a well-written and finished article.

It is, furthermore, obvious that only a starry-eyed optimist would embark on a dissentient report without reasonable confidence that it would be accepted as such, even if it had no weight in law but merely represented a point of view. The presentation of a minority report is after all an accepted procedure in our conduct of public affairs. In the event, the Commission, by majority vote, rejected the report and it was still-born, although, as we know from the Minister's reply, it was submitted to him as a document for perusal. He is not bound to make the contents public, and the compiler is consequently also restricted from doing so. One would think that the bulky report of the majority would be able to withstand the onslaught of a minuscule minority report, but the majority of the Commission evidently considered their decision to be the better part of their valour.

An informed criticism of the report of the Remuneration Commission will appear in the SAMJ over the name of the General Secretary of MASA, and there is no one better equipped to deal with this unfortunate document.

For 'representative of the medical profession' read the undersigned.

WHOLE BLOOD OR COMPONENTS — A NATIONAL PROBLEM?

To the Editor: Whole blood is the traditional way of correcting anaemia, and any deviation from this well-established practice requires careful evaluation before it can become an accepted alternative. It is therefore appropriate that the question of component therapy should be critically examined in the light of an increasing demand upon the limited supply of blood available in this country. A prime consideration is the fact that a single unit of whole blood contains many fractions which, if separated and then used selectively, will adequately correct anaemia, provide components which can be used rationally to treat a variety of other deficiencies and, equally important, reduce at least one risk associated with blood transfusion — serum hepatitis.

Many difficulties attend the use of whole blood, including the belief that it is physiological. It is important to appreciate that a low pH and a potassium concentration which rise progressively with storage, create a situation which is far from physiological, and this becomes positively dangerous as the volume of whole blood infused rises. Similarly, the belief that whole blood is the most appropriate way for reseeding clotting factors is also incorrect, since the balance between red cells and plasma elements is grossly disproportionate. Undoubtedly, indications for the use of fresh whole blood do exist, but the rational use of components would go a long way towards restricting irresponsible requests for whole blood — an important consideration regarding the special blood typing policy necessary to provide fresh blood. Thus, with regard to the red cell concentrates, there is no longer any doubt that this is the component of choice for the treatment of patients with reduced oxygen-carrying capacity and normal blood volume. When there is associated reduction in blood volume, the packed red cells are conveniently combined with a crystalloid, such as saline — a practice clearly shown to be as effective as transfusing whole blood in those situations where the initial haemoglobin is approximately 10 g/100 ml and total blood loss is less than 2 000 ml. An additional benefit is the fact that long-term storage at low temperature is becoming a practical way of red-cell preservation with oxygen-carrying capacity maintained intact. While the initial cost of such a programme is somewhat higher than that of fresh packed cells, the advantages must be measured in terms of availability of rare blood groups and the ability to balance a varying supply and demand. Any such system must take into account the special advantages offered by newer anticoagulants and additive solutions designed to promote improved shelf-life of packed red cells.
The provision of platelets is a further excellent example of the benefits that a properly structured component therapy programme may offer. High concentrations may be administered at relatively little volume, and stored platelets may retain significant activity for up to 72 hours under carefully controlled conditions, although some 4 hours are required in the circulator for platelet function to return to normal. The increasing dependence of clinicians upon platelet concentrates for intensive haematological support underlines the need for prospective, controlled research programmes of those centres where, for example, aggressive cytotoxic chemotherapy programmes are in operation for the treatment of patients with acute leukaemia.

It is important to recognize that platelets are maximally effective in situations where production is defective and unlikely to achieve significant improvement where antithymocyte globulin or chemotherapy is in use. Furthermore, the assessment of biological activity of the infused platelets is vital and depends upon a precise knowledge of platelet life-span and the characterization of the patient's haemostatic response to therapy, and an inflexible quality control programme offered by the transfusion service, including the definition of such things as platelet survival in normal and abnormal recipients.

Repeated platelet infusions may be associated with shortened survival on the basis of isoantibody production, and in these situations additional benefits will accrue from the use of HL-A matched platelets. Such an approach places an additional load on the transfusion service, but there can be no doubt that such a challenge must be accepted when all available evidence indicates an increasing need for greater sophistication in the production and use of platelets.

In much the same way, granulocytes are now indispensable to the treatment of drug-induced bone-marrow failure, with its associated granulocytopenia. There can be no doubt that this component will be increasingly required in haematology and oncology. The recognition that patients with granulocytopenia who have obtained yields of functionally intact granulocytes may be obtained by different techniques, including continuous-flow blood separation. This aspect of component therapy is somewhat limited, since granulocytes do not readily lend themselves to storage, and it seems prudent, at this time, to restrict their production and use to specialized units committed to the care of patients with haematological malignancies and equipped with the necessary machinery and expertise for their production and objective evaluation. Furthermore, the likelihood of obtaining, and HL-A matching, is very largely restricted to sibling donation, while high yields from patients with chronic granulocytic leukaemia will, of necessity, be available only in the special setting of a leukaemia centre.

Among the many other components that are derived from the plasma, which include cryoprecipitate, a variety of hyperimmune sera, and a selection of high-potency clotting factor concentrates, including fibrinogen. All these are now in standard production by modern transfusion services, and there is no doubt that their use provides the best available means for selective replacement therapy in the haematologically unbalanced patient.

It is clear from these arguments that compelling reasons exist for providing components which can be dispensed by the blood banks in much the same way as a pharmacist provides individual products on specific indication. The amount of blood in this country is limited and the demand is increasing steadily, so that it is incumbent upon the medical profession to make the best possible use of this precious commodity, and it is self-evident that a properly structured component programme provides the one practical way of achieving this highly desirable objective. There are certain implications for such a suggestion, in that university and hospital staff must acknowledge the shortage of blood, they must recognize the need for a component programme as a responsible means of meeting this difficulty, and thus implement teaching at undergraduate levels and encourage it actively at the practical postgraduate level. In turn, the transfusion services must gear themselves to the provision of components, must accept the full responsibility for the introduction of properly designed quality control programmes, and must ensure that the products offered are dependable and in adequate stock. In the interests of national unity, the question of centralisation of much of the component programme has much to recommend it, and serious consideration needs to be given to the establishment of a single centre which will provide an environment suitable for research into all related aspects of blood transfusion, perhaps coupled with satellite regional services geared for distribution and the provision of specific needs less well suited to centralisation. Urgent thought needs to be given to the provision of such a facility before it is too late, and an opportunity for realistic consolidation is lost forever.

METABOLIC ACIDOSIS IN THE ACUTE ABDOMEN

To the Editor: The article by Mendelow and Miency1 was of interest.

In group I, patients with mesenteric vascular occlusion, 3 patients were shocked and had base deficits of 13, 21 and 22. One patient was not shocked and had a base deficit of 4. No other patient in the study was shocked. Statistical comparison between the base deficit of the shocked patients and the control group (group IV) using a non-paired r test revealed r = 5.5; N = 6; P = 0.0075. The assumption must thus be made that shock, and probably dehydration, from whatever the cause, were the prime movers in the production of a basic deficit.

It is known that hypoxia produces a secondary lactic acidosis2 and it may well be of interest to study lactic acid concentrations in patients with infarcted bowel. If the results of such a study were significant, lactic acid levels could still be used as a clinical diagnostic aid, since the assay takes only 1 hour, and could probably be accelerated.

THE TECHNICAL ASPECTS OF CRYOPRESERVATION OF HAEMATOPOIETIC STEM AND PROGENITOR (CFUc) CELLS

Peter Jacobs and Mona Bracher

The University of Cape Town Leukaemia Centre and the Department of Haematology, Groote Schuur Hospital, Observatory, Cape.

The capacity of haematopoietic stem and committed progenitor (CFUc) cells to withstand long-term low-temperature storage, whilst retaining their viability, has considerable potential in experimental and clinical medicine. The establishment of dependable techniques for cryopreservation will provide a practical means for autograft rescue of patients using their own bone marrow and therefore freedom from transplantation complications such as rejection and graft-versus-host disease. The individuals most likely to benefit from such a technique are those with haematologic and non-haematologic malignancy where myelotoxicity is the factor limiting the delivery of radiotherapy or cytotoxic drugs in doses aimed at disease eradication. Bone marrow is collected under sterile conditions in thromboliquine. It has been established that freezing of the entire buffy layer is unsatisfactory due to a high cell loss consequent upon post-freeze agglutination. The cells are separated on a ficoll-hypaque density gradient using a modification of Boyum's method in which the marrow is diluted in tissue culture medium containing foetal calf serum rather than in a protein-free balanced salt solution. An improved recovery of CFUc has been documented. The cells are frozen in a final concentration of 10% dimethylsulfoxide and the 1% remaining at the time of tissue culture is non-toxic to CFUc. The freezing chamber is pre-cooled and after loading with the samples temperature is reduced at a rate of 10°C per minute. This point is critical and recorded using a carefully insulated probe in one of the actual samples. Cell viability is improved by anticipating the temperature rise associated with the latent heat of fusion and no plateau is allowed to develop at this point. The reconstitution of cells from the liquid phase of nitrogen storage is adversely influenced by failure to rapidly thaw the specimen from -196 and from this point to reconstitute slowly with tissue culture medium. The viability of cells is characterised by in vitro bone marrow culture and in vivo capacity for bone marrow repopulation potential using an animal model.
PERSPECTIVES IN BONE MARROW TRANSPLANTATION

To the Editor: The establishment of an active human bone marrow transplantation programme at Groote Schuur Hospital, as a participant in the international aplastic anaemia collaborative study group, has indicated the need to place in perspective the anticipated benefits and the recognised limitations of this procedure.

The technique is not new, but until recently it has enjoyed only limited application in clinical medicine, largely because the earlier attempts had an unacceptably high morbidity and mortality. However, results reported in the past 5 years are much more encouraging; these undoubtedly reflect an awareness of the place of meticulous tissue typing in donor selection, the availability of protected environments, and an increasing use of all-antigenic granulocyte support. Other factors which contribute to the improved success rate include better methods for the control of rejection and graft-versus-host disease coupled with more effective therapy for the infections that are particularly complex in the immunocompromised host.

For these reasons it is appropriate to review the place that this procedure occupies in selected clinical situations, especially in the management of patients with aplastic anaemia and those with refractory haematological malignancies.

Bone marrow transplantation is not to be undertaken lightly and it is mandatory to recognize and accept the wide-ranging commitment that is an integral part of the successful and responsibly conducted programme. Thus, at laboratory level, reliable facilities are required for meticulous tissue typing and the performance of mixed lymphocyte cultures, upon which proper donor selection rests. Similarly, it is essential that all the necessary methods are available to characterize each graft in terms of cellularity, viability and stem cell content, the last monitored by colony growth in soft agar. In this regard, the first human bone marrow transplant in the Western Cape was performed more than 2 years' experimental work in animals to allow for the adequate development and standardization of these procedures.

Similarly, no programme should be initiated at clinical level without full access to a protected environment, intensive care nursing facilities of the highest order, and a thorough familiarity with the drugs that need to be used. The surgical technique must be accurately controlled, and the whole programme revolves around an active cell support section to provide properly matched and irradiated granulocytes and platelets during the post-transplant period and should be readily available. To retain a high degree of flexibility, we operate both the NC1/IBM continuous flow blood fraction separator and the Fahnert blood separator; in selected situations bone marrow reconstitution is a multidisciplinary undertaking which involves microbiology, respiratory pathology, psychiatry and gastro-enterology, to mention but a few associated groups.

The Cape Town bone marrow transplant programme was initially entered upon to provide definitive treatment for individuals with aplastic anaemia; of the 14 patients admitted during 1972, 13 died and the median survival was under 4 months. There is little reasonable doubt that aplastic anaemia, which must be clearly distinguished from varying degrees of bone marrow hypoplasia, is critically dependent upon marrow reconstitution, since other forms of therapy have been shown to be of very limited benefit to these patients. On the basis of available data, the use of an identical twin as a donor is associated with a success rate of approximately 50%. HLA-identical and MLC non-reactive siblings make possible engraftment in a similar percentage of recipients, with survival approached 50% in some. Observations extend from 4 to 40 months. It must be emphasised that while rejection, infection and graft-versus-host disease continue to challenge the investigators, the greatly improved survival underlines the importance of improving, in concert with the development of this therapeutic modality.

A second group of individuals likely to benefit from the availability of bone marrow transplantation are those with acute leukaemia in whom conventional forms of therapy have been unsuccessful. Patients with refractory tumours, where a severe degree of bone marrow depression with residual disease are obviously unsuitable for further cytotoxic chemotherapy. In this situation aggressive cytoreductive chemotherapy, followed by whole-body irradiation and transplantation, offers a new dimension in treatment. The Seattle group has reported that, with a suitable donor, approximately 25% of these patients in this group achieve complete remission. The magnitude of this particular problem is not, as yet, defined in either the Western Cape or in the Republic of South Africa.

The question of bone marrow transplantation in patients with non-identical bone marrow donation has now emerged as a major challenge for groups dedicated to the study of this disease.

Die Oorplanting van Beenmurg

P. Jacobs, MB BCh MD PhD (Med) WWRand, FCP SA, MRC (Path) UK, FACP

Opsomming

Beenmurgoorplanting het gevestig geraak as die voorkeurbehandeling vir pasiënte met ernstige akute aplastiese anemie of immuuntekortsiets. Indien 'n geskikte donor beskikbaar is, is in hierdie omstandighede vroeë verwysing, voordat isolimmunisering volg op bloedtransfusies, granulosielwat- of plaatjes, tot die grootste voordeel van die pasiënt. Konservatiewe versorging met anabole en androgene by aplastiese anemie blyk oneffektief te wees en behoort dus vermy te word.

By die leukemieëse pasiënt kan allogeneiese oorplanting gebruik word vir die eindstadium van die siekte; maar die herstelkoers is teen beste tussen 10 en 15%. Onlangsse gegewens bevestig die aandeel van hierdie proce- dure by die eerste volledige remissie by volwassenes met leukemie en soortgelyk by kinders waar swak prognostiese tekens aanwezig is. Die eindrol van beenmurgoorplanting in hierdie omstandighede moet nog opge- geklaar word.

Bykomende immunologi- see metodes sal ontwikkel moet word vir die uitkenning en daaropvolgende verwydering van be- smettende tumoroselle van die ent voor sy herin- fuus. Beenmurgoorplanting is dus 'n duidelijk gevestigde terapeutiese prozedure. Alhoewel nog in die vroeë fase van ontwikkeling is duidelike aanduidings omskryf en is 'n vaste toewydig nou tans nodig om die plaslike deskundigheid te ontwikkel asook geneewes om die toenemende aantal verwysde pasiënte te onderskep.

Summary

Bone marrow transplantation is established as the preferred form of treatment for patients with severe acute aplastic anemia or immunodeficiency diseases. In these situations, provided a suitable donor is available, early referral before isolation has resulted from transfusion of blood, granulocytes or platelets in the patients' best interest. Conservative management with anabolic androgens in aplastic anaemia has been shown to be ineffective and should therefore be avoided.

In the leukaemic patient allogeneic transplantation can be used for end stage disease but the salvage rate is at best between 10 and 15%. Recent data have established the place of this procedure in first complete remission for adults with leukaemia and, similarly for children, where bad prognostic signs are demonstrable. The final role of bone marrow transplantation in these situations remains to be clarified.

should decrease with improving general education and early re- ferral of patients. Secondly, graft versus host disease is frequent and poorly understood complication. This unique immunologic phenomenon places limitations on the use of transplantation and presents investigators with their greatest current research challenge.

Autologus bone marrow transplantation has neither of these complications. It however presents a formidable investment of time in technology necessary for the collection, concentration and cryopreservation of haematopoietic stem cells. Additionally immunologic methods will need to be developed for the recognition and subsequent removal of contaminating tumour cells from the graft before its reinfusion. It is concluded that bone marrow transplantation is a clearly established therapeutic procedure. Although still in its early phases of development clear indications have been defined and a firm commitment is now necessary to develop local expertise and facilities to meet increasing patient referral.

Die oorplanting van hematopoetiese stamselle uit die beenmurg van een persoon na die van 'n ander het sy regmatige plek ingeneem by die goedgevestigde, alhoewel nog ontwikkelende, oorplantings- tegnieke beskikbaar in die moderne mediese praktiek. Dit word aanvaar dat die ernstige akute aplastiese anemie of by immuunetekortsietsie dit nou die behandeling van keuse is met statisties duidelike voordeel bo die van konservatiewe behandeling. Minder duidelikheid bestaan wanneer leukemie, Fanconi-anemie of sommige van die lateverlopende genetiese siekte soos homosigoti- se talassemie oorweeg word. Dit is 'n groot mate hang hierdie beperking, in die omvang van beenmurgoorplanting, saam met die gepaarde gane en sterfte te wye aan die onvermoë om implantering te bewerkstellig, aan hul diegene en aan die unieke immunologi- se verskynsel van ent-teen-gasheer-siekte. Laasge- noemde, met die paradox dat dit slegs
by geslaagde inplanting voorkomt, kan tot bij 60% van de pasiente voorkomen en bovendien dodelijk verloop. Om de huidige aandeel van beenmurgoorplanting in perspectief te stellen, is dit nuttig om sommige van de studies op diepe en in

Skenergevaar. Pasiëntgevaar.

Na-oorplanting

Die komplikasies vóór oorplanting kan tot 'n minimum beperk word deur die opleiding van die huisarts en vroeër verwysing van die pasiente.

Tydens oorplanting is die skener in gevaar vanweë die algemene markse en ook volgende op die meervoudige naaipuntes vir die ver- krywing van die beenmurg. Die gevaar vir die pasiente is klein; dit is die gevolg van 'n tyde- like daling in okusgering volgende op die ent-infus.

In die periode na oorplanting is dit gebiedend dat voldoende skelaan beskikbaar is om bloeding en infekkie te behandel. In hierdie tyd neem verwerping toe direk in verhouding tot die aantal voorafgaande bloedtransfusies. Ent-teen-gasheer-siekte is onvoorspelbaar en dus die onderwerp van navorsing.

Die laboratorium met hul tegnieke procedures en resultate in oënsku te neem.

Dierestudies

Die moontlikheid van beenmurgoor- planting is meer as 25 jaar geleide gestel met die aantoon dat die hematopoe- tie se heerlikheid wel plaasvind by le- tantalbestande knaagdie indien die milt van die straalveld beskerm is, of indien murg intravenerus ingeborg is. Kliniese studies is bevorder toe Mathie e.m. oor- plantings gedaan het op 'n aantal pas- inte wat aplasties geword het g.e.v. 'n onwel met 'n kernreaktor. Sederdien is hierdie procedures meermale aangedurf en is die gegevens deur Botin' sistematies ontleed. Die betreklik swak resultate wat tot op daardie tydspan verkry is, toon die swak instig oor die belangrikheid van weefselstaping. Oor die afgelope 5 jaar het bekend geword dat meer as 100 persoon selle hematopoiëtiese funksie kon handhaaf vir meer as 'n jaar van langer na beenmurgoorplanting. Hierdie stand- houende verbeurting is te wye aan beter passing tussen skener en ont- vanger.

Dit was deur die gebruik van inge- tekte dierstamme, wat dieselfde weefsel- antige deel en dus geen immunologi- seke skies tot oorplanting of geënt, wat die modelle verskaf is om 'n aantal belang- rike oorplantingsbeginne te omskryf. Hulle bevat: die minimum aantal selle benodig vir geslaagde oorplanting, die handgrepe benodig om oorbliveende immuunfunktie by die ontvanger te onder- druk en sodoende oorplanting meer uni- form te maak, en die moontlikheid dat immunologieskompetente selle van die skener ook antitumorwerking na die gasheer kan oordra.

Die diermodel is het ook 'n belangrike rol gehad in die onderzoek van ent-teen- gasheer-siekte waarin ontstekingsreakties gerig is teen lewer, vel, en maagdiemka- naal deur selle van die nuutgevestigde oorplanting. Met die meganisme nog onbekend word gemaan dat limfosiëte en makrofage in die patogenese betrokke is en KAY7 die belangrikheid bekleen- toon van antigenie-dispariteit, infektie, en voorafgaande geneesmiddelbeurting of besturings om die felheid van hierdie ver- skynsels te verhoog.

Dierestudies het verder getoon dat in- feksies nie maklik onderskei kan word van ent-teen-gasheer-siekte nie (Jones e.m.), daar sowel die voorokse as die felheid verminder is wanneer muis 'n klein vrye omgewing onderhoud word. 3, 16, 11 Die daartussen van 'n soortgelyke on- standigheid by die mens is 'n geweldige groter uitdaging en dit is te betwyfel of volledige vrywaring teen besmetting deur mense moontlik is.

Proefdierroutines i.v.m. die beheer van ent-teen-gasheer-siekte is bekend. By beenmurgoorplanting is daar die oordrag van hematopoëtie se stamsele saam met 'n aantal immunologieskompetente lim- fosiëte na die gasheer; in daardie omstandig- heid waar laagvemde tolerant is teenoor antigene van die ontvanger, 2008 by singeneesi oorplanting, kom ent- teen-gasheer-siekte nie voor nie. Die allo- geniese oorplanting is oor die meer ge- bruiklike en hierby is pogings minder geslaag om die ontstaan van die uitbreiding te voorkom, of die felheid daarvan indien geestig te verminder. Studies is teens daaropmerking waarin gepoog word om die verweterende werking van immunologi- sekompetente selle te wysig, bepaal in dierroutines is sowel parenterale Coryne- bacterium parvum as SIKLOPOOR- A3 doeltreffend. Dit moet nog vasgestel word of die gebruik van hierdie immunolo- giese adjuvante by die mens 'n soortgelyk effekt kan bereik.

Laboratoriumstudies

Een van die hooflikers wat die doel- treffendheid van die ont bepaal, is die
verskaffing van 'n voldoende aantal hematoïde stamcellen. Terwyl die aantal kernstelle oore Gedraad dit in die algemeen kan verseker, is aangetoon dat bekamurkultuur 'n emnoude praktiese wyse is om uit te ken welke infusies minder as die benodigde aantal voorlopers bevat. Met 'n uitgestrekte tektork beheer oorweging gegee te word aan die aanvulling van die aantal stamcelle deur daglike infusie van geëepeen verkry van die skenner deur senufruger in bloedeffraktes met deurkopende vloei.13

Beemurkultuur in die laboratorium kan ook ter sake wees in die poging om pasiënte uit te ken met ernstige akute aplastiese anemie waar die letse te wyte is aan 'n defektiwe stamcel en die verwanking van hierdie bevolking nodig is. Daaromnoor is 'n aantal pasiënte tans uitgekeer waar immunologiese oppressive oorheers, en reaksies gevolg het op immunoonderdrukkende terapie waar plomptege gelaat het.16

Murgoorplanting by Mense

Pasing vir weeselsanaarbaarheid blyk te wees een van die belangrikste bepalers vir geslaagde implantatie. Die belangrikste komplices van weeselsanaarbaarheid by die mens is bepaal deur 'n reeks genes wat antagon steur op die seopepervlak kudde, sommige waarvan serologie bepaal kan word, andere gedeelte deur 'n reaksie in vreemde limfosië.17 Terwyl daar weinig twyfel bestaan dat hierdie stelsel van oorwonebare basis in die berekening van die beste pas van skenner en ontvanger, is daar nog meningsverskl onder die relatiewe belang van die twee tegnieke vir antigeneuitkenning.

Ongetwyfeld is volmaakte pas die beste manier om ontwerpvering te vermindere ('n hierdie probleem op 'n laagste voorkom al by identifiseerde tweelingoorplanting of waar ingegteelde stamme van dieprepers gevoel is. In allogenese oorplanting waar gepasse broer of suster as skenker dien, is dit noodsaaklik om die immuunfokus vir oorplanting in die pasiënt maksimaal te onderduik gewoonlik deur die gebruik van intensiewe toediening van sitorioksi. By pasiënte met leukemie bestaan die verdere probleem om die residuele skiik uit te wus sodat heellangamendelkiew dié gepas word en die medikamente as deel van die voorbereiding. Hierdie procedures bring wees 'n aansienlike graad van skiik. Baie werk word gedaan om te bepaal welke van die verskeie programvorsing die meeste immunoonderdrukkende of verdraagbare neew effekte bereik.

In bepaalde omstandighede waarin die lewensvare eentjie met die eerste poging faal, is verdere voorbereiding noodsaaklik gevolg deur heroorplanting. Die ervaring tot dusver is beperk maar by 'n aantal pasiënte was dit geslaagd.18

### Fig. 2: Die Aandag van Laboratorytngemie in Murgoorplanting

Die boomsurkultuur in vitro met gebruik van 'n gestandardiseerde tegniek (Jacobs et al, 1979) is 'n nuttige laboratoriumgid in boomsurgoorplanting. Die groei in kultuur is swak by aplastiese anemie maar waar dit verbeter in die aanwesigheid van antimitosiegolulien (ATG) kan die pasiënt reageer met of sonder 'n ent. Hierdie tegniek is 'n belangrike metode om 'n ontstrekende ent van te stel wat dan aangeval kan word met 'n infusie van hematoïde stamcelle daaruit versamel deur aanbouwende vloeis en senufruger van bloedeffraktes. Waar toetrekke groei in vitro aangetoon is kan die vat van die ent verwag word.

### Tegniek van Beenmurgoorplanting

**Thomas c.m.** het na langdurige en sorgevulde werk die metodes gestandardiseer. Die ontvanger se retikubendoteelstel word aanvanklik geprikkel met antigene bekoom uit die skenner se geel laag, en voorbereiding met siklosofo mied 24 uur later begin. Hierdie gevolgeverbouingse infusie18 prikkel die kompetente limfosië tot vermeerdering wat hulle selekty gevoelig maak vir die sitoriokië verwerking van die allikheerstof.

Beemurkultuur word deur meerder aspirasies van kleinvolume uit die sterone en die leukamia versamel. Nagenoeg 500 ml van murgkybloed word stadig intraveneus aan die ontvanger toegedien. Gedurende die omstandighede 14-21 dae benodig vir implantaat, by die pasiënt swaar pasiëntoenies en benodig hulle intem ei steun met witselu en platoor. Dit word geraakaf vanaf die skenker verskaf deur deurhendue-vloeiskeile, of waar onnodig vooraf 'n standaard skenkerpanel. In die meeste oorplantingseenhede vorm die afdeling selstel 'n integrale deel van die oorplantingseenheid.

**Ydeus** hierdie pasiëntoenies tydepest is swak mikrobioloogise beheer oor eksogene organismes belangrik vanwee die cepte onderdrukking van die immuneheer van die ontvanger, wat hulle hoogvatbaar maak vir fulminerende bakte riole infeksies en die inval deur opportu nistiese organismes.

Inplanting is gewoonlik waarneembaar tussen 10e en 21e dag en kan deur beenmurgkybloed of trebenbiopsie bevestig word.

---

Met die implantaat aldis bereik, staan die pasiënt voor die volgende en miskien ernstiger gevaar nl. die ent-teens gasheerskie. Ondanks bestendige verbetering in die bepaling van weeselsanaarbaarheid en in die ontvanger se voorbereiding by die voorsom en die eres van hierdie immunologiese besonderhede onverander. In 'n prospektiewe ewekansige studie het Thomas en sy groep20 getoon dat die geslagraffmising tussen skenker en ontvanger en suggers die weerspanningheid van die gasheer tot luktlike skenkerplanet in die omstandighede van die skenkerpatroon en terwyl dit dikwels selfverwerking is, kan dit to 'n wydspreided sklerodermatose uitbrey. Tot dusver was profilaksie nie geslaag nie en is bebehandeling van die gevegste skiekie slegs ten dele geslaag.21 Van besondere betekenis is die onlangse verslag dat een-teens-gas heer-skiekie effekief is in die vermindering van die voorsom van leukemiese tegrug by pasiënte waar oorplanting vir hierdie rede onderwerp is. Onthoud egter van die algehele sterfte toon weinig voordeel vir hierdie groep omdat dit dusver pasiënte wat hierdie komplikasies ontwikkeld 'n hoër voorsom by volwassenes van kleale respiratoriese sparringsvorm toon.
Beenuurgaplasie

Die grootste probleem met die ontlen-
ding van resultaat bereik met konserwa-
tiewe behandeling teenoor die by buen-
murgoorplanting vir pasiënte met apla-
tiase anemie, is die versui in bly wer-
kers om hul kriteria duidelijk te umkryf.
Die onlangs ooreenkomstig 'n interna-
tionale saamwerkende studiegroep1 het daardie subgroep van pasiënte duidel-
lik uitgeken waar buenmurgoorplanting aansienlik beter oorlewing as ander
vorms van behandeling bied. Hierdie pa-
siënte word gerekend deur 'n plaatjie-
telling van minder as 20 x 10⁶/µL, granu-
losiie minder as 0,5 x 10⁹/L en 'n aangep-
paste retikulatoietelling van minder as 1%.

Thomas e.m.20 het by so 'n uitgesoekte
groep aangetoon dat met gebruikmaking
geneeskrachtige oorplanting dit 'n doen-
like procedure is, met drie van hul pa-
siënte nog in lewe en gesond en die
langere oorlewingstyd meer as 16 jaar.
Die verdere belang van hierdie waar-
neming is dat dit die fout in die samentew-
derstreep wat vervang kan word vanaf
' n gepaste skenker. Hierdie gegewens,
gepaard met resultate van die internatio-
naal saamwerkende studiegroep, bevesti-
g duidelijk die plek van buemurgoor-
planting by aplastiase pasiënte. Dit is
eiger nodig om te beklemtoon dat ver-
wysing onmiddellik by die diagnostie-
king gebiedend is om in vitro-sensitise-
rings soveel moontlik te verminder wat
die kans op sukses met opvolgende oor-
plantingspogings op te werk.

Van onlangs belang is die verslak25,16
dat, volgende op aggressiewe sitiatieska,
enkele pasiënte 'n hemopoietiese her-
stel sal ondervind ondanks die feit dat in
planting gefaal het. Hierdie waan-
nemings bring die vraag na vore van alter-
natiwe patogeeniese mekanisme en die
kiesing dat immunoogebiede disfunksie van hemopoietiese voorlo-
perscele, of 'n ongunstige mikrooomgewing
ween, buemurgoorplanting kan meebring.
Daar word ook op gelet dat hoe dorstings
siklofoamfie van hierdie individue, blykbaar met die residuele bloedvorm-
ende selle vernietig nie aangestig hulle
later 'n spontane herstel meegebring het.
Dit skyn dus belangrik om te bepaal
welke pasiënte met enkele buenmurgoor-
plantasie herstel benodig op die basis van
diegete samentewende teorien die
ingeenheid van die immunoogebiede
mechanisme van her-
sters.

Hierdie gegewens van geneeskrachtige
oorplanting en die risiko van samentew-
ding van hierdie pasiënte word dalk
as se foto genoem. Die resultaat van die
planting met enkele selle wat in die
ent ontstaan.

Chroniese Granuloomse Leukemie

Die gebruik van buemurgoorplanting
by hierdie pasiënte bly nog onduidelik
van aard. Alhoewel sitiatieska chemote-
rapie of melngetralief 'n tydelike beheer
bereik, is die mediane oorlewing nie we-
senlik verleng nie. Teories is dit moont-
kan ook ontstekende vleigmentering
verwek en onduidelik skiel in die vorm
van skleromaatk. Vreug uitkoms en
behandeling met kortkortkortkortkort
korttektiesproses. Die
dag word
gemeen dat in die chroniese pasiënte
van die siekte, die aanvallende limfosiite
as deel van die ontstaanste in
ontstaan.

Versoepelingsbehandeling is
behandeling in onbevredigend. In
prof-
diere is pogings om die iets van die en-
teen-gasheer-siekte te wyk nie geslaagd
t nie. (Parker et al, 1976, Jacobs et al,
1979.)
lik om sirkulerende stamcellen te versamel en hulke vir in 'n auto-entherstel te berg, na uitwissende stiotoskiese of 'n gekombineerde modaliteit van behandeling by die aanval van versamelde siekte of blas-tomvorming. Sodanige benadering bly in wees verdrag daarin dat leukemische selye in die pasiënt teruggebring word.

Van groter betekenis is die waarne-mings dat die Philadelphiachromosoomarmende kloon uitgewas kan word deur aggressiewe voorbereiding van allo-geneiese beenmurgoorplanting.28 Met bevordering van hierdie studies asook van die versuim om die neoplastiese kloon te hergrys, sal beenmurgoorplanting ver-skyn as die eerste keuse van behandeling met enige kans op sukses by pasiënt met chroniese granuloidse leukemie.

Akute Leukemie

Beennmurgoorplanting by leukemie was oorspronklik beperk tot pasiënt met 'n gapeaste broër of suster nadat die gebruiklike medicamente gebruik het. Dit is ongelukkig nie aangebied na meerdere terugvalle of waar weerspannige siekte gevestig geraak het. Selof onder sodanig hoog ongunstige omstandighede het tussen 10 en 15% van pasiënte tot langer as 2 jaar siektervry gebleek. Hierdie gereg-wens verskaf wetenskaplike bewys om die gebruik van beennmurgoorplanting by sowel volwassenes as kinders te ondersteun selfs nadat die eerste terugval gebeur het.

Tot op datum is sodanige individue nie veilig uitkenbaar nie wat as 'n verdere argument dien ten gunste daarvan om die prosedure aan te bied aan diegene waar, alles in ag geneem, die vooruitstig oungunstig is. Die uiteindelike plek van beenmurgoorplanting by hierdie pasiënte bly onbepaald en sal 'n klein aantal sentrum suggereer dat hul vermoënt moet betrek om inligting te bekom. Beheerdata sal uiteindelike beskikbaar kom in die vorm van pasiënte waarvoor ge-paste skenkers nie beskikbaar nie of by diegene wat om een of ander rede en goed ingelig, tog verkeers om beennmurgoorplanting nie te aanvaar nie.

Ootola Beennmurgoorplanting

Die ontwikkeling van tegnieke vir die berging — by lae temperature en oor laagtermyn — van sorgvuldig versamelde en uitgewasen stamcellen uit menslike beennmurg of perifere bloed, het 'n aantal nuwe en aantreklike behandeldingsmogelijkhede meegebring. Alhoewel auto-entherstel — soos bosp forasio en chroniese granuloidse leukemie —, van beskikbaar is dit waarskynlik met voldoende leukemiese blastes besit om die murg te herbeseend en nuwe siekte te verwek, is dit nie noodwendig die geval by solide tumore nie. By laaggenoemde bestaan die moontlikheid om onbesmet beennmurg van pasiënte te bekom en dit vir hervorming in 'n tydspan waar murg reorgeniëring deur radioterapie of chemoterapie 'n beperking bring op die hoeveelheid van behandeling wat met veiligheid toegedien kan word.

Weer eens sal dan die aandeel van auto-entherstel in die geneeskundige praktiek uit- eindelik pas heder word soos geegens inkom en sukses as geldige vergelykings moontlik maklik tussen resultate by pasiënte met oorplantings en pasiënte met ander vorms van behandeling.

Samevatting en Gevolgtrekkings

Beennmurgoorplanting is 'n goedgeves-tigde vorm van behandeling by pasiënte met ernstige akute aplastiese anemie en immuunpostskietes. Met die voorbe- houd dat 'n geskikte skenker beskikbaar is, is die duidelike bevordering van voorkeur by hierdie individue die onmiddel- like verwysing vir 'n beennmurgoorplanting. In die lig van beskikbare getuiskes is daar min regverdiging om behandeling in afwagting toe te dien wat slegs die moontlikheid van later toebehoors planting kan benadeel.

Die aandeel van beennmurgoorplanting by volwassenes en kinders met akute of chroniese leukemie, Fanconi-anemie, leukeatogenetiese siektes, en volwassenes, word tans intensief nagevors. By akute leukemie met terugval by die aarde van hierdie procedure aan te bring by volwassenes en kinders met oungunste.

---

**Fig. 5: Resultate by Oorplanting**

A. Ernstige saamgestelde immuunpostskiekte. Min imulie enige oorlewende is vermeld onder oorplanting. Waa dons beskikbaar is kan syfers so hoog 50% gevind word.

B. Ernstige akute aplastiese anemie. Afhangende van die kriteria gebruik in die rekke vermeld, het die kontrolepasiënte nagenoeg 2 jaar oorlewing in die streek van 10%.

Gee dat vergelyk met diegene volgende op beennmurgoorplanting met geno- singssyfer nagenoeg 50%.

C. Weerspannige leukemie. Die oorlewing sonder in oorplanting is nut: dit kan 15% siektervry wees by 2 jaar.

D. Remissie-oorplanting vir akute leukemie. By volwassenes met mieloblastiese leukemie behandel met stiotoskies is wisselende oorlewing meestal in die gebied van 15% by 2 jaar vermeld.

In voorlopige gegevens waar murg-oorplanting gebruik is en waar pasiënte hul eerste volledige remissie bereik het, is die siektervry plato nagenoeg 60%.

296

**Geneeskunde — June 1980**
n Krachtige anti-prostaglandien moet als frontlinie-behandeling vir die pyt en inflammasie van artritis beskou word. Aangesien daar 'n soortige korrelasie tussen anti-prostaglandien-aktiviteit en kliniese aktiviteit is, is die logieuse eerste keuse vir maksimum-beheer oor die pyt en inflammasie van artritis 'n besonder krachtige anti-prostaglandien, Froben.

Aanbevoe doses: 150 mg tot 200 mg daglik in verdeelde doses. In pasiënte met ernstige symptomte van siekte van onlangs oorsprong, of tydens akute toenames, mag die doses vermeerder word tot 300 mg daglik in verdeelde dosisse.

Aangewys in osteoartrrose, rumatoïde artritis en gewrigsverstydende spondilitis.

NATURAL COALITION OF IDEOLOGIES
MEDICAL PROGRESS

BONE-MARROW TRANSPLANTATION

E. DONNALL THOMAS, M.D., RAINER STORR, M.D., REGINALD A. CLIFT, F.I.M.L.T.,

KENNETH G. LERNER, M.D., HAROLD GLUCKSBERG, M.D., AND C. DEAN BUCKNER, M.D.

THE modern era of bone-marrow transplantation was ushered in by the experiments of Jacobsen, Lorenz and their colleagues, who showed that mice could be protected against otherwise lethal irradiation by shielding of the spleen or by intravenous infusion of marrow. At first it was thought that this protective effect was due to a humoral factor. By 1956, however, several laboratories, using a variety of blood genetic markers, demonstrated that the protective effect against lethal irradiation was due to the colonization of the recipient marrow by donor cells.

An article on clinical marrow transplantation that appeared in this journal showed that large amounts of marrow could be infused intravenously with safety, and described a transient marrow graft in man. It also provided estimates of the number of marrow cells needed and pointed out the potential application of marrow grafting to radiation accident victims, to the therapy of leukemia and to the therapy of patients with immunologic deficiency disorders (at that time collected under the heading of agammaglobulinemia). In the following year, Maché et al. attempted the dramatic treatment, by marrow transplantation, of six human victims of an irradiation accident. Despite the promising potential usefulness of marrow transplantation, the next decade was one of frustration and disappointment. Most marrow grafts were carried out in terminally ill patients who did not live long enough for a graft to be evaluated. The few successful allogeneic grafts were followed by a lethal immunologic reaction of the graft against the host. Recent advances in the knowledge of histocompatibility typing, in the prevention and management of graft-versus-host disease and in supportive measures for patients with no marrow function have renewed interest in the subject of marrow transplantation. In this article we shall attempt to review the basic immunobiology relating to and derived from the field of marrow transplantation and to describe the clinical progress that has been made, recognizing that this is only the beginning of a new phase in the development of a medical therapy.

EXPERIMENTAL BACKGROUND

Studies in Rodents

The availability of inbred strains of mice has made possible extensive study of the genetic systems that govern acceptance or rejection of a tissue graft. The most widely studied immunosuppressive regimens to prepare the recipient for allogeneic marrow engraftment in rodents have been total-body irradiation or cyclophosphamide (or both), with occasional addition of antilymphocyte serum. The amount of radiation required to permit engraftment and prevent rejection of incompatible marrow is higher than that which will induce fatal marrow aplasia. Total-body irradiation is most immunosuppressive if administered within 24 hours before the antigen, regardless of the nature of the antigen. Cyclophosphamide is an effective immunosuppressant in nonlethal doses, but is more suppressive if administered one day after exposure to tissue antigens of the marrow donor. Although cyclophosphamide can suppress an established cell-mediated immune response against some

antigens in some animal models.\textsuperscript{18} It did not permit marrow engraftment in a rodent host presensitized to donor antigens several days before the cyclophosphamide administration and marrow infusion.\textsuperscript{19}

Graft-versus-host disease occurs whenever marrow or other tissue containing immunologically competent allogeneic cells is infused into a host who is unable to reject the infused donor cells. The pathophysiology remains unclear,\textsuperscript{20} especially the contribution of the host to the disease. The effector cell mediating graft-versus-host disease is probably a T cell, but involvement of other cells populations is likely.\textsuperscript{21} Although rodents with graft-versus-host disease die of infection that is presumably due to the immunoincompetence caused by the disease,\textsuperscript{22} it is possible that infection is an intrinsic part of the graft-versus-host disease process with activation of latent infectious agents.

The treatment of graft-versus-host disease is a formidable problem. Methotrexate has been effective prophylactically.\textsuperscript{23,24} Cyclophosphamide, procarbazine, the combination of cyclophosphamide and procarbazine, and cyclophosphamide and arabinoside are somewhat effective even against established graft-versus-host disease in some rodents models.\textsuperscript{25-28} Other approaches reported to have some effect in some models included administration of host lymphoid cells and antibody directed against donor isoantigens or against host isoantigens (as a form of enhancement).\textsuperscript{29,30} To date, the most impressive therapeutic results have been reported in mice kept in a germ-free environment and prepared with lethal total-body irradiation.\textsuperscript{31,32} When the animals were given allogeneic marrow the rate of fatal graft-versus-host disease markedly decreased, but spleen cells still resulted in fatal graft-versus-host disease. Finally, the literature is replete with approaches to specific or preferential elimination of lymphoid cells capable of inducing graft-versus-host disease from donor marrow suspensions.\textsuperscript{33,34,35,36} These approaches remain highly experimental and variably efficacious.

The application of marrow transplantation to tumor therapy received early attention on the basis of the rationale that tumors, especially hematologic neoplasms, might be eradicated by lethal doses of total-body irradiation and that donor marrow would repopulate the host and prevent radiation-induced death. The attempts to use such an approach have been based largely on studies in readily manipulable rodents bearing a variety of tumors as recently reviewed.\textsuperscript{37} Interpretation of the results of syngeneic marrow transplantation in tumor-bearing mice has been influenced by several findings in the area of tumor immunology: most murine tumors possess tumor-associated antigens capable of evoking a cell-mediated as well as humoral antibody response against them; adoptively transferred lymphoid cells can inhibit tumor growth but only if the cells are immune to tumor-associated antigens, but with rare exceptions, such adoptive tumor immunotherapy, although characterized by unique antitumor specificity, can cope with only a small tumor load; and in several murine tumor models such syngeneic adoptive immunotherapy when used as an adjunct to sublethal chemotherapy can eradicate even clinically evident leukemia if the syngeneic lymphoid cells are immune to tumor-associated antigens.

Allogeneic marrow transplantation for leukemia represents a final common pathway between the problems of transplantation immunology posed by the graft and the problem of antitumor chemotherapy and immunotherapy posed by the presence of leukemia. The only additional element introduced is that of the effect of graft-versus-host disease on the leukemia and possibly the effect of the leukemia on the severity or expression of the graft-versus-host disease. Barnes et al.\textsuperscript{38} postulated that allogeneic marrow infused into leukemic mice after lethal total-body irradiation would colonize the host and would "destroy," by the action of the immunity these residual leukemic cells — and perhaps also the host. Many studies with histocompatible cells have shown that graft-versus-host disease when sufficiently severe will affect some tumors, but most mice will die of graft-versus-host disease whereas a few mice will survive the fatal disease and will be tumor free. Maté suggested the possibility that one might use the graft-versus-host disease against the tumor\textsuperscript{39} but then treat the graft-versus-host disease and save the cured host. Unfortunately it is extremely difficult to control the graft-versus-host disease once it is established, even in non-tumor-bearing mice. One approach was recently illustrated in a murine tumor model in which nonlethal subclinical graft-versus-host disease was effective against a disseminated leukemia, but the same reaction was immunotherapeutically more effective when induced by lymphoid cells from donors preimmunized against tumor-associated antigens.\textsuperscript{40}

Studies in Dogs

In our laboratory we have carried out extensive studies with dogs, as an animal model of random-bred species, for studies of principles and techniques applicable to man.\textsuperscript{41} Dogs have a major histocompatibility complex called DL-A (reviewed by Albert et al.\textsuperscript{42}). Canine families are readily available for genetic studies of transplantation antigens, and canine litters provide matched sibling pairs simulating the HLA-matched human sibling pairs. Important observations include the following:

1. Studies in dogs indicated that cyclophosphamide can be substituted for total-body irradiation to condition recipients for marrow transplantation.\textsuperscript{43}

2. Marrow can be effectively stored at low temperatures in dimethyl sulfoxide for use in marrow grafting.\textsuperscript{44}

3. Stem cells in the buffy coat from the peripheral blood are able to repopulate the irradiated marrow spaces.\textsuperscript{45} Such stem cells are absent among thoracic-duct lymphocytes.

4. The dog was the first animal in which the predictive value of in vitro histocompatibility testing for the outcome of marrow grafts was demonstrated.\textsuperscript{46} Canine littersmates matched at the major histocompatibility complex survive better than mismatched ones, but approximately 50 per cent of the animals succumb to late graft-versus-host disease.\textsuperscript{47} This result indicates that "minor" histocompatibility differences also can play a part in the development of fatal graft-versus-host disease. Such disease can be pre-
vented or reduced in severity by the prophylactic use of methotrexate after grafting. \(^\text{46}\) The drug can be discontinued approximately three months after transplantation without subsequent development of graft-versus-host disease. Antithymocyte serum is of value in treating established graft-versus-host disease.\(^\text{49}\)

5. Blood transfusions before grafting, even from a donor compatible at the major histocompatibility complex, may sensitize the intended marrow-graft recipient and make graft rejection much more likely to occur.\(^\text{50,51}\) A regimen of procarbazine and antithymocyte serum preceding total-body irradiation appears to be of value in abrogating such prior sensitization.\(^\text{52}\)

6. Long-term healthy marrow chimeras can be achieved in this random-bred species,\(^\text{53}\) with chimerism persisting for at least 10 years. These animals can be used in studies on the nature of the operational “tolerance” necessary to maintain the stable chimeric state.\(^\text{54}\)

7. Certain canine spontaneous diseases such as hemophilia, cyclic neutropenia, malignant lymphoma, leukemia and other malignant solid tumors as well as hemolytic anemia associated with congenital pyruvate kinase deficiency are valuable models to study the use of marrow grafting for the treatment of these diseases. For instance, it was possible to show that canine cyclical neutropenia is not due to a deficiency of marrow regulation, but rather to a stem-cell defect that can be corrected by marrow transplantation.\(^\text{55,56}\) In canine hemophilia, orthotopic transplantation of a normal liver into a hemophilic dog resulted in complete correction of the deficiency of factor VIII. However, there are noteworthy extrahepatic sources of factor VIII, since hepatocellular normal dogs bearing a transplanted liver from a hemophilic dog show factor VIII levels equivalent to that seen in the heterozygous state.\(^\text{57}\) Marrow grafting studies ruled out the hematopoietic and lymphoid systems as sources of factor VIII production.\(^\text{58}\)

**Studies in Nonhuman Primates**

It was thought that the monkey was the animal of choice for study of problems in marrow transplantation because of its close phylogenetic relation to man. The work of the Dutch researchers has focused on the early occurrence of fatal graft-versus-host disease in the monkey after transplants between randomly selected donor and recipient.\(^\text{59,60}\) It was believed that the monkey differed in that respect from the dog and mimicked more closely the human situation, in which rapid onset of graft-versus-host disease with fatal outcome had been reported. When dog and monkey were compared, however, severity of graft-versus-host disease, time of onset and fatality rate did not seem to be different if donor and recipient were known to differ at the major histocompatibility complex.\(^\text{61,62}\) Van Bekkum and DeVries have provided excellent descriptions of the histopathology of the lesions of graft-versus-host disease observed in the monkey.\(^\text{11}\) Other studies in primates have focused on conditioning regimens. It was observed that very high doses of cyclophosphamide are needed to obtain successful grafts of allogeneic marrow. It was also found that the limiting toxicity of the antineoplastic drug in the primate is fatal cardiac toxicity.\(^\text{63}\) The problem with the monkey model is related to the fact that the animals are scarce, expensive and breed slowly. For these reasons, studies on grafts between monkey siblings have not yet been reported. The monkey is difficult to handle during the necessary intensive-care post-grafting. Also, monkeys with spontaneous hematologic and neoplastic diseases are rarely available.

**Human Marrow Transplantation**

**Histocompatibility**

Syngeneic or isogeneic marrow grafts, as between inbred mice or between identical twins, involve donors and recipients carrying the same tissue antigens, and thus there is no immunologic barrier to transplantation. A special kind of syngeneic graft, an autologous marrow transplantation, refers to infusion of the patients' own marrow that was set aside before intensive radiation therapy or chemotherapy.

An allogeneic marrow graft involves a donor and recipient of different genetic origin within the same species. Such transplants involve moderate to severe histoincompatibility and present a bidirectional immunologic barrier to transplantation. In the first place, the recipient may react against the graft and reject it. Secondly, a problem unique to the transplantation of tissue containing immunologically competent cells, the infused marrow cells from the donor may react against the host to produce the illness known as graft-versus-host disease.

In the mouse the major histocompatibility complex, called H-2, is composed of at least two serologically detected loci, an immune recognition locus and two lymphocyte-detected loci recognized by reactivity in mixed leukocyte culture.\(^\text{64}\) In addition to the H-2 region, a number of minor histocompatibility loci have been identified. The complexity of the major histocompatibility complex in the mouse seems to be reflected in the outbred species studied, principally the dog (reviewed by Albert et al.\(^\text{65}\)), the monkey\(^\text{66}\) and man.\(^\text{67,68}\)

In man, the major histocompatibility complex involves two closely associated serologically detected loci, the first, or "A," locus, and the second, or "four," locus. Antigens determined by the serologically detected loci are recognized by cytotoxic isoantisera raised by immunization or that arise during the course of pregnancy. More than 13 first-locus and 15 second-locus antigens can now be identified, and the resulting very large numbers of haplotypes make this the most complex genetic region yet recognized in man.\(^\text{69,70}\) The term haplotype was introduced by Cepellini to indicate the products of the major histocompatibility complex in haploid form. In addition to the serologically detected loci, there is a closely associated lymphocyte-detected locus just outside the "four" locus.\(^\text{61}\) Studies of the lymphocyte-detected locus are currently under way utilizing lymphocyte-detected homoyzogous cells as identified in the progeny of related marriages. Already several lymphocyte-detected types have been identified.\(^\text{67}\)

Marrow grafts between unrelated human beings carry a
high probability of major histoincompatibility due to the complex polymorphism of the major histocompatibility complex. Within a family, however, the situation is simplified considerably, since only four haplotypes can be involved (two from each parent) and since unrecognized, closely linked loci may be expected to segregate with the recognized HL-A antigens.60 HL-A typing of the family usually permits a genetic analysis of the four haplotypes, and offspring who have inherited the same two haplotypes are referred to as "genotypically matched." The apparent match can be confirmed by nonreactivity in one-way mixed leukocyte culture. Some loss of potential donors occurs as a result of ABO incompatibility, although a few marrow grafts have succeeded despite ABO differences. The number of patients with matched siblings is quite large, particularly since many patients have more than one sibling. In practical terms, in the course of HL-A typing of 533 patients with at least one sibling, we have found 255 (48 per cent) who had HL-A matched siblings.

With a large "bank" of individuals of known HL-A phenotype, it is possible to identify unrelated individuals who are phenotypically HL-A matched, some of whom will not react in mixed leukocyte culture.60 However, in our laboratory 28 such pairs have reacted in mixed leukocyte culture, indicating that a strong incompatibility still exists. The current research on lymphocyte-detected typing, mentioned above, offers a potential solution to this problem.

Preparation of the Recipient

The recipient of a syngeneic graft requires no immunosuppressive preparation. Similarly, the patient with severe combined immunologic deficiency disease requires no immunosuppressive preparation because of the nature of his disease. All other recipients of marrow grafts must have some form of immunosuppressive preparation so that they will not reject the graft. The type of preparation is influenced by the nature of the underlying disease.

In marrow grafting for non-malignant conditions, the preparation of the recipient can be directed solely at the problem of immunosuppression without concern for the problem of eradicating malignant cells. Most of our patients with aplastic anemia have been prepared with a modification of the regimen of Santos, which involves the administration of 50 mg of cyclophosphamide per kilogram on each of four days followed 36 hours later by the marrow infusion. Cyclophosphamide is administered 24 hours after infusion of antigen from the prospective donor, usually in the form of mononuclear cells.46,72 Nausea and vomiting accompanying administration are usually severe but transient. A high urine flow must be maintained to avoid severe cystitis due to cyclophosphamide metabolites excreted in the urine. The use of diuretics is recommended because of an antidiuretic effect of the drug.51,73 Since in aplastic anemia marrow "space" is already available, Amiel et al.74 conditioned seven patients with the disorder for allogeneic marrow grafting by injection of horse anti-lymphocyte serum. In three patients they observed engraftment of erythroid marrow, but not lymphoid cells, although the grafts generally were transient.

In malignant disorders, specifically acute leukemia, preparation of the recipient must involve not only immunosuppression but also therapy designed to kill all or nearly all of the leukemic cells. Total-body irradiation has been the most common means of conditioning a marrow-graft recipient. Studies in dogs showed that a midline tissue exposure of 500 rad of total-body irradiation, although lethal, was not sufficiently immunosuppressive to permit successful grafting of allogeneic marrow.64 Consistent and sustained engraftment of allogeneic marrow in the dog was achieved only when the irradiation was raised to 950 rad.61 Canine radiation chimeras have always been "complete" chimeras — i.e., analyses of karyotypes of cells in peripheral blood, marrow and lymph nodes up to eight years after marrow grafting have consistently shown only cells with donor karyotype61 — whereas dogs prepared with cyclophosphamide were "mixed" chimeras — i.e., both donor and host cells were present.49 The finding of persisting host cells indicates that cyclophosphamide may be less desirable than total-body irradiation in efforts to treat hemopoietic neoplasias by marrow grafting.

In preparing leukemic patients for grafting, we have routinely administered a 1000-rad midline tissue dose of total-body irradiation. Opposing 60Co sources are used in an effort to achieve more homogenous irradiation.79 Rotating the patient to achieve homogeneity not only is cumbersome but may be undesirable when one is dealing with a migrating population of malignant cells (leukemia). Acceptable homogeneity might be achieved with a single very high energy source but successful marrow grafts in large animals have not been reported with those technics. The acute nonmarrow toxicity is generally well tolerated, consisting of low-grade fever, immediate but transient nausea, vomiting and diarrhea and tender swelling of the parotid gland that resolves within 24 to 48 hours.76

Leukemic cells are sensitive to irradiation; irradiation penetrates to all "privileged" sites and is an effective immunosuppressive agent. However, when we used irradiation only, we observed a high rate of recurrent leukemia. To increase the leukemic-cell kill we decided to give cyclophosphamide, 60 mg per kilogram, five and six days before irradiation. The result has been a striking decrease in the rate of recurrent leukemia. In the present series of patients, we are administering additional antileukemic therapy just before the administration of cyclophosphamide and irradiation with the intent of obtaining maximum leukemic cytoreduction within the range of tolerable nonmarrow toxicity.

Graw et al.77 prepared patients with acute leukemia for engraftment by the administration of 45 mg of cyclophosphamide per kilogram given on each of four successive days. They observed early recurrence of leukemia. Santos et al.78 prepared leukemic patients with 50 mg of cyclophosphamide per kilogram given on each of four days. They observed the complete disappearance of host-type cells in the first few weeks after grafting. Unfortunately, most of their patients did not live long enough for complete evaluation, but one patient did have a remission of 11 months' duration before relapse with host-type leukemic cells. More recently, Graw and his colleagues79 have
prepared four leukemic patients for engraftment with a four-day drug regimen involving high doses of cyclophosphamide, cytosine arabinoside, 6-thioguanine and 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU). One of their patients with acute myelogenous leukemia is still in complete remission with a successful graft more than two years after grafting, suggesting that it may be possible to eradicate a leukemic cell population with drugs without the use of irradiation. Gengozian et al. prepared two patients with acute myelogenous leukemia with antithymocyte globulin and 375-rad total-body irradiation. They observed successful engraftment, indicating the adequacy of the immunosuppressive regimen and apparent absence of graft-versus-host disease, but one patient died of infection and the other of an early return of leukemia.

**Technic of Marrow Transplantation**

In the laboratory, marrow has been administered by a variety of routes, including intravenous, intra-arterial, intraperitoneal and intramedullary. Van Bekkum studied the problem of the route of administration in the mouse and found the intravenous route to be the best since the intraperitoneal route required about 70 times as much marrow for successful engraftment. Recent studies of this problem in the monkey showed that two to three times as much marrow is required when it is given intraperitoneally as compared to intravenously. Although some patients with immunologic deficiency disorders have had successful engraftment after intraperitoneal administration, most investigators now use the intravenous route.

Histocompatible donors are most likely to be found among members of a patient's family, and, thus, living volunteers are at present the principal source of donors for marrow grafts. One unit of blood is obtained from the marrow donor a few days before the procedure, stored in acid citrate dextrose, and returned to the donor during the aspiration, thus avoiding exposure of the normal donor to the risks of blood transfusion from another person. Marrow is obtained by multiple aspirations from the iliac bones in an operating room under sterile conditions. Spinal anesthesia is preferred, but occasionally general anesthesia is indicated. When the needle point is inserted into the marrow cavity, vigorous suction is applied while the needle is rotated. The volume aspirated from each site is limited to 1 to 3 ml to minimize dilution with peripheral blood. Marrow is aspirated and transferred quickly into a beaker containing tissue-culture medium and heparin without preservative. The pooled aspirated marrow, usually 400 to 800 ml, is passed successively through stainless-steel screens of 0.3-mm and then 0.2-mm opening, screening produces a single-cell suspension permitting accurate cell counts and, most importantly, avoids potentially lethal marrow emboli. Cooling the marrow suspension is unnecessary and may lead to clumping of fat. The recipient must be monitored carefully during the intravenous infusion. Signs of fluid overload or strain on the right side of the heart dictate slowing of the infusion or, occasionally, phlebotomy before the infusion is completed. We have carried out marrow aspirations on more than 200 donors. Invariably, the procedure has been well tolerated. No long lasting effects are to be expected from the removal of a small fraction of a rapidly replicating tissue. The risk of anesthesia remains a legitimate concern.

**Supportive Care**

Before grafting, almost all marrow-graft recipients go through a period of no marrow function owing to their disease or to preparation for engraftment. After grafting, there is a period of 10 to 20 days before the graft begins to function. Effective supportive measures during these periods of marrow aplasia are absolutely essential to success in a marrow-transplantation program.

Before transplantation it is very important that blood products from family members should not be administered to potential recipients of sibling marrow transplants because of possible sensitization against non-HLA tissue antigens of the donor. An exception is that children of the prospective recipient may be used when the donor is to be a sibling of the recipient. After the marrow graft the family may be used as blood-product donors. The intensive use of one or two donors greatly reduces the potential exposure to cytomegalovirus, toxoplasma and hepatitis. All blood products infused into recipients of allogeneic marrow transplants are exposed to 1500 R of Co irradiation to prevent the proliferation of lymphoid cells, which might produce or enhance graft-versus-host disease.

Our policy is to attempt to maintain a circulating platelet count of greater than 20,000 per cubic millimeter. Platelet consumption due to infection or the underlying disease is a frequent problem. Platelets from HLA-matched siblings are probably not subject to immunologic destruction.

Available technics do not provide the same transfusion support capability for granulocytes as for platelets. Even small elevations of circulating granulocyte levels require very large numbers of infused cells owing to their dilution in the marginal pool, the short half-life (six hours) of normal granulocytes and their rapid utilization in the face of infection. Most groups involved in granulocyte transfusion therapy of infected agranulocytic patients have concluded that such transfusions are beneficial, but objective data supporting these conclusions are understandably scarce. The largest controlled studies were conducted by Gray and McCredie and their associates. If recipient sensitization to allogeneic granulocytes is suspected, the suitability of a donor can be assessed by determination of the survival of the potential donor's platelets. For our patients the granulocyte donor has usually been the marrow donor or another family member. Such donors are well motivated to tolerate the daily inconvenience. We initiate granulocyte transfusion therapy when a serious bacterial or fungal infection develops in an agranulocytic transplant recipient. Once started, the transfusions are continued daily until the recipient is able to support levels of circulating granulocytes higher than can be achieved by granulocyte transfusion. We are investigating the potential benefits of prophylactic granulocyte transfusion for uninfected agranulocytic patients in a controlled study.

We harvest granulocytes with two National Cancer Institute-IBM continuous-flow cell separators using arteriovenous shunts in the donor. This procedure is well tolerated by the donor and permits the processing of
larger quantities of blood on a daily basis. Approximately 18 ± 8.7 (± S.D.) × 10⁶ granulocytes can be collected daily by this technic. The granulocyte-rich buffy coat often contains sufficient platelets to satisfy the platelet requirements of the recipient. Reversible leukoadehesion with use of Leukopaks was developed by Djerassi.⁵⁸ Equipment for this procedure is commercially available and relatively inexpensive. There are reports of severe recipient reactions to Leukopak-collected granulocytes,⁵⁹ but this has not been a problem in our experience.

Because of the susceptibility to infection, it seems reasonable to isolate the patient from possible contact with pathogenic micro-organisms. Recent developments in techniques of laminar-air-flow isolation and of suppression of the gastrointestinal flora with nonabsorbable antibiotics have increased the ability to achieve the "sterile" patient.⁶¹,⁶² The observation that the clinical manifestations of graft-versus-host disease can be less severe in gnotobiotic mice than in normal mice has prompted the speculation that attempts to render human recipients of marrow transplants bacteria-free might reduce the frequency and severity of this complication. These procedures are complicated and expensive and involve patient discomfort and inconvenience. It is therefore very important that their benefits be accurately evaluated. Controlled studies of this problem are under way in our center, but no firm conclusions are available at present. As a practical matter, almost all our marrow transplants have been carried out with simple mask reverse isolation. In the absence of controlled studies, the published suggestion that marrow grafts should only be done in a sterile environment should be regarded as speculative.⁶³,⁶⁴

**Clinical Results of Marrow Transplantation**

**Immunodeficiency**

This review is concerned primarily with marrow transplantation in persons who have achieved immunologic maturity. Studies of marrow and thymus transplantation in patients with immunologic deficiency have provided important basic information, despite the rarity of these disorders. Details of these studies are provided in review articles.⁶¹,⁶² In reading these reviews, one must keep in mind that patients with severe combined immunologic deficiency are different from the cases in this report in two important respects: the disease represents an experiment of nature in which the recipient does not require immunosuppression to accept a graft; and because some myeloid marrow function is usually present, rapid marrow engraftment is not mandatory, permitting the use of very small numbers of marrow cells, given repeatedly if necessary. These differences permit the design of highly informative experiments that are not possible in patients with aplastic anemia or leukemia.

**Aplastic Anemia**

*Syngeneic (monozygotic twin) transplants.* Despite introduction of broad-spectrum antibiotics, androgens, corticosteroids, and support with cellular blood elements, the mortality in severe cases of aplastic anemia is 80 to 90 per cent, with many patients dying within the first three months of diagnosis.⁶⁶,⁶⁷ Treatment of this illness by infusion of marrow cells from a normal identical twin is of great interest since the fate of the infused hematopoietic cells might provide valuable information about the cause and the pathogenesis of aplastic anemia. Up to the present, 10 cases have been described involving patients with acquired aplastic anemia whose identical twins donated marrow.⁶⁸ Two patients died within a few hours or days of marrow infusion. In five of the remaining eight, signs of beginning marrow regeneration were observed one to two weeks after grafting, and full recovery followed. The three patients treated in Seattle are alive and well with normal hemopoietic function six to 12 years later.⁶⁹ Although proof of engraftment cannot be obtained in the syngeneic situation, these observations suggest that most cases of aplastic anemia are due to a persistent abnormality induced in the stem-cell population. Otherwise, infusion of normal, syngeneic stem cells would not be expected to correct the abnormality. The patient with marrow failure who is fortunate enough to have a normal identical twin is a natural candidate for marrow transplantation and should be treated promptly since this form of therapy is essentially devoid of risk and has a high probability of success.

*Allogeneic transplants.* Through the end of February, 1974, we had treated 37 patients with aplastic anemia with transplants of marrow from major-histocompatibility-complex-matched siblings.⁶⁸,⁷⁰ Briefly, the patients' ages ranged from three to 67 years, with a median of 19. Twenty-three of the 37 had aplastic anemia of unknown cause; in seven the disease was associated with drugs, and in four with hepatitis; in two it occurred after a prolonged period of acquired paroxysmal nocturnal hemoglobinuria and in one it was associated with Fanconi's syndrome. The duration of the anemia ranged from one to 53 months, with a median of three months. Thirty-one patients had received therapy with androgenic steroids and had failed to respond. All but two had received multiple transfusions from unrelated donors before transplantation. Eight patients had received transfusions from parents or siblings. Eighteen patients were refractory to random platelet transfusions. Seventeen were infected at the time of admission. Granulocyte levels at admission ranged from 0 to 1000 and platelet counts from 1000 to 22,000 per cubic millimeter. Thirty-six patients were estimated to have less than 10 per cent normal megakaryocyte numbers in the marrow, 30 had less than 10 per cent granulocyte precursors, and 29 had less than 10 per cent erythroblast precursors at the time of admission.

Twenty-eight patients were conditioned for marrow grafting by administration of cyclophosphamide, 50 mg per kilogram, intravenously on each of four successive days. Nine patients were conditioned by a 1,000-rad midline tissue exposure of total-body irradiation. The day of marrow infusion was designated "day 0." After marrow grafting, methotrexate was administered intermittently as described below. Survival curves for these patients are shown in Figure 1.

Three patients died too early to evaluate success or failure of marrow grafting; one died on the day of grafting of congestive heart failure, possibly related to cyclophos-
phamide cardiac toxicity; two died on the sixth and eighth days from bacterial infection. One patient had no evidence of marrow engraftment and died on the 24th day of infection. The marrow at autopsy was extremely hypocellular.

Thirty-three patients gave evidence of marrow engraftment as indicated by rising peripheral blood counts between the 10th and 21st days after marrow infusion. Examination of marrow aspirates and biopsies confirmed marrow engraftment. Twenty-one of the 33 had donors of opposite sex. Cytogenetic analyses of marrow and peripheral blood cells carried out as early as the 14th day after grafting proved engraftment. Only cells of donor karyotypes have been found up to the present in surviving patients. In other patients, other blood genetic markers such as red-cell antigens and enzymes were used to monitor allogeneic engraftment. After initial marrow engraftment, six patients rejected their grafts, with progressively falling peripheral blood counts leading to marrow hypoplasia. Five of the six died between the 33rd and 67th days with infection. One of the six showed autochthonous marrow recovery as evidenced by cytogenetic analyses of marrow and peripheral blood cells and is well more than one year later. Of the patients with a graft, one died with a fungal infection on the 18th day, three died from cytomegalovirus pneumonia between the 54th and 91st days and one died of unknown causes on the 427th day. Six patients died with graft-versus-host disease between the 19th and 95th days. Sixteen patients are alive, with functioning grafts.

The results show that normal allogeneic hematopoietic stem cells can repopulate the marrow in patients with aplastic anemia and that the disease is usually related to a failure of the hematopoietic stem cells. An exception to this rule may be the one patient with autochthonous marrow recovery after rejection of the marrow transplant from his sister. Our experience shows that long-term stable chimerism is possible in man. Clearly, major problems remain to be solved. Even so, the survival and hematologic reconstitution of almost half our patients with advanced aplastic anemia treated by allogeneic marrow grafts compare favorably with results obtained by conventional management of this disease. Initially, we restricted this procedure to critically ill patients. The results, however, indicate that marrow transplantation has emerged as a definitive form of therapy for aplastic anemia provided an HL-A matched sibling can be identified as a potential marrow donor. Marrow grafting should be considered before major infection and refractoriness to blood transfusions occur. Other centers have now reported successful marrow grafts in aplastic anemia that confirm this suggestion. 102, 103

Acute Leukemia

Syngeneic (monozygotic twin) transplants. Since lethal total-body irradiation can exert a definite antileukemic effect, and since syngeneic marrow infusion can prevent death from the irradiation-induced aplasia, the rare leukemic patient with advanced disease who is fortunate enough to have a normal identical twin is the logical candidate for attempts to eradicate the leukemia by total-body irradiation and twin marrow transplantation. Very early encouraging results in mice prompted Thomas et al. 104 to try such an approach in three patients with acute lymphoblastic leukemia. Although normal hematopoiesis was restored, leukemia recurred within seven to 12 weeks. A fourth patient with acute lymphoblastic leukemia received cytosine arabinoside before the total-body irradiation and methotrexate after the marrow transplant, but still relapsed within seven weeks (Table 1).

Beginning in 1969 potential "immunotherapy" was added to the basic regimen of total-body irradiation and twin marrow with the hope of delaying leukemic recurrence. 105 It was based on principles outlined in the above section on studies in rodents and on studies supporting the existence of human leukemia-associated antigens. Since we would not expose normal twins to tumor material, the immunotherapy after total-body irradiation and marrow transplantation consisted of infusion of normal-twin buffy-coat lymphocytes three times a week for three weeks and weekly subcutaneous injections of lethally irradiated, autologous, leukemic cells, in the hope of providing a continual antigenic stimulus to the infused donor lymphocytes. The leukemic cells were stored at -180°C in 10 percent dimethyl sulfoxide and irradiated with 10,000 rad to prevent cell replication. The results obtained in three patients treated with total-body irradiation, marrow transplantation and immunotherapy are

*Death at 4 mo of pneumonitis in remission.

1 Patient died of pneumonitis at 2 mo in remission.
shown in Table 1. A 15-year-old patient with acute lymphoblastic leukemia relapsed within a month, a 26-year-old patient with acute myelogenous leukemia went into remission but died of interstitial pneumonitis at seven weeks, and a 33-year-old patient with acute myelogenous leukemia relapsed at 10 months.

We assumed that the addition of a high dose of chemotherapy to the treatment regimen would be beneficial by decreasing the tumor load to be handled by the total-body irradiation or immunotherapy or both. Therefore, 29 subsequent patients received cyclophosphamide (60 mg per kilogram on each of two days), total-body irradiation (1000 rad), twin marrow transplants and, in 13 cases, immunotherapy. All patients had received chemotherapy and were considered to be in the terminal phase of the illness. The seven patients who did not receive immunotherapy either had not had readily accessible tumor cells for storage or had normal-twin donors who were unable to donate regularly the necessary buffy-coat cells. Thus, this was not a randomized study to determine the contribution, if any, of immunotherapy to the overall results. The results are shown in Table 1. One patient died of hepatitis too early to be evaluated, and two failed to clear their marrow of leukemic cells. Seventeen experienced complete remission. Eight of them (three with acute lymphoblastic, four with acute myelogenous, and one with lymphosarcoma leukemia) remain in complete remission at three to 49 months without any maintenance chemotherapy. All the normal-twin donors remain in excellent health without evidence of hematologic neoplasia.

As predicted from rodent models, although normal hematopoiesis was restored in our twin transplant recipients, the principal problem was that of resistance of the hematologic neoplasms in almost half our patients, as reflected by persistence of leukemic cells or recurrence of leukemia after several months of remission. This resistance has also been a problem in four patients with leukemia treated by others with high-dose combination chemotherapy with marrow infusion from a normal twin—all relapsed within a few months.\textsuperscript{39,109} We are now adding intensive combination chemotherapy before the cyclophosphamide and total-body irradiation to further reduce the tumor burden. Our results are sufficiently encouraging to recommend this approach to any patient who has an identical twin and hematologic neoplasia even before the patient becomes demonstrably resistant to all chemotherapy. Furthermore, this approach may also be applicable to the treatment of other tumors such as lymphomas, neuroblastomas, and anaplastic carcinomas known to be sensitive to high doses of chemotherapy and total-body irradiation.

\textbf{Allogeneic transplants:} The majority of marrow grafts for acute leukemia have been performed between ABO-compatible, HLA-identical siblings and siblings not reactive in mixed leukocyte culture. The main differences in the approach to marrow grafting have centered on methods of conditioning the patient for the marrow graft and of post-grafting immunosuppression.\textsuperscript{14} Table 2 details the approaches described in reports published by others since 1970. Of the conditioning regimens so far tried, reproducible, high-level chimerism and sustained remission have been obtained only with cyclophosphamide in doses of at least 45 mg per kilogram per day for four days, high-dose chemotherapy (BACT)\textsuperscript{19} and, as will be described, total body irradiation alone or in combination with cyclophosphamide. Conditioning with antilympho-

In Seattle, 1000-rad total-body irradiation, initially alone and subsequently with the addition of cyclophosphamide and, more recently, cytoreduction as described, have been used as the conditioning regimen in the 70 patients receiving marrow grafts for acute lymphoblastic or acute myelogenous leukemia between July 1969, and June 1974 (Table 3). A review of this five-year experience illustrates the changing problems but the definite progress evident in marrow grafting for acute leukemia.

*Of these patients were prepared with total-body irradiation only.
†Patient relapsed with central-nervous-system leukemia at 18 mo; all other patients relapsed by 3 mo.
‡Chronic myelogenous leukemia in blast crisis.

Thirty-six patients, two to 56 years of age (average of 23 years) received marrow grafts for acute myelogenous leukemia, and 54 patients, five to 22 years of age (average of 11 years) for acute lymphoblastic leukemia. Relevant to evaluating this approach is the clinical condition of these patients at the time of grafting. All patients received transplants at a time when conventional and experimental chemotherapy was failing. The duration of disease from diagnosis averaged 24 months in patients with acute lymphoblastic leukemia, spanning an average of three relapses, and in acute myelogenous leukemia, it averaged 10 months, with 15 patients not achieving a remission with chemotherapy. Overall, 64 of the 70 patients were in relapse, 68 had previously been transfused with red cells or platelets (or both), and 22 were infected at the time of transplantation.

Two patients died in less than 10 days, and five did not show engraftment. Sixty-three obtained functional grafts demonstrated by rapidly rising peripheral counts, histologic evidence of a graft, and, when possible, cytogenetic analysis and red-cell or white-cell antigen or enzyme studies. In 46 of these 63 patients (73 per cent) graft-versus-host disease developed, ranging from an erythematous skin rash lasting only several days to the fatal syndrome of a desquamating erythematous skin rash, gross liver-function abnormalities and profuse diarrhea. There was no difference in the incidence of graft-versus-host disease in the two disorders — 21 of 31 patients with acute lymphoblastic and 25 of 32 patients with acute myelogenous leukemia.

The overall survival data for this group of patients are shown in Figure 2. Although the median survival for patients with the two types of leukemia remains short, the five-year period is characterized by marked improvement in supportive care of patients and more effective conditioning regimens. Analysis of the results according to the year of transplantation demonstrates the progress now evident in two respects: the prolongation of survival beyond the first 50 days; and the increasing number of long-term survivors. Thus, the percentage of patients surviving beyond 50 days has increased from less than 50 per cent in those receiving transplants between 1969 and 1971 to 100 per cent in those with transplants in the first six months of 1974.

Relapse was the basic cause of failure in 15 patients, four with acute myelogenous and 11 with acute lymphoblastic leukemia. Included are four patients (two in each group) whose leukemic cell population was so refractory that serial marrow aspirations demonstrated persistence of blast cells. Such refractoriness suggests a spectrum of degrees of reduction of the leukemic cell load. One could anticipate, therefore, that a substantial fraction of the patients might retain a malignant cell population too large for a putative antileukemic effect of a marrow graft to do much good. In fact, we have observed four patients in whom leukemia recurred in seven to 23 weeks after marrow engraftment, and in whom cytogenetic evidence showed that the recurrence was composed of cells derived from the original host leukemia. Furthermore, the more recent aggressive conditioning regimens appear to have modified the relapse rate. Of the first six patients with acute lymphoblastic leukemia prepared with total-body irradiation alone, five had evidence of recurrence (including a child who died primarily of bilateral interstitial pneumonia and had extramedullary microscopic evidence of leukemia). With the subsequent addition of high-dose chemotherapy to the conditioning regimen, only six of 29 patients with acute lymphoblastic leukemia have shown a recurrence. As the median survival increases, however, more cases of recurrence may also become evident, although relapse beyond seven months has occurred in only one patient.

Nineteen of the 70 patients remain in complete remission beyond three months, nine for one to four years after transplantation. From the data presented, indications are that such a remission rate is increasing (Fig. 2). In many patients with acute myelogenous leukemia and adult acute lymphoblastic leukemia, and after relapse in acute leukemia of any kind, long-term unmaintained remissions are not possible with available chemotherapy. The results with marrow transplantation, far from ideal, are nonetheless encouraging and offer a therapeutic opportunity for the patient with a suitable donor whose leukemia by virtue of type or relapse augurs a predictably short prognosis.

The results of marrow grafting for the blastic crisis of
chronic myelogenous leukemia cannot yet be evaluated. Two patients died early of infection, and one with a graft is in remission after four months (Table 5).

Current Results in Miscellaneous Conditions

Three other applications of marrow grafting have long been recognized: radiation accidents; solid malignant tumors that are particularly sensitive to chemotherapy and radiotherapy; and genetic disorders such as thalassemia and sickle-cell disease.

Apart from transplants after radiation accidents, there are to date no published reports of long-term survival after allogeneic transplants for the disease categories listed. In these disorders, either the transplantations have been performed before the recognition of the importance of HLA and mixed-leukocyte-culture matching, patients having succumbed to overwhelming infections in the early post-grafting period, or there has been no evidence of engraftment.

Within our center allogeneic marrow grafting has been carried out in single patients with neuroblastoma, malignant histiocytosis, and Hodgkin's disease. All succumbed within 40 days of transplantation, two from overwhelming sepsis and one from viral pneumonia.

A major factor limiting the total eradication of a disseminated malignant neoplasm by current available chemotherapy and radiotherapy is irreversible damage to the marrow. Transplantation of marrow should remove this barrier and would permit the administration of much larger doses of these agents. Neuroblastoma, lymphosarcoma, Hodgkin's disease and oat-cell carcinoma are examples of tumors that appear to be particularly sensitive to chemotherapy and to radiotherapy, and in such neoplasms the application of marrow transplantation may enable potentially curable doses to be given.

Two approaches are feasible: the infusion of the patient's own normal marrow aspirated and stored before chemotherapy and radiotherapy (autologous marrow infusion); or the use of marrow from a major histocompatibility-complex-matched donor. In the late 1950's there were several case reports of remissions with use of autologous marrow infusion after high doses of chemotherapy or radiotherapy or both. Death of most patients from bacterial sepsis and the doubt whether marrow recovery in the long-term survivors was in any way related to the marrow infusion led to a general loss of interest in this technic. The development of methods for long-term storage of marrow at -180°C in dimethyl sulfoxide, better chemotherapeutic agents, and more effective supportive care of patients have renewed interest in this form of therapy, which, like identical twin transplants, does not carry the risk of rejection or graft-versus-host disease. Currently, we are storing marrow from patients with chronic myelogenous leukemia early in their disease. When blast crisis occurs, the patient will be treated with intensive chemotherapy and radiotherapy followed by return of the stored marrow, with the intent of restoring the chronic disease. Preliminary results indicate feasibility.

Current Problems

Success or Failure of Marrow Engraftment and Marrow-Grat Rejection

A review of the literature of human marrow transplantation before 1967 showed a high incidence of complete failure of engraftment. Failure of initial allogeneic engraftment is no longer a major problem. Excluding five patients who died too soon to be evaluated, 33 of 34 grafts
in patients with aplastic anemia were successfully established, and 63 of 68 in acute leukemia were successful. The quantity of marrow infused ranged from 1.1 to 10.9 x 10^6 per kilogram of recipient body weight (Table 4). Despite this range of one order of magnitude, there was no correlation between marrow dose and success or failure of engraftment nor of nadir of white-cell count or time to recovery above 1000 per cubic millimeter. Although there has been concern about the dose of marrow cells required for engraftment, precise determination of this number seems to be neither practical nor necessary.

Experiments in canine literates matched at the major histocompatibility complex have shown that prior exposure to transfusion of whole blood from the marrow donor may jeopardize the success of a subsequent marrow graft even in this "compatible" donor-recipient combination. Data similar to those in dogs have been reported in irradiated mice and also in mice treated with cyclophosphamide. Presumably, rejection was due to immunization of the recipient to histocompatibility antigens on platelets and leukocytes. With blood transfusions from random donors or from family members other than the marrow donor, immunization of the recipient and rejection of the graft might be expected only when the marrow donor and the transfusion donors share "minor" histocompatibility antigens not present in the recipient. The results of allogeneic marrow grafting for the treatment of aplastic anemia have shown that patients given transplants from family members have a high rate of failure of marrow engraftment or of marrow-graft rejection. The two patients who had not been transfused before grafting had prompt engraftment and are among the long-term survivors. One patient who rejected his graft had had transfusions from both parents, which should have exposed him to the risk of sensitization to all family "minor" transplantation antigens that he did not inherit. Although Mathé et al. had earlier reported an apparent harmful effect of transfusions before grafting in patients with leukemia, we have not observed graft rejection in our patients with acute leukemia, and most of the failures of engraftment occurred in the earlier patients. More aggressive modern chemotherapy is one explanation for this difference as well as the difference between acute leukemia and aplastic anemia.

At present no reliable laboratory tests are available to determine which patient is sensitized against his HL-A-

matched marrow donor although research on this problem is in progress. Recent data using DLA-incompatible, unrelated donor recipient pairs of dogs indicate that the presensitized state can be abrogated by a combination of procarbazine and rabbit antidiog antithymocyte serum before total-body irradiation resulting in successful marrow engraftment in most cases. We have initiated a randomized study in patients with aplastic anemia to determine the role of pre-treatment with procarbazine and antithymocyte globulin. Initial results have shown that the regimen is well tolerated and that successful engraftment is possible.

**Graft-versus-Host Disease**

The distinction between illness due to the active immunologic assault of donor lymphoid cells against host target organs and the consequences of this assault, deranged organ function and infection, is indeed subtle and, in this discussion, both are considered a part of graft-versus-host disease. For unknown reasons, the principal target organs of graft-versus-host disease in both animals and man are skin, gastrointestinal tract and liver. Despite the use of sibling donors matched at the major histocompatibility complex and despite post-grafting immunosuppression, graft-versus-host disease has occurred in approximately 70% of patients with successful marrow grafts. Evidently, compatibility or incompatibility for histocompatibility regions other than the major histocompatibility complex are important determinants of the graft-versus-host disease. There have been too few successful marrow transplantations between siblings not matched at the major histocompatibility complex to know the frequency of graft-versus-host disease in this situation, but, from studies in animals as well as from the results of marrow grafting in immunodeficient children, it seems reasonable to expect that graft-versus-host disease (and graft rejection) will be major problems. We described a marrow transplant involving a one-antigen mismatch. Graft-versus-host disease was severe but not more severe than that seen in some transplants matched at the major histocompatibility complex.

**Clinical graft-versus-host disease.** The proposed clinical staging of the disease is shown in Table 5. The initial organ

| Table 5. Proposed Clinical Stage of Graft-versus-Host Disease According to Organ System. |
|-----------------|----------------|----------------|----------------|
| **STAGE**       | **SKIN**       | **LIVER**      | **INTESTINAL TRACT** |
| Maculopapular rash <25% of body surface | Bilirubin 2-3 mg/100 ml | > 500 ml diarrheaday |
| Maculopapular rash 25-30% body surface | Bilirubin 3-6 mg/100 ml | > 1000 ml diarrheaday |
| Generalized erythroderma | Bilirubin 6-15 mg/100 ml | > 1500 ml diarrheaday |
| Generalized erythroderma with bullous formation & desquamation | Bilirubin > 15 mg/100 ml | Severe abdominal pain, with or without ileus |
involved in almost all cases is the skin. Biopsy is mandatory for diagnosis since not all rashes in these patients are due to graft-versus-host disease. Hepatic and intestinal involvement usually appears several days after the rash. Intestinal involvement is mainly in the form of diarrhea but may progress to abdominal pain and ileus. Liver disease is manifested by rises in bilirubin (mainly conjugated). Serum glutamic oxalacetic transaminase is usually in the range of 150 to 750 IU. Rises in alkaline phosphatase are also observed especially in chronic graft-versus-host disease. Intestinal and hepatic abnormalities are not unique to this situation. Therefore, alterations in function of these organs should be attributed to graft-versus-host disease only when its involvement of the skin is clearly established or when there is biopsy confirmation in gut or liver. Fever, wasting and a decreased performance status are also regularly seen with severe involvement. Although liver may be a manifestation of graft-versus-host disease per se, it is most commonly due to an associated infection, often an occult viral infection.

We and others have attempted to classify the overall severity of clinical graft-versus-host disease on a grading system ranging from 0 to IV (Table 6). Currently, analysis of survival among our patients suggests that patients can be grouped in two ways: those without clinically evident graft-versus-host disease (Grade 0) and those with graft-versus-host disease involving skin (Grade I) show a survival of 55 percent, whereas patients with Grades II to IV have a survival of only 15 percent. Its strong association with infection indicates that graft-versus-host disease itself is a critical factor contributing to the poor immunologic reactivity, debility and compromised mucosal barriers in marrow-graft recipients. The grading system may become more meaningful as advances are made in the treatment of graft-versus-host disease and accompanying infections.

Chronic graft-versus-host disease characterized by a more indolent clinical course, with involvement of skin, liver and intestinal tract, has been observed in three long-term survivors. This picture may appear after complete or partial resolution of acute graft-versus-host disease. Whether the chronic form is the result of an immunologic attack of donor lymphoid cells against host tissue or of deficient immunologic reactivity of the graft, with accompanying opportunistic infections, or of a combination of both is not well understood at present.

Table 6. Overall Clinical Grading of Severity of Graft-versus-Host Disease.

Histologic criteria. Table 7 summarizes the proposed histopathologic staging of graft-versus-host disease based on scale ranging from + to + + +. Hepatic involvement was characterized by degeneration and eosinophilic necrosis of parenchymal cells and degeneration and necrosis of the epithelium of small bile ducts. Because the effect on parenchymal cells was variable whereas small bile ducts were consistently involved, the grading was correlated with the percentage of pathologically altered small bile ducts.

Serial biopsies of the skin are easily obtained, but biopsies of the gut and liver cannot be done regularly and the histopathologic stage may therefore require revision. Histopathologic staging varied between organs and did not always correlate with the clinical grade except for mild or severe graft-versus-host disease.

Prevention and treatment. From the animal studies as well as from the clinical marrow-grafting experience it has become clear that some form of immunosuppressive therapy must be used after grafting to diminish or prevent graft-versus-host disease. The literature on this topic has recently been reviewed. To be effective, treatment with immunosuppressive agents must be started before graft-versus-host disease has become apparent. Of the many agents studied, methotrexate and cyclophosphamide have been found to be useful. Methotrexate was found to ameliorate graft-versus-host disease in mice, dogs and monkeys when given immediately after grafting. Studies in dogs have shown that methotrexate was most effective when continued for a long time (three months), and stable grafted long-term chimera (measured in years) was achieved in some DLA incompatible recipients. Cyclophosphamide had some effect in mice, rats and monkeys, but was ineffective in dogs. Studies using cycsine arabinoside, procarba- zine, 6-mercaptopurine, and antilymphocyte serum in the immediate post-grafting period have been disappointing.
Prevention of graft-versus-host disease has been attempted with use of antilymphocyte serum given just before grafting in rodents, dogs, and monkeys, with only slight prolongation of survival.

Our current post-grafting regimen in human patients consists of methotrexate, 15 mg per square meter on the first day and 10 mg per square meter on the third, sixth, and 11th days and weekly thereafter for the first 100 days.96,108 Santos et al. have used cyclophosphamide, 7.5 mg per kilogram for five doses on alternate days, beginning on the first day after marrow grafting, followed by doses at irregular intervals.96 The frequency of fatal graft-versus-host disease in patients given a marrow graft from an HLA-matched sibling and no post-grafting immunosuppression is unknown. Despite post-grafting immunosuppression with either methotrexate or cyclophosphamide, severe and fatal graft-versus-host disease has been observed in 10 to 20 per cent of human marrow-graft recipients.

Surprisingly enough, only a few studies have been reported in which established graft-versus-host disease was treated either with cytostatic agents or with antilymphocyte serum. For the most part, these studies were negative—i.e., the agents used failed to influence the course of events or the authors failed to document sustained chimerism. A review of these studies has been presented recently.109 An exception was the study by Owens and Santos, who inoculated C57BL/6 × DBA 2 F1 hybrid mice with BALB/c spleen cells and were able to suppress clinically established graft-versus-host disease by cyclophosphamide.27 Cyclophosphamide was used to treat established graft-versus-host disease in a patient given a graft from an HLA-matched sibling and was ineffective.100

On the basis of encouraging studies in the canine model we have recently started using antithymocyte globulin for treatment of human patients with graft-versus-host disease.128 With this therapy, 12 of 19 patients showed complete resolution of the graft-versus-host disease, five showed improvement of most organ systems involved, and two showed no changes except for improvement in skin lesions. Six of the 19 became long-term survivors. Five of the six are alive now between 232 and 865 days after grafting, and one died on the 346th day with chronic respiratory failure. Of the remaining 13 patients, 11 died of interstitial pneumonitis of predominantly viral origin, and two died with fungal and bacterial infections. These findings demonstrated the partial effectiveness of antithymocyte globulin in reversing human graft-versus-host disease. This treatment of established graft-versus-host disease certainly does not represent the solution of the problem, but it appears to have modified the grim outlook in a hopeful way. It is obvious, however, that continued animal and clinical research efforts have to be directed to a better understanding of the nature and control of graft-versus-host disease.

Albumin-gradient cell-separation techniques have been used in an attempt to eliminate immunocompetent cells from the marrow inoculum while retaining the hematopoietic stem cell.28 Proof, however, that this approach is useful in modifying graft-versus-host disease in grafts between random bred non-rodenl animals is missing. The technic has been applied in a number of human transplants.91 The result was either failure of engraftment or death from graft-versus-host disease when histo-incompatible marrow was used. Aside from the technical problems, a number of theoretical reasons would argue against the efficacy of "stem-cell" separation technic. Even if it should be possible to separate completely lymphoid cells from stem cells, it is likely that the recipient still might be susceptible to the late form of graft-versus-host disease, which is presumably caused by subsequent regeneration of reactive lymphoid cells derived from the "common" stem cell. If there is not a "common" stem cell giving rise to lymphoid cells, successful separation would create a recipient who is severely deficient in immune function and thus might succumb to infection. At present, therefore, stem-cell separation does not appear to be a promising approach.

Infection After Engraftment

Leukopenia, immunoincompetence and graft-versus-host disease have, as their principal consequence, infection, which is the usual proximate cause of death. These complications may overlap in time and clinical manifestation, but it is possible to discern time periods in which one of the other underlying causes predominates.

The infectious hazards of agranulocytosis are maximally apparent during the two to three weeks immediately after transplantation. In a series of 71 allogeneic marrow-transplant recipients who survived for at least 50 days, and who achieved engraftment, the median number of days with a granulocyte count of < 100 per cubic millimeter was 11, and that of patients with a count of < 500 was 18. The pattern of infection in agranulocytic patients has been well delineated,121 mostly in patients with acute leukemia, and infectious-disease experience in marrow-transplant patients during the immediate post-grafting period conforms closely to this pattern. Bacterial and candidal infections are particularly frequent and serious in agranulocytic patients. Gram-negative bacteremia is a common event. There is convincing evidence that antibiotic therapy is less effective in curing infectious disease in patients lacking granulocytes and that the apparent complete resolution of an infectious process may be insecure unless adequate granulocytes are present. Organisms usually considered of low virulence acquire enhanced consequence in the absence of granulocytes. The frequency of systemic candidiasis is difficult to assess since techniques for its detection are of low sensitivity. Mucosal infections due to candida, however, are common. Bacterial infection appropriately treated rarely jeopardizes the achievement of successful engraftment, even in patients infected at the time the facilitation procedure is initiated, but it does cause considerable morbidity. Of 47 patients surveyed in a recent review,122 only two died from bacterial disease in the first 21 days, but in 22 bacteremia developed. Aside from the role of granulocyte transfusion the recently improved survival prospects of infected agranulocytic patients owe much to the development of new and more po-
tent antibiotics properly administered.

Because of decreased immune reactivity in these patients, it is not surprising that the incidence of infection, particularly viral disease, is increased during the first 100 days after transplantation. Perhaps the most troublesome single infectious complication is that of interstitial pneumonia. The syndrome has occurred at any time during the first four months after transplantation, but has its usual onset after the establishment of a functioning marrow graft. The overall incidence among 114 marrow-graft recipients in Seattle over the time period from 1969, through June, 1973, is 28 per cent. However, in the 24 identical-twin transplants in this series, the condition was documented in only three patients (13 per cent). Furthermore, as previously discussed, some allogeneic marrow recipients died without achieving effective hematopoietic function (or after marrow-graft rejection) in the period before the risk of interstitial pneumonia is very great. If these are excluded, and we consider only patients who achieved functional allogeneic transplants, the incidence of this syndrome is closer to 50 per cent. Mortality among this group of patients, death being primarily due to respiratory insufficiency from progressive pulmonary infiltration, is distressingly high at between 50 to 60 per cent. Whereas all groups of allogeneic marrow-graft recipients have contracted this syndrome, both the statistics on incidence and particularly those on mortality are worse in patients with grades II to IV graft-versus-host disease. In this connection, an apparent increase in incidence of interstitial pneumonia in marrow-transplant recipients has been reported in Seattle. However, it remains to be established whether this observation reflects a genuine increase in the attack rate or a manifestation of the enhanced chronicity of severe and moderate graft-versus-host disease (producing a longer period of maximum risk) resulting from the introduction of new methods of support and immunosuppressive treatment discussed above.

From the standpoint of cause about half the patients dying with interstitial pneumonia have unambiguous evidence of disseminated cytomegalovirus in the form of characteristic inclusion bodies on histologic examination of the lungs and other organs, as well as isolation of the organism in culture. A total of six histologically proved cases of Pneumocystis carinii has been noted at autopsy, three of which were found in the presence of cytomegalovirus. In two patients lethal varicella-zoster pneumonia developed. No recognizable pathogens have been associated with the remainder of the fatal interstitial pneumonias, although these are histologically indistinguishable from those caused by cytomegalovirus and pneumocystis (except for the specific signs of these agents). Of marrow-graft recipients who gave clinical evidence of interstitial pneumonia and subsequently recovered, about half also had serologic or cultural (or both) evidence of cytomegalovirus infection. The cause in the other half remains obscure.

A retrospective review of cytomegalovirus infection and serologic response among marrow-graft recipients provided the following observations: cultural and histologic data taken together indicated that a minimum of one third of these patients contract or activate latent cytomegalovirus infections during the first few months after engraftment; and patients with marked rises in complement-fixing antibody titer either had no clinical manifestations or recovered from transient interstitial pneumonia. Most of these patients excreted cytomegalovirus in urine. In contrast, patients with fatal cytomegalovirus pneumonia rarely demonstrated a noteworthy rise in complement-fixing antibody titers and have not, in our experience, excreted cytomegalovirus in urine at the time of the disseminated infection. The implications of these findings, as well as their precise relation to immune reconstitution and other factors that might affect the pattern of response to cytomegalovirus infection in transplant recipients, deserve more thorough prospective study. Finally, very little can be said about the clinical management of interstitial pneumonia and disseminated cytomegalovirus infection. All the severely infected patients have received antibiotics and pentamidine isethionate. Cytosine arabinoside, adenine arabinoside and corticosteroids have also been used but there is no clear evidence of benefit from any of these drugs at present.

In contrast to the problems associated with cytomegalovirus infection (and whatever additional and unknown agent or agents may account for interstitial pneumonia) the experience in Seattle with other opportunistic viral infections is relatively modest. Herpes simplex virus infections of the mouth and lips are frequent complications in the first few weeks after transplantation, but, with one exception, have subsided and healed without widespread dissemination. Later, cutaneous herpes zoster occurs occasionally over the period in which cytomegalovirus infections are seen. These lesions have frequently spread over several dermatomes before subsiding. Antibody responses to these viruses have been observed. The documented incidence of P. carinii pneumonia has been referred to and, perhaps surprisingly, is quite low. Antibody responses to this organism are very rare in our population of marrow-graft recipients, with only two documented cases, both of which were not in patients with proved P. carinii pneumonia.

Immunologic Status of Long-Term Survivors

Immunologic reactivity of syngeneic marrow-transplant recipients (monozygotic twins). Three patients treated with twin marrow grafts for hematologic neoplasia have been tested for immunologic reactivity. Absolute lymphocyte counts were above 1000 per cubic millimeter in all patients within one to three months after transplantation. No consistent changes in serum immunoglobulin levels were noted. Two of the three patients — both of whom had received twin peripheral blood lymphocytes as well as marrow — exhibited normal primary and secondary antibody responses to bacteriophage OX174 at six weeks and at one year after marrow transplantation. Two patients did not exhibit cutaneous delayed hypersensitivity reactions to the usual battery of skin tests, even though one of the donors was positive to candida and mumps. The third patient became positive to candida at one year. Two patients responded to dinitrochlorobenzene at one and two years. Lymphocytes from all three were stimulated in the test
with mixed leukocyte culture by irradiated allogeneic cells and by phytohemagglutinin to an extent almost comparable to that observed with the normal twin’s lymphocytes during the first few months after marrow transplantation. The three long-term syngeneic transplant survivors studied had no serious infections. Thus, the results suggest an impressive restoration of immunologic function in the three patients. It is assumed, of course, that the immunologic system tested is totally of donor type, although no markers are available. Efforts are under way to study the immunologic reactivity of twin marrow-transplant recipients early after marrow transplantation with additional measurements of immunologic function.

Immunologic reactivity of allogeneic marrow-transplant recipients (major-histocompatibility-complex-matched donors). The recovery of immune reactivity in allogeneic chimeras would be expected to be slower than that of syngeneic chimeras owing to at least three possible mechanisms: it has been hypothesized that lymphoid depletion occurs in allogeneic chimeras as a result of destruction of donor lymphoid cells during graft-versus-host disease; allogeneic chimeras have often been treated with immunosuppressive drugs after grafting, which not only delay or prevent graft-versus-host disease but also suppress the response of chimeric lymphocytes to other antigens; and the combination of toxic conditioning regimens, post-grafting immunosuppression and graft-versus-host disease causes gut damage leading to a malabsorption syndrome, which given enough time, can lead to immunodeficiency. In general, allogeneic resident chimeras are less immunologically active than their syngeneic counterparts even if studied as late as 300 days after grafting (reviewed elsewhere). In a recent study, the immune system of random-bred canine chimeras was surveyed for periods up to eight years after grafting. After a prolonged period of decreased immune reactivity lasting for 200 to 300 days after grafting, cellular and humoral immunity in these chimeras returned to the normal range. Although there was a delayed rise in antibody titers during the primary immune response, long-term chimeras showed normal peak titers and a normal qualitative and quantitative secondary antibody response. Animals were able to live in an unprotected environment without apparent increased occurrence of infection, supporting the conclusion that, after an initial phase of impaired immune function, these canine chimeras regained normal immune reactivity.

In an initial study we described evaluation of immunologic reactivity in 10 human recipients of allogeneic marrow observed for five to 20 months after engraftment. Five patients had hematologic neoplasia, and five aplastic anemia. Serum IgG, IgA and IgM levels declined in all recipients and then returned to normal by the 100th day. Absolute lymphocyte counts were above 1000 per cubic millimeter in all patients within one to three months after grafting. The recipients showed a markedly decreased antibody response to bacilliophage Ø ×174. In contrast, several of these recipients acquired cytomegalovirus or herpes zoster infections from which they recovered, and they developed good antibody titers against these agents. Testing in mixed leukocyte culture showed that recipients of allogeneic grafts had a wide range of responsiveness, but clear stimulation was observed on nearly all occasions even within the first month of grafting. Despite this in vitro activity, the allogeneic recipients, with one exception, could not be sensitized to dimethylbenzene when tested between 28 and 365 days after grafting. We concluded that recipients of allogeneic grafts showed a long-lasting immunologic deficiency that points out the necessity for vigilance in early detection and treatment of infection and the need for additional measures to restore immunologic competence in these patients.

Malignant Transformation of Donor Cells

A mechanism of leukemic relapse that was not anticipated was the possibility of malignant transformation of the engrafted marrow. Nevertheless, there is unambiguous evidence that this event has occurred twice in leukemic marrow-graft recipients. Two female patients with childhood acute lymphoblastic leukemia received total-body irradiation as their only cytoreduction in preparation for engraftment, followed by allogeneic marrow infusion from histocompatible male siblings. Both escaped the serious complications that follow marrow transplantation and appeared to achieve normal marrow status, only to suffer a florid leukemic relapse 69 and 135 days after engraftment. In both cases careful cytogenetic study of a large number of metaphase chromosomes, and in the second case, fluorescent staining for y chromatin in interphase nuclei, indicated that the recurrent leukemia was composed of male cells and was therefore of donor origin. There are only four other patients in our series who are strictly comparable to these two—that is, children with acute lymphoblastic leukemia prepared only with total-body irradiation. Three of these have also shown leukemic relapse, but in no case was an opportunity presented to determine the host or donor origin of the recurrent leukemia. The one leukemia-free patient in this group is our longest survivor at four years after grafting.

What caused the malignant transformation of the marrow graft? Several explanations have been discussed. It has been suggested that leukemia, at least in some cases, could be a disease of "regulation" such that any marrow in a leukemic host will become leukemic. Another theory advanced involves a cell-fusion event between donor and host cells followed by a loss of extra chromosomal material or "diploidization" with retention of the y chromosome. Still another suggestion is that immunodepression in the marrow-graft recipients could conceivably lead to a breakdown in the putative immune surveillance defenses against spontaneously arising malignant cell clones in the regenerating engrafted tissue. Furthermore, it should be noted that graft-versus-host reactions are themselves leukemogenic, at least in mice. Against the last two proposals is our failure to observe malignant transformation of marrow grafts in non-leukemic recipients. In addition, leukemogenesis mediated by graft-versus-host disease in mice appears to involve activation of endogenous C-type murine leukemic viruses. This point raises a final and perhaps most plausible hypothesis—specifically, that a leukemogenic virus or similar etiologic agent
resident in a recipient infected and transformed the transplanted marrow. Ionizing radiation will induce production of occult C-type leukemia viruses in some experimental animal systems. Moreover, oncovirus infections can be transmitted by fragments of cellular DNA containing an integrated DNA provirus, at least in some systems. Thus, one need not postulate the presence of recognizable whole-virus particles, but rather could envision transmission through the agency of subviral or other oncogenic subcellular material released from the degenerating host leukemic-cell population.

This list may well not exhaust all the possibilities underlying marrow-graft transformation, but in the absence of information on the ultimate mechanism, there are a number of questions of immediate consequence. The most important of these is the frequency and prevalence of leukemic transformation. The existence of a mechanism for the frequent induction of neoplasia in new populations of cells in the course of acute leukemia and related diseases might potentially threaten the ultimate success of intensive intermittent-therapy programs dependent upon the stepwise destruction of the tumor-cell population. At present, however, there is no conclusive evidence that induction of malignant transformation in new clones of cells does occur with noteworthy frequency outside of the two cases discussed here and the observation of apparent reversion of new tumor clones in certain late relapses of African Burkitt’s lymphoma.

Adoptive Immunotherapy

The data on allogeneic marrow transplantation for hematologic neoplasia permit no conclusion about the existence or absence of an antileukemic effect of graft-versus-host disease as anticipated from animal studies. The principal evidence that graft-versus-host disease, whether or not clinically detectable, did exert an antileukemic effect stems from the observation that leukemia recurred more frequently in recipients of twin marrow than in recipients of allogeneic marrow — in which the potential for graft-versus-host disease existed. Analysis of data on the patients whose leukemia cleared from the marrow and who survived for more than 60 days reveals that 13 out of 22 such patients exhibited recurrent leukemia after twin marrow grafts whereas leukemia recurred in only 5 out of 49 patients treated with an allogeneic graft. It must be emphasized, however, that clinically detectable graft-versus-host disease does not correlate with presence or absence of recurrence of leukemia. Most importantly, clinically detectable graft-versus-host disease is not essential for long-term, complete remissions. Of nine long-term survivors free of acute lymphoblastic leukemia, seven never had clinically evident graft-versus-host disease, and neither did five of nine patients whose leukemia relapsed. Of the long-term survivors free of acute myelogenous leukemia six of 10 did have graft-versus-host disease, but so did two patients whose leukemia recurred. Thus, it is not possible to recognize an antileukemic effect of graft-versus-host disease from the data currently available.

**Current Directions of Research**

**Nature of “Tolerance”**

In a stable long-term chimera, the immunologically competent foreign graft does not mount a harmful reaction against its host. The most common explanation is that the lymphoid cell clones that would have been reactive against host alloantigens have been made "tolerant" — i.e., specifically non-reactive. Another possibility is that the reactive cell clones have been eliminated in the course of an immunologic interaction. Alternatively, a form of immunologic enhancement may be involved, by which a factor in the chimeric individual’s serum can protect against cellular immune reactions. We studied nine canine irradiation chimeras between 178 days and 7.5 years after transplantation of allogeneic marrow. The lymphocyte populations were foreign to their hosts and, therefore, theoretically capable of mounting a graft-versus-host reaction. Lymphocytes from the chimeric dogs were found to inhibit colony formation by their "own" fibroblasts, whereas lymphocytes from other chimeras or from normal dogs did not (the test used was the colony-inhibition assay). Serum from the chimeras specifically abrogated this inhibitory effect. These initial results suggested that the immunologic "tolerance" of the chimeric dog was mediated in vivo by blocking serum substances. Subsequently, similar findings were reported in rodent radiation chimeras, in mice made tolerant by neonatal injections of allogeneic lymphocytes and in tetraparental mice.

More recently we studied nine canine irradiation chimeras and their DL-A-matched marrow donors between 545 and 1226 days after marrow grafting, using a microcytotoxicity or cell-inhibition assay. Before testing, marrow donors were immunized against their chimeras by repeated skin grafts, which they rejected. Skin fibroblasts from chimeras and their donors were tested for cell inhibition by exposure to sera from lymphocytes from chimeras, donors and normal dogs. Lymphocytes from sensitized marrow donors inhibited fibroblasts from their chimeras (eight of nine dogs); cell inhibition was abrogated by chimeric serum in only three of eight cases. Only one chimera showed consistent cell inhibition of its "own" fibroblasts, and the serum did not block cell inhibition. The remaining eight chimeras did not show consistent cell inhibition. In conclusion, the cell-inhibition assay is able to detect immunity across "minor" histocompatibility barriers in dogs. Results in chimeras suggest that serum blocking factors are not a prerequisite for maintenance of stable graft-host "tolerance" in DL-A-matched recipients. Similar findings were made in a subsequent study, in which 18 canine marrow-graft recipients were studied sequentially between 50 and 450 days after grafting.

Studies are now in progress involving the use of additional test systems and involving sequential studies of individual patients starting very early after the graft in an attempt to elucidate the complex problem of the "tolerant" state in the human marrow-graft recipient.
Marrow Transplantation from Unrelated Donors

It is obvious from the clinical experiences cited above that a multitude of problems remain to be solved when marrow donor and recipient are siblings matched at the major histocompatibility complex. At the same time, since less than half the patients will have matched siblings, efforts must be directed toward identifying unrelated persons who are perfect matches at the major histocompatibility complex for the patient. With computer technology, and with a large panel of donors, matching for the serologically detected loci can now be accomplished. Rapid advances in the ability to detect and evaluate lymphocyte-determined loci are occurring at present. Thus, we can expect in the near future to be able to identify unrelated donors matched at the major histocompatibility complex, either living donors or cadaver donors whose marrow has been stored. When this goal is achieved, it is important to realize that the unrelated donor matched at the major histocompatibility complex will be no better than the sibling similarly matched. The patient will still encounter the same spectrum of problems described above for the patient with a matched sibling. Hence, it is important to continue to try to solve these clinical and immunologic problems, especially since the vast majority of patients with matched siblings are not now being considered for marrow transplantation.

DISCUSSION

It seems likely that in the near future marrow transplantation will be attempted as therapy for any variety of malignant neoplasia that is sensitive to irradiation or chemotherapy and for non-malignant disorders of the marrow such as thalassemia and sickle-cell disease. At present each new patient with acute leukemia or aplastic anemia should undergo histocompatibility testing along with the members of the family. If the patient has a sibling matched at the major histocompatibility complex, transfusion of blood products should be minimized, and transfusion from family members should be avoided. Marrow grafting can be planned at an appropriate time, perhaps immediately for patients with severe aplastic anemia or acute myelogenous leukemia but only after failure of conventional therapy for patients with mild aplastic anemia and acute lymphoblastic leukemia. Proper selection of the type of patient and the time of grafting raises too many questions to be enumerated here. For example, are the extremely refractory leukemias, described above, the result of prior intensive chemotherapy, and could this problem be avoided by earlier marrow grafting?

Allogeneic marrow grafting in man is still an exceedingly complex and difficult endeavor. Therefore, certain supportive facilities should be considered as mandatory for any center undertaking a marrow-transplantation program, including means of providing the large numbers of platelets and granulocytes that may be required, facilities for the proper administration of total-body irradiation, protection against infection, and bacteriologic monitoring. Laboratory capability should include histocompatibility typing, mixed leukocyte culture and other immuno-

logic studies, production of antithymocyte globulin, cytogenetics and blood genetic markers. The marrow-graft team, including physicians, nurses and technicians, should have experience in transplantation biology and medicine with a successful program of animal transplantation using the techniques to be applied to man. In this setting the patient should have the maximum opportunity to benefit.

Noteworthy advances in the knowledge of the cause and pathogenesis of human diseases may be expected as a corollary of marrow-transplantation studies. Examples already at hand are the demonstration, by the fact of successful engraftment, that the marrow microenvironment is normal in most patients with aplastic anemia and a demonstration that in vivo malignant transformation of normal human cells can occur in acute lymphoblastic leukemia. Marrow transplantation will also provide insights into many aspects of transplantation biology and tumor immunology. Despite the many discouraging complexities associated with marrow transplantation, some degree of satisfaction may be derived from the fact that knowledge of normal and abnormal immunology and physiology is being increased during endeavors to provide new therapeutic approaches for the patient with otherwise fatal disease.

We are indebted to Dr. Eloise Giblett, who carried out the blood genetic marker studies, and to the entire nursing staff of the Division of Oncology for their management of these patients.

Canine models of bone marrow transplantation.

Ladiges WC, Storb R, Thomas ED.

Fred Hutchinson Cancer Research Center, Seattle, WA.

Progress in experimental bone marrow transplantation in dogs has provided for the direct transfer of research data to the clinical setting and the therapeutic application of marrow grafting to a variety of human diseases. Animal models of total body irradiation, engraftment and graft-versus-host disease are still needed to solve the existing clinical problems of marrow transplantation. Therefore, work in various canine model systems continues to be of interest. Pet dogs with spontaneously occurring lymphomas are used to study the clinical parameters necessary for applying the technique of transplanting their own marrow (autologous), in conjunction with high dose radiation and/or chemotherapy, to human patients with cancer. A major consideration in the successful transplantation of donor bone marrow (allogeneic) is overcoming histocompatibility barriers to assure engraftment and the prevention of graft-versus-host disease, a major limiting aspect of clinical marrow transplantation. Chemicals, radiation, radiotherapeutic techniques, antisera and monoclonal antibodies have been and continue to be developed in laboratory bred dogs. These approaches suppress the immune system either nonspecifically by ablation of immune reactive tissue, or specifically by affecting certain types of immune reactive cells. Parameters such as clinical effectiveness (engraftment or prevention of graft-versus-host disease), immune reconstitution and undesirable side effects in long-term survivors are all used to determine whether new technology can be transferred from preclinical canine studies to human bone marrow transplantation protocols.

Fatty Acid Composition of Adipose Cells in Red and Yellow Marrow: A Possible Determinant of Haematopoietic Potential

Mehdi Tavassoli, Donald N. Houchin & Peter Jacobs

Scripps Clinic and Research Foundation, La Jolla, California
and
University of Cape Town, South Africa

The fatty acid composition of whole bone marrow and that of isolated, disaggregated adipose cells from red and yellow marrow was examined by gas chromatography. Consistent and significant shifts from myristic and palmitic acids (in red marrow) to their respective monounsaturated derivatives myristoleic and palmitoleic acids (in yellow marrow) were found. These differences in the fatty acids correlate with histochemical studies and lend further support to the concept that the composition of lipid in the adipose cells of bone marrow may determine their relative stability in relation to haematopoietic requirements.

Key words: adipocytes – bone marrow – fatty acid composition – haematopoietic potential

Accepted for publication October 15, 1976

Correspondence to: Dr. Mehdi Tavassoli, The L. C. Jacobson Blood Center, Scripps Clinic and Research Foundation, La Jolla, California, 92037, USA

Man, like some of the other mammals, has areas of haematopoiesis unevenly distributed throughout the medullary cavity. In peripheral sites only adipose tissue or yellow marrow occurs and this seldom participates in blood formation even when demands are increased (Maniatis et al 1971, Tavassoli et al 1974). This situation contrasts with the more centrally located red marrow where the fat cells are intimately associated with haematopoietic elements and here they are in a state of flux being readily replaced by expansion of blood-forming tissue (Tavassoli et al 1972).

This striking difference in the physiology of marrow fat cells has not been elucidated, but there is evidence to suggest that those associated with the red marrow are functionally and structurally distinct from the morphologically similar cells comprising yellow marrow. For example, Cohen & Gardner (1965) reported that the yellow marrow partially defends itself against starvation whereas fat in red marrow is readily mobilized in parallel with the extramedullary adipose tissues. We have confirmed these findings (Tavassoli 1974a) and extended them with the observation that
phenylhydrazine-induced haemolysis leads to resorption of lipid contained in fat cells of red marrow whereas the yellow marrow is relatively stable (Tavassoli et al 1972, Tavassoli 1976).

Furthermore, in the course of histochemical studies of bone marrow, it was noted that the lipid substance contained within the fat cells of red marrow stained with performic acid-Schiff (PFAS), whereas those in yellow marrow did not. Significantly, when haematopoietic tissue hypertrophied in response to experimentally induced haemolysis, the former resorbed while the latter remained unchanged (Tavassoli 1976). These clear differences in the lipid composition of fat cells or adipocytes in the 2 types of marrow may account for their contrasting behaviour and, therefore, more precise characterisation was undertaken using gas chromatography. Since the bulk of this material has been shown both biochemically and histochemically to be triglyceride (Lund et al 1962, Tavassoli 1974) analysis was restricted to the fatty acids.

MATERIALS AND METHODS

Materials. New Zealand white rabbits, 10 to 12 months old, were used in the study. The sternum, 3 thoracic vertebrae, one or both femora, the tibias and os calcis were removed, weighed, broken into small pieces and separately homogenized in a blender. Vertebræ were taken as representative red marrow and os calcis as yellow marrow. Samples were also processed directly for lipid analysis.

Preparation of adipose cells. The adipose cells are disaggregated and separated from haematopoietic and stromal elements of the bone marrow after Rodbell (1964) and Adebonojo (1975). The bone marrow is sliced into small pieces and placed in 10 ml of McCoy's medium in a 25 ml siliconized Erlenmeyer flask to which is added 10 mg of collagenase for each g of tissue. The mixture is incubated at 37°C with slow constant gyratory rotation (50-100 rpm) for 1 h. Thereafter the contents of the flasks are gently stirred, the cells dispersed with a plastic spatula and any residual pieces of tissue are removed before centrifuging the suspension at 400 g. Fat cells and droplets of fat ruptured cells float to the surface forming a layer which is decanted, resuspended in fresh medium and again centrifuged. The latter step is repeated, after which the cells were plated in monolayer using 25 ml plastic culture flasks and incubated at 37°C during which time the adipocytes adhere to the bottom of the flasks. After 4 h the medium was changed and the cells were removed using EDTA and trypsin. Microscopic examination of these preparations, stained with oil Red O, confirmed them to be a pure preparation of adipocytes containing lipid vacuoles. Since individual preparations did not yield sufficient material for analysis, this was carried out on pooled samples.

Extraction of fatty acids for gas chromatography. The lipid fraction was extracted into chloroform (Hammarstrand 1966) by adding 20 ml of a chloroform-methanol mixture (2:1 by volume) to each g of tissue in the homogenate. Protein precipitate was removed by filtration through coarse fat-free filter paper and saline added to the extract in an amount equivalent to ¼ of the extract volume. The mixture was then vigorously shaken and allowed to stand overnight. The following day the upper aqeous phase was discarded and the lower chloroform phase, which contained the lipid, was evaporated to dryness under a stream of nitrogen and the residue containing the total fraction was weighed.

This residue was saponified by adding 50 ml of ethanol-ethyl ether (3:1 by volume) and 0.5 ml of 10 N KOH and allowing it to stand in a boiling water bath for 2 h. Sufficient water was then added to the soap solution to obtain a 50% ethanol-water solution of soap, after which 75 ml of petroleum ether were added and the solution was allowed to stand overnight. The following day the upper phase was discarded and the free fatty acids were liberated from the lower phase with 10 ml 0.5 N HCl, and these were extracted into a further 75 ml of petroleum ether.

Free fatty acids were methylated by the addition of 0.5 ml H2SO4 in 10 ml methanol and the esters extracted in 30 ml petroleum ether. The ex-
tract was evaporated to dryness below 40°C under nitrogen to prevent evaporation of the short chain methyl esters. The dry residue, a measure of total fatty acids, was weighed. The distribution of the various fatty acids was studied in a Varian Aerograph using a 12" x 1/8" stainless steel column packed with 20% diethylglycosuccinate on Chromosorb W, 60/80 mesh at a temperature of 205°C. The carrier gas was N₂ at a flow rate of 25 ml per min. All reagents were of analytical grade.

RESULTS

Terminology. In bone marrow, the bulk of fat is contained within the adipocytes which have a diameter between 140–160 μm, most of which is occupied by a single fat globule and several smaller ones (Tavassoli 1974). Lipid analysis (Lund et al 1962, Tavassoli 1974) has demonstrated that fat globules consist almost entirely of neutral fat and

Figure 1. Representative chromatograms for fatty acids of isolated, disaggregated marrow adipose cells from (A) vertebrae and (B) os calcis. Vertebral marrow is representative of red marrow while that of os calcis is representative of yellow marrow. Note the shift from palmitate (in red marrow) to palmitoleate (in yellow marrow); the pattern in tibial marrow is intermediate. Similar shifts can also be seen in myristate and myristoleate.

Free fatty acids: phospholipids are absent. In adult rabbits nearly half the volume of marrow in the axial skeleton (ribs, vertebrae and sternum) consists of fat, that of the os calcis almost entirely of adipocytes with the tibial and femoral marrow being intermediate (Tavassoli 1974, 1976).

**Lipid analysis.** The data for both whole marrow and isolated adipocytes from the 3 representative areas are set out in the table and figure.

Firstly, it can be seen that gas chromatographic analysis exposes distinct differences in the pattern of the individual fatty acids depending on the area from which the material has been collected. The proportion of myristate decreases gradually as the areas of yellow marrow are approached, with the highest levels being present in vertebrae and
and in marrow adipose cells from different rabbit bones

s sternum and lowest in the os calcis with intermediate figures obtained for femur and tibia. By contrast myristoleate increases from vertebrae towards os calcis. A similar but much more dramatic shift from palmitate to palmitoleate is evident and the prominence of this change reflects the greater contribution of palmitate to total fatty acid pool.

A comparable pattern is evident when isolated adipose cells are examined with a consistent shift from myristate and palmitate in vertebrae to their monounsaturated derivatives (myristoleate and palmitoleate respectively) in os calcis. These differences are statistically all highly significant.

The bulk of the fatty acids in both red and yellow marrow consists of stearate and oleate which, together, account for nearly half of the bone marrow fatty acids. There was no apparent difference in the proportion of these two substances in red and yellow marrow when whole tissue is studied. However, the data from isolated adipose
cells suggest a shift from stearate in vertebral adipocytes to oleate in those from the os calcis.

Furthermore, it is clear that the fatty acid fraction of total lipid is lowest in the vertebral marrow and highest in that from the os calcis with intermediate values being obtained for femur and tibia. This gradient parallels both the proportion of fat cells and the total fat content within the respective bones and is inverse to that of the blood forming elements, suggesting that the fatty acid content of marrow is contributed largely by the adipocytes.

Finally, the ratio of saturated to unsaturated fatty acids is somewhat higher in the red when compared to the yellow marrow.

DISCUSSION

The bone marrow is a dynamic organ normally capable of rapidly changing its fat content in response to expansion or contraction of the haematopoietic mass. That 2 apparently distinct types of fat cells can be identified and that differences in their composition can be related to the kinetics of haematopoiesis, suggest an important biological role for the adipocyte. This concept is supported by our observation that clear and consistent variations exist between the fatty acid composition of red and yellow marrow and, furthermore, that these reside in the adipose cells of this organ. Earlier histochemical studies (Tavassoli 1976) correlating areas of haematopoiesis with PFAS-positive cells are now given quantitative expression by chromatographic fatty acid profiles documenting a constant shift from myristate and palmitate in the red marrow to their monounsaturated analogues in yellow marrow. While acknowledging that the dissimilarities demonstrated in this and previous studies (Cohen & Gardner 1965, Tavassoli et al 1974, Tavassoli 1976) are not necessarily related to the functional differences between red and yellow marrow, the close correlation of fatty acid profile to the extent of haematopoietic activity strongly suggest a causal relationship. Furthermore, other works (Snyder 1965, Levis et al 1975) have also reported experimental studies in which the lipid composition of marrow is altered as medullary haematopoiesis changes.

We advance the hypothesis that the composition of lipid in the adipose cells of the bone marrow may determine their relative stability in relation to haematopoietic requirement. These changes can be reconciled with suggestions that differential blood formation in red and yellow marrow may relate to variations in temperature between the bones (Huggins & Blockso 1936, Weiss & Wislocki 1956, Petrakis 1965, Van Dyke 1967, Tavassoli 1970) by postulating that this is mediated through the lipids of the marrow. For example, a temperature gradient may alter lipid composition which could then modulate the potential of marrow for replacement of fat cells by haematopoietic elements. Additional support for the importance of bone marrow lipid structure in the regulation of haematopoietic cell proliferation derives from recent studies that these substances are implicated as bioregulators of cell growth and proliferation (Holley et al 1974, Inbar & Schinitzky 1974, Leder & Leder 1975).

We conclude that the striking and reproducible differences that exist between the fatty composition of red and yellow marrow support the concept that these substances within the adipocytes are important factors in determining the ability and the extent of the marrow contained in different bones to
respond to the expansion of blood forming elements under physiologic circumstances.

MEDICAL PROGRESS

BONE-MARROW TRANSPLANTATION

E. Donnall Thomas, M.D., Rainer Storb, M.D., Reginald A. Clift, F.I.M.L.T.,
Alexander Fefer, M.D., F. Leonard Johnson, M.B., B.S., Paul E. Neiman, M.D.,
Kenneth G. Lerner, M.D., Harold Glucksberg, M.D., and C. Dean Buckner, M.D.

The modern era of bone-marrow transplantation was ushered in by the experiments of Jacobsen, Lorenz and their colleagues, who showed that mice could be protected against otherwise lethal irradiation by shielding of the spleen or by intravenous infusion of marrow. At first it was thought that this protective effect was due to a humoral factor. By 1956, however, several laboratories, using a variety of blood genetic markers, demonstrated that the protective effect against lethal irradiation was due to the colonization of the recipient marrow by donor cells.

An article on clinical marrow transplantation that appeared in this journal showed that large amounts of marrow could be infused intravenously with safety, and described a transient marrow graft in man. It also provided estimates of the number of marrow cells needed and pointed out the potential application of marrow grafting to radiation accident victims, to the therapy of leukemia and to the therapy of patients with immunologic deficiencies (at that time collected under the heading of agammaglobulinemia). In the following year, Mathé et al. attempted the dramatic treatment, by marrow transplantation, of six human victims of an irradiation accident. Despite the promising potential usefulness of marrow transplantation, the next decade was one of frustration and disappointment. Most marrow grafts were carried out in terminally ill patients who did not live long enough for a graft to be evaluated. The few successful allogeneic grafts were followed by a lethal immunologic reaction of the graft against the host.

Recent advances in the knowledge of histocompatibility typing, in the prevention and management of graft-versus-host disease and in supportive measures for patients with no marrow function have renewed interest in the subject of marrow transplantation. In this article we shall attempt to review the basic immunobiology relating to and derived from the field of marrow transplantation and to describe the clinical progress that has been made, recognizing that this is only the beginning of a new phase in the development of a medical therapy.

Experimental Background

Studies in Rodents

The availability of inbred strains of mice has made possible extensive study of the genetic systems that govern acceptance or rejection of a tissue graft. The most widely studied immunosuppressive regimens to prepare the recipient for allogeneic marrow engraftment in rodents have been total-body irradiation or cyclophosphamide (or both), with occasional addition of antilymphocyte serum. The amount of irradiation required to permit engraftment and prevent rejection of incompatible marrow is higher than that which will induce fatal marrow aplasia. Total-body irradiation is most immunosuppressive if administered within 24 hours before the antigen, regardless of the nature of the antigen. Cyclophosphamide is an effective immunosuppressant in nonlethal doses. It is effective when given one day before the allogeneic marrow, but is more suppressive if administered one day after exposure to tissue antigens of the marrow donor. Although cyclophosphamide can suppress an established cell-mediated immune response against some
antigens in some animal models, it did not permit marrow engraftment in a rodent host presensitized to donor antigens several days before the cyclophosphamide administration and marrow infusion.

Graft-versus-host disease occurs whenever marrow or other tissue containing immunologically competent allogeneic cells is infused into a host who is unable to reject the infused donor cells. The pathophysiology remains unclear, especially the contribution of the host to the disease. The effector cell mediating graft-versus-host disease is probably a T cell, but involvement of other cell populations is likely. Although rodents with graft-versus-host disease die of infection that is presumably due to the immunoincompetence caused by the disease, it is possible that infection is an intrinsic part of the graft-versus-host disease per se with activation of latent infectious agents.

The treatment of graft-versus-host disease is a formidable problem. Methotrexate has been effective prophylactically. Cyclophosphamide, procarbazine, the combination of cyclophosphamide and prednisolone, and cyclosporine arabinoside are somewhat effective even against established graft-versus-host disease in some rodent models. Other approaches reported to have some effect in some models included administration of host lymphoid cells and antibody directed against donor isoantigens or against host isoantigens (as a form of enhancement). To date, the most impressive therapeutic results have been reported in mice kept in a germ-free environment and prepared with lethal total-body irradiation. When the animals were given allogeneic marrow the rate of fatal graft-versus-host disease markedly decreased, but spleen cells still resulted in fatal graft-versus-host disease. Finally, the literature is replete with approaches to specific or preferential elimination of lymphoid cells capable of inducing graft-versus-host disease from donor marrow suspensions. These approaches remain highly experimental and variably efficacious.

The application of marrow transplantation to tumor therapy received early attention on the basis of the rationale that tumors, especially hematologic neoplasms, might be eradicated by lethal doses of total-body irradiation and that donor marrow would repopulate the host and prevent radiation-induced death. The attempts to use such an approach have been based largely on studies in readily manipulable rodents bearing a variety of tumors as recently reviewed. Interpretation of the results of syngeneic marrow transplantation in tumor-bearing mice has been influenced by several findings in the area of tumor immunology: most murine tumors possess tumor-associated antigens capable of evoking a cell-mediated as well as humoral antibody response against them; adoptively transferred lymphoid cells can inhibit tumor growth but only if the cells are immune to tumor-associated antigens, but with rare exceptions, such adoptive tumor immunotherapy, although characterized by unique antitumor specificity, can cope with only a small tumor load; and in several murine tumor models such syngeneic adoptive immunotherapy when used as an adjunct to sublethal chemotherapy can eradicate even clinically evident leukemia if the syngeneic lymphoid cells are immune to tumor-associated antigens.

Allogeneic marrow transplantation for leukemia represents a final common pathway between the problems of transplantation immunology posed by the graft and the problem of antitumor chemotherapy and immunotherapy posed by the presence of leukemia. The only additional element introduced is that of the effect of graft-versus-host disease on the leukemia and possibly the effect of the leukemia on the severity or expression of the graft-versus-host disease. Barnes et al. postulated that allogeneic marrow infused into leukemic mice after lethal total-body irradiation would colonize the host and would "destroy, by the action of the immunity these residual leukemic cells — and perhaps also the host." Many studies with histoincompatible cells have shown that graft-versus-host disease when sufficiently severe will affect some tumors, but most mice will die of graft-versus-host disease whereas a few mice will survive the fatal disease and will be tumor free. Mathé suggested the possibility that one might use the graft-versus-host disease against the tumor, but then treat the graft-versus-host disease and save the cured host. Unfortunately it is extremely difficult to control the graft-versus-host disease once it is established, even in non-tumor-bearing mice. One approach was recently illustrated in a murine tumor model in which nonlethal subclinical graft-versus-host disease was effective against a disseminated leukemia, but the same reaction was immunotherapeutically more effective when induced by lymphoid cells from donors preimmunized against tumor-associated antigens.

Studies in Dogs

In our laboratory we have carried out extensive studies with dogs, as an animal model of random-bred species, for studies of principles and techniques applicable to man. Dogs have a major histocompatibility complex called DL-A (reviewed by Albert et al.). Canine families are readily available for genetic studies of transplantation antigens, and canine litters provide matched sibling pairs simulating the HL-A-matched human sibling pairs. Important observations include the following:

1. Studies in dogs indicated that cyclophosphamide can be substituted for total-body irradiation to condition recipients for marrow transplantation.

2. Marrow can be effectively stored at low temperatures in dimethyl sulfoxide for use in marrow grafting.

3. Stem cells in the bulky coat from the peripheral blood are able to repopulate the irradiated marrow spaces. Such stem cells are absent among thoracic duct lymphocytes.

4. The dog was the first animal in which the predictive value of in vitro histocompatibility testing for the outcome of marrow grafts was demonstrated. Canine littermates matched at the major histocompatibility complex survive better than mismatched ones, but approximately 50 percent of the animals succumb to late graft-versus-host disease. This result indicates that "minor"histocompatibility differences also can play a part in the development of fatal graft-versus-host disease. Such disease can be pre-
vented or reduced in severity by the prophylactic use of methotrexate after grafting. The drug can be discontinued approximately three months after transplantation without subsequent development of graft-versus-host disease. Antithymocyte serum is of value in treating established graft-versus-host disease.

5. Blood transfusions before grafting, even from a donor compatible at the major histocompatibility complex, may sensitize the intended marrow-graft recipient and make graft rejection much more likely to occur.

6. Long-term healthy marrow chimeras can be achieved in this random-bred species with chimerism persisting for at least 10 years. These animals can be used in studies on the nature of the operational "tolerance" necessary to maintain the stable chimeric state.

7. Certain canine spontaneous diseases such as hemophilia, cyclic neoplasia, malignant lymphoma, leukemia and other malignant solid tumors as well as hemolytic anemia associated with congenital pyruvate kinase deficiency are valuable models to study the use of marrow grafting for the treatment of these diseases. For instance, it was possible to show that canine cyclic neutropenia is not due to a deficiency of marrow regulation, but rather to a stem-cell defect that can be corrected by marrow transplantation.

In canine hemophilia, orthotopic transplantation of a normal liver into a hemophilic dog resulted in complete correction of the deficiency of factor VIII. However, there are noteworthy extrahepatic sources of factor VIII, since hepatotransplanted normal dogs bearing a transplanted liver from a hemophilic dog show factor VIII levels equivalent to that seen in the heterozygous state. Marrow grafting studies ruled out the hemopoietic and lymphoid systems as sources of factor VIII production.

Studies in Nonhuman Primates

It was thought that the monkey was the animal of choice for study of problems in marrow transplantation because of its close phylogenetic relation to man. The work of the Dutch researchers has focused on the early occurrence of fatal graft-versus-host disease in the monkey after transplants between randomly selected donor and recipient.

It was believed that the monkey differed in that respect from the dog and mimicked more closely the human situation, in which rapid onset of graft-versus-host disease with fatal outcome had been reported. When dog and monkey were compared, however, severity of graft-versus-host disease, time of onset and fatality rate did not seem to be different if donor and recipient were known to differ at the major histocompatibility complex. Van Bekkum and DeVries have provided excellent descriptions of the histopathology of the lesions of graft-versus-host disease observed in the monkey. Other studies in primates have focused on conditioning regimens. It was observed that very high doses of cyclophosphamide are needed to obtain successful grafts of allogeneic marrow. It was also found that the limiting toxicity of the antineoplastic drug in the primate is fatal cardiac toxicity. The problem with the monkey model is related to the fact that the animals are scarce, expensive and breed slowly. For these reasons, studies on grafts between monkey siblings have not yet been reported. The monkey is difficult to handle during the necessary intensive-care post-grafting. Also, monkeys with spontaneous hematologic and neoplastic diseases are rarely available.

HUMAN MARROW TRANSPLANTATION

Histocompatibility

Syngeneic or isogeneic marrow grafts, as between inbred mice or between identical twins, involve donors and recipients carrying the same tissue antigens, and thus there is no immunologic barrier to transplantation. A special kind of syngeneic graft, an autologous marrow transplantation, refers to infusion of the patient's own marrow that was set aside before intensive radiation therapy or chemotherapy.

An allogeneic marrow graft involves a donor and recipient of different genetic origin within the same species. Such transplants involve moderate to severe histoincompatibility and present a bidirectional immunologic barrier to transplantation. In the first place, the recipient may react against the graft and reject it. Secondly, a problem unique to the transplantation of tissue containing immunologically competent cells, the infused marrow cells from the donor may react against the host to produce the illness known as graft-versus-host disease.

In the mouse the major histocompatibility complex, called H-2, is composed of at least two serologically detected loci, an immune recognition locus and two lymphocyte-detected loci recognized by reactivity in mixed leukocyte culture. In addition to the H-2 region, a number of minor histocompatibility loci have been identified. The complexity of the major histocompatibility complex in the mouse seems to be reflected in the outbred species studied, principally the dog (reviewed by Albert et al.), the monkey and man.

In man, the major histocompatibility complex involves two closely associated serologically detected loci, the first, or "L.A," locus, and the second, or "four," locus. Antigens determined by the serologically detected loci are recognized by cytotoxic isoantisera raised by immunization or that arise during the course of pregnancy. More than 13 first-locus and 15 second-locus antigens can now be identified, and the resulting very large numbers of haplotypes make this the most complex genetic region yet recognized in man. The term haplotype was introduced by Cepelini to indicate the products of the major histocompatibility complex in haploid form. In addition to the serologically detected loci, there is a closely associated lymphocyte-detected locus just outside the "four" locus. Studies of the lymphocyte-detected locus are currently under way utilizing lymphocyte-detected homozygous cells as identified in the progeny of related marriages. Already several lymphocyte-detected types have been identified.

Marrow grafts between unrelated human beings carry a
high probability of major histoincompatibility due to the complex polymorphism of the major histocompatibility complex. Within a family, however, the situation is simplified considerably, since only four haplotypes can be involved (two from each parent) and since unrecognized, closely linked loci may be expected to segregate with the recognized HL-A antigens. HL-A typing of the family usually permits a genetic analysis of the four haplotypes, and offspring who have inherited the same two haplotypes are referred to as “genotypically matched.” The apparent match can be confirmed by nonreactivity in one-way mixed leukocyte culture. Some loss of potential donors occurs as a result of ABO incompatibility, although a few marrow grafts have succeeded despite ABO differences. The number of patients with matched siblings is quite large, particularly since many patients have more than one sibling. In practical terms, in the course of HL-A typing of 533 patients with at least one sibling, we have found 255 (48 per cent) who had HL-A matched siblings.

With a large “bank” of individuals of known HL-A phenotype, it is possible to identify unrelated individuals who are phenotypically HL-A matched, some of whom will not react in mixed leukocyte culture. However, in our laboratory 28 such pairs have reacted in mixed leukocyte culture, indicating that a strong incompatibility still exists. The current research on lymphocyte-detected typing, mentioned above, offers a potential solution to this problem.

Preparation of the Recipient

The recipient of a syngeneic graft requires no immunosuppressive preparation. Similarly, the patient with severe combined immunologic deficiency disease requires no immunosuppressive preparation because of the nature of his disease. All other recipients of marrow grafts must have some form of immunosuppressive preparation so that they will not reject the graft. The type of preparation is influenced by the nature of the underlying disease.

In marrow grafting for non-malignant conditions, the preparation of the recipient can be directed solely at the problem of immunosuppression without concern for the problem of eradicating malignant cells. Most of our patients with aplastic anemia have been prepared with a modification of the regimen of Santos, which involves the administration of 50 mg of cyclophosphamide per kilogram on each of four days followed 36 hours later by the marrow infusion. Cyclophosphamide is administered 24 hours after infusion of antigen from the prospective donor, usually in the form of buffy-coat cells. Nausea and vomiting accompanying administration are usually severe but transient. A high urine flow must be maintained to avoid severe cystitis due to cyclophosphamide metabolites excreted in the urine. The use of diuretics is recommended because of an antidiuretic effect of the drug. Since in aplastic anemia marrow “space” is already available, Amiel et al. conditioned seven patients with the disorder for allogeneic marrow grafting by injection of horse antilymphocyte serum. In three patients they observed engraftment of erythroid marrow, but not lymphoid cells, although the grafts generally were transient.

In malignant disorders, specifically acute leukemia, preparation of the recipient must involve not only immunosuppression but also therapy designed to kill all or nearly all of the leukemic cells. Total-body irradiation has been the most common means of conditioning a marrow-graft recipient. Studies in dogs showed that a midline tissue exposure of 500 rad of total-body irradiation, although lethal, was not sufficiently immunosuppressive to permit successful grafting of allogeneic marrow. Consistent and sustained engraftment of allogeneic marrow in the dog was achieved only when the irradiation was raised to 950 rad. Canine radiation chimeras have always been “complete” chimeras — i.e., analyses of karyotypes of cells in peripheral blood, marrow and lymph nodes up to eight years after marrow grafting have consistently shown only cells with donor karyotype — whereas dogs prepared with cyclophosphamide were “mixed” chimeras — i.e., both donor and host cells were present. The finding of persisting host cells indicates that cyclophosphamide may be less desirable than total-body irradiation in efforts to treat hematopoietic neoplasias by marrow grafting.

In preparing leukemic patients for grafting, we have routinely administered a 1000-rad midline tissue dose of total-body irradiation. Opposing 60Co sources are used in an effort to achieve more homogenous irradiation. Rotating the patient to achieve homogeneity not only is cumbersome but may be undesirable when one is dealing with a migrating population of malignant cells (leukemia). Acceptable homogeneity might be achieved with a single very high energy source but successful marrow grafts in large animals have not been reported with those technics. The acute nonmarrow toxicity is generally well tolerated, consisting of low-grade fever, immediate but transient nausea, vomiting and diarrhea and tender swelling of the parotid gland that resolves within 24 to 48 hours.

Leukemic cells are sensitive to irradiation; irradiation penetrates to all “privileged” sites and is an effective immunosuppressive agent. However, when we used irradiation only, we observed a high rate of recurrent leukemia. To increase the leukemic-cell kill we decided to give cyclophosphamide, 60 mg per kilogram, five and six days before irradiation. The result has been a striking decrease in the rate of recurrent leukemia. In the present series of patients, we are administering additional antileukemic therapy just before the administration of cyclophosphamide and irradiation with the intent of obtaining maximum leukemic cytociduction within the range of tolerable nonmarrow toxicity.

Graw et al. prepared patients with acute leukemia for engraftment by the administration of 45 mg of cyclophosphamide per kilogram given on each of four successive days. They observed early recurrence of leukemia. Santos et al. prepared leukemic patients with 50 mg of cyclophosphamide per kilogram given on each of four days. They observed the complete disappearance of host-type cells in the first few weeks after grafting. Unfortunately, most of their patients did not live long enough for complete evaluation, but one patient did have a remission of 11 months’ duration before relapse with host-type leukemic cells. More recently, Graw and his colleagues have.
prepared four leukemic patients for engraftment with a four-day drug regimen involving high doses of cyclophosphamide, cytosine arabinoside, 6-thioguanine and 1,3-bis-(2-chloroethyl)-1-nitrosourea (BCNU). One of their patients with acute myelogenous leukemia is still in complete remission with a successful graft more than two years after grafting, suggesting that it may be possible to eradicate a leukemic cell population with drugs without the use of irradiation. Gengozian et al. prepared two patients with acute myelogenous leukemia with antithymocyte globulin and 375-rad total-body irradiation. They observed successful engraftment, indicating the adequacy of the immunosuppressive regimen and apparent absence of graft-versus-host disease, but one patient died of infection and the other of an early return of leukemia.

**Technic of Marrow Transplantation**

In the laboratory, marrow has been administered by a variety of routes, including intravenous, intra-arterial, intraperitoneal and intramedullary. VanBekkum studied the problem of the route of administration in the mouse and found the intravenous route to be best since the intraperitoneal route required about 70 times as much marrow for successful engraftment. Recent studies of this problem in the monkey showed that two to three times as much marrow is required when it is given intraperitoneally as compared to intravenously. Although some patients with immunologic deficiency disorders have had successful engraftment after intraperitoneal administration, most investigators now use the intravenous route.

Histo compatible donors are most likely to be found among members of a patient's family, and, thus, living volunteers are at present the principal source of donors for marrow grafts. One unit of blood is obtained from the marrow donor a few days before the procedure, stored in acid citrate dextrose, and returned to the donor during the aspiration, thus avoiding exposure of the normal donor to the risks of blood transfusion from another person. Marrow is obtained by multiple aspirations from the iliac bones in an operating room under sterile conditions. Spinal anesthesia is preferred, but occasionally general anesthesia is indicated. When the needle point is inserted into the marrow cavity, vigorous suction is applied while the needle is rotated. The volume aspirated from each site is limited to 1 to 3 ml to minimize dilution with peripheral blood. Marrow is aspirated and transferred quickly into a beaker containing tissue-culture medium and heparin without preservative. The pooled aspirated marrow, usually 400 to 800 ml, is passed successively through stainless-steel screens of 0.3-mm and then 0.2-mm opening. Screening produces a single-cell suspension permitting accurate cell counts and, most importantly, avoids potentially lethal marrow emboli. Cooling the marrow suspension is unnecessary and may lead to clumping of fat. The recipient must be monitored carefully during the intravenous infusion. Signs of fluid overload or strain on the right side of the heart dictate slowing of the infusion or, occasionally, phlebotomy before the infusion is completed. We have carried out marrow aspirations on more than 200 donors. Invariably, the procedure has been well tolerated. No long lasting effects are to be expected from the removal of a small fraction of a rapidly replicating tissue. The risk of anesthesia remains a legitimate concern.

**Supportive Care**

Before grafting, almost all marrow-graft recipients go through a period of no marrow function owing to their disease or to preparation for engraftment. After grafting, there is a period of 10 to 20 days before the graft begins to function. Effective supportive measures during these periods of marrow aplasia are absolutely essential to success in a marrow-transplantation program.

Before transplantation it is very important that blood products from family members should not be administered to potential recipients of sibling marrow transplants because of possible sensitization against non-HLA tissue antigens of the donor. An exception is that children of the prospective recipient may be used when the donor is to be a sibling of the recipient. After the marrow graft the family may be used as blood-product donors. The intensive use of one or two donors greatly reduces the potential exposure to cytomegalovirus, toxoplasma and hepatitis. All blood products infused into recipients of allogeneic marrow transplants are exposed to 1500 R of 60Co irradiation to prevent the proliferation of lymphoid cells, which might produce or enhance graft-versus-host disease.

Our policy is to attempt to maintain a circulating platelet count of greater than 20,000 per cubic millimeter. Platelet consumption due to infection or the underlying disease is a frequent problem. Platelets from HL-A-matched siblings are probably not subject to immunologic destruction.

Available technics do not provide the same transfusion support capability for granulocytes as for platelets. Even small elevations of circulating granulocyte levels require very large numbers of infected cells owing to their dilution in the marginal pool, the short half-life (six hours) of normal granulocytes and their rapid utilization in the face of infection. Most groups involved in granulocyte transfusion therapy of infected agranulocytic patients have concluded that such transfusions are beneficial, but objective data supporting these conclusions are understandably scarce. The largest controlled studies were conducted by Graw and McCredie and their associates. If recipient sensitization to allogeneic granulocytes is suspected, the suitability of a donor can be assessed by detection of the survival of the potential donor's platelets. For our patients the granulocyte donor has usually been the marrow donor or another family member. Such donors are well motivated to tolerate the daily inconvenience. We initiate granulocyte transfusion therapy when a serious bacterial or fungal infection develops in an agranulocytic transplant recipient; once started, the transfusions are continued daily until the recipient is able to support levels of circulating granulocytes higher than can be achieved by granulocyte transfusion. We are investigating the potential benefits of prophylactic granulocyte transfusion for uninfected agranulocytic patients in a controlled study.

We harvest granulocytes with two National Cancer Institute-IBM continuous-flow cell separators using arteriovenous shunts in the donor. This procedure is well tolerated by the donor and permits the processing of...
larger quantities of blood on a daily basis. Approximately 18 ± 8.7 (± S.D.) × 10^9 granulocytes can be collected daily by this technic. The granulocyte-rich buffy coat often contains sufficient platelets to satisfy the platelet requirements of the recipient. Reversible leukodetachment with use of Leukopaks was developed by Djerassi. Equipment for this procedure is commercially available and relatively inexpensive. There are reports of severe recipient reactions to Leukopak-collected granulocytes, but this has not been a problem in our experience.

Because of the susceptibility to infection, it seems reasonable to the patient from possible contact with pathogenic micro-organisms. Recent developments in techniques of laminar-air-flow isolation and of suppression of the gastrointestinal flora with nonabsorbable antibiotics have increased the ability to achieve the "sterile" patient. The observation that the clinical manifestations of graft-versus-host disease can be less severe in neutropenic mice than in normal mice has prompted the speculation that attempts to render human recipients of marrow transplants bacteria-free might reduce the frequency and severity of this complication. These procedures are complicated and expensive and involve patient discomfort and inconvenience. It is therefore very important that their benefits be accurately evaluated. Controlled studies of this problem are under way in our center, but no firm conclusions are available at present. As a practical matter, almost all our marrow transplants have been carried out with simple mask reverse isolation. In the absence of controlled studies, the published suggestion that marrow grafts should only be done in a sterile environment should be regarded as speculative.

**Clinical Results of Marrow Transplantation**

**Immunodeficiency**

This review is concerned primarily with marrow transplantation in persons who have achieved immunologic maturity. Studies of marrow and thymus transplantation in patients with immunologic deficiency have revealed important basic information, despite the rarity of these disorders. Details of these studies are provided in review articles. In reading these reviews, one must keep in mind that patients with severe combined immunologic deficiency are different from the cases in this report in two important respects: the disease represents an experiment of nature in which the recipient does not require immunosuppression to accept a graft; and because some myeloid marrow function is usually present, rapid marrow engraftment is not mandatory, permitting the use of very small numbers of marrow cells, given repeatedly if necessary. These differences permit the design of highly informative experiments that are not possible in patients with aplastic anemia or leukemia.

**Aplastic Anemia**

Syngeneic (monozygotic twin) transplants. Despite introduction of broad-spectrum antibiotics, androgenic steroids, corticosteroids, and support with cellular blood elements, the mortality in severe cases of aplastic anemia is 50 to 90 per cent, with many patients dying within the first three months of diagnosis. Treatment of this illness by infusion of marrow cells from a normal identical twin is of great interest since the fate of the infused hemopoietic cells might provide valuable information about the cause and the pathogenesis of aplastic anemia. Up to the present, 10 cases have been described involving patients with acquired aplastic anemia whose identical twins donated marrow. Two patients died within a few hours or days of marrow infusion. In five of the remaining eight, signs of beginning marrow regeneration were observed one to two weeks after grafting, and full recovery followed. The three patients treated in Seattle are alive and well with normal hemopoietic function six to 12 years later. Although proof of engraftment cannot be obtained in the syngeneic situation, these observations suggest that most cases of aplastic anemia are due to a persistent abnormality induced in the stem-cell population. Otherwise, engraftment of normal, syngeneic stem cells would not be expected to correct the abnormality. The patient with marrow failure who is fortunate enough to have a normal identical twin is a natural candidate for marrow transplantation and should be treated promptly since this form of therapy is essentially devoid of risk and has a high probability of success.

**Allogeneic transplants.** Through the end of February, 1974, we had treated 37 patients with aplastic anemia with transplants of marrow from major-histocompatibility-complex-matched siblings. Briefly, the patients' ages ranged from three to 67 years, with a median of 19. Twenty-three of the 37 had aplastic anemia of unknown cause: in seven the disease was associated with drugs, and in four with hepatitis; in two it occurred after a prolonged period of acquired paroxysmal nocturnal hemoglobinuria and in one it was associated with Fanconi's syndrome. The duration of the anemia ranged from one to 53 months, with a median of three months. Thirty-one patients had received therapy with androgenic steroids and had failed to respond. All but two had received multiple transfusions from unrelated donors before transplantation. Eight patients had received transfusions from parents or siblings. Eighteen patients were refractory to random platelet transfusions. Seventeen were infected at the time of admission. Granulocyte levels at admission ranged from 0 to 1000 and platelet counts from 1000 to 22,000 per cubic millimeter. Thirty-six patients were estimated to have less than 10 per cent normal megakaryocyte numbers in the marrow, 50 had less than 10 per cent granulocyte precursors, and 29 had less than 10 per cent erythroblast precursors at the time of admission.

Twenty-eight patients were conditioned for marrow grafting by administration of cyclophosphamide, 50 mg per kilogram, intravenously on each of four successive days. Nine patients were conditioned by a 1,000-rad midline tissue exposure of total-body irradiation. The day of marrow infusion was designated "day 0." After marrow grafting, methotrexate was administered intermittently as described below. Survival curves for these patients are shown in Figure 1.

Three patients died too early to evaluate success or failure of marrow grafting: one died on the day of grafting of congestive heart failure, possibly related to cyclophos-
phamide cardiac toxicity; two died on the sixth and eighth days from bacterial infection. One patient had no evidence of marrow engraftment and died on the 24th day of infection. The marrow at autopsy was extremely hypocellular.

Thirty-three patients gave evidence of marrow engraftment as indicated by rising peripheral blood counts between the 10th and 21st days after marrow infusion. Examination of marrow aspirates and biopsies confirmed marrow engraftment. Twenty-one of the 33 had donors of opposite sex. Cytogenetic analyses of marrow and peripheral blood cells carried out as early as the 14th day after grafting proved engraftment. Only cells of donor karyotypes have been found up to the present in surviving patients. In other patients, other blood genetic markers such as red-cell antigens and enzymes were used to monitor allogeneic engraftment. After initial marrow engraftment, six patients rejected their grafts, with progressively falling peripheral blood counts leading to marrow hypoplasia. Five of the six died between the 33rd and 67th days with infection. One of the six showed autologous marrow recovery as evidenced by cytogenetic analyses of marrow and peripheral blood cells and is well more than one year later. Of the patients with a graft, one died with a fungal infection on the 18th day, three died from cytomegalovirus pneumonia between the 5th and 91st days and one died of unknown causes on the 427th day. Six patients died with graft-versus-host disease between the 19th and 95th days. Sixteen patients are alive, with functioning grafts.

The results show that normal allogeneic hemopoietic stem cells can repopulate the marrow in patients with aplastic anemia and that the disease is usually related to a failure of the hemopoietic stem cells. An exception to this rule may be the one patient with autochthonous marrow recovery after rejection of the marrow transplant from his sister. Our experience shows that long-term stable chimerism is possible in man. Clearly, major problems remain to be solved. Even so, the survival and hematologic reconstitution of almost half our patients with advanced aplastic anemia treated by allogeneic marrow grafts compare favorably with results obtained by conventional management of this disease. Initially, we restricted this procedure to critically ill patients. The results, however, indicate that marrow transplantation has emerged as a definitive form of therapy for aplastic anemia provided an HL-A matched sibling can be identified as a potential marrow donor. Marrow grafting should be considered before major infection and refractoriness to blood transfusions occur. Other centers have now reported successful marrow grafts in aplastic anemia that confirm this suggestion.

Acute Leukemia

Syngeneic (monosygotic twin) transplants. Since lethal total-body irradiation can exert a definite anti-leukemic effect, and since syngeneic marrow infusion can prevent death from the irradiation-induced aplasia, the rare leukemic patient with advanced disease who is fortunate enough to have a normal identical twin is the logical candidate for attempts to eradicate the leukemia by total-body irradiation and twin marrow transplantation. Very early encouraging results in mice prompted Thomas et al. to try such an approach in three patients with acute lymphoblastic leukemia. Although normal hemopoiesis was restored, leukemia recurred within seven to 12 weeks. A fourth patient with acute lymphoblastic leukemia received cytosine arabinoside before the total-body irradiation and methotrexate after the marrow transplant, but still relapsed within seven weeks (Table 1).

Beginning in 1969 potential "immunotherapy" was added to the basic regimen of total-body irradiation and twin marrow with the hope of delaying leukemic recurrence. It was based on principles outlined in the above section on studies in rodents and on studies supporting the existence of human leukemia-associated antigens. Since we would not expose normal twins to tumor material, the immunotherapy after total-body irradiation and marrow transplantation consisted of infusion of normal-twin buffy-coat lymphocytes three times per week for three weeks and weekly subcutaneous injections of lethally irradiated, autologous, leukemic cells, in the hope of providing a continual antigenic stimulus to the infused donor lymphocytes. The leukemic cells were stored at -180°C in 10 per cent dimethyl sulfoxide and irradiated with 10,000 rad to prevent cell replication. The results obtained in three patients treated with total-body irradiation, marrow transplantation and immunotherapy are presented in Table 1.

*Death at 4 mo of pneumonia in remission.

*1 patient died of pneumonitis at 1 mo while in remission.
shown in Table 1. A 15-year-old patient with acute lymphoblastic leukemia relapsed within a month, a 26-year-old patient with acute myelogenous leukemia went into remission but died of interstitial pneumonitis at seven weeks, and a 33-year-old patient with acute myelogenous leukemia relapsed at 10 months.

We assumed that the addition of a high dose of chemotherapy to the treatment regimen would be beneficial by decreasing the tumor load to be handled by the total-body irradiation or immunotherapy or both. Therefore, 20 subsequent patients received cyclophosphamide (60 mg per kilogram on each of two days), total-body irradiation (1000 rad), twin marrow transplants and, in 13 cases, immunotherapy. All patients had received chemotherapy and were considered to be in the terminal phase of the illness. The seven patients who did not receive immunotherapy either had not had readily accessible tumor cells for storage or had normal-twin donors who were unable to donate regularly the necessary buffy-coat cells. Thus, this was not a randomized study to determine the contribution, if any, of immunotherapy to the overall results. The results are shown in Table 1. One patient died of hepatitis too early to be evaluated, and two failed to clear their marrow of leukemic cells. Seventeen experienced complete remission. Eight of them (three with acute lymphoblastic, four with acute myelogenous, and one with lymphosarcoma leukemia) remain in complete remission at three to 49 months without any maintenance chemotherapy. All the normal-twin donors remain in excellent health without evidence of hematologic neoplasia.

As predicted from rodent models, although normal hemopoiesis was restored in our twin transplant recipients, the principal problem was that of resistance of the hematologic neoplasms in almost half our patients, as reflected by persistence of leukemic cells or recurrence of leukemia after several months of remission. This resistance has also been a problem in four patients with leukemia treated by others with high-dose combination chemotherapy with marrow infusion from a normal twin—all relapsed within a few months. Thus we are now adding intensive combination chemotherapy before the cyclophosphamide and total-body irradiation to reduce further the tumor burden. Our results are sufficiently encouraging to recommend this approach to any patient who has an identical twin and hematologic neoplasia even before the patient becomes demonstrably resistant to any chemotherapy. Furthermore, this approach may also be applicable to the treatment of other tumors such as lymphomas, neuroblastomas, and anaplastic carcinomas known to be sensitive to high doses of chemotherapy and total-body irradiation.

Allogeneic transplants. The majority of marrow grafts for acute leukemia have been performed between ABO-compatible, HLA-identical siblings and siblings not reactive in mixed leukocyte culture. The main differences in the approach to marrow grafting have centered on methods of conditioning the patient for the marrow graft and of postgrafting immunosuppression. Table 2 describes the approach adopted in several institutions since 1970. Of the conditioning regimens so far tried, reductive, high-level chimerism and sustained remission have been obtained only with cyclophosphamide in doses of at least 45 mg per kilogram per day for four days, high-dose chemotherapy (BACT) and, as will be described, total body irradiation alone or in combination with cyclophosphamide. Conditioning with antilympho-

In Seattle, 1000-rad total-body irradiation, initially alone and subsequently with the addition of cyclophosphamide and, more recently, cyto reduction as described, have been used as the conditioning regimens in the 70 patients receiving marrow grafts for acute lymphoblastic or acute myelogenous leukemia between July, 1969, and June, 1974 (Table 3). A review of this five-year experience illustrates the changing problems but the definite progress evident in marrow grafting for acute leukemia.

*Of these patients were prepared with total-body irradiation only.
1 Patients relapsed with central nervous system leukemia at 18 mo; all other patients relapsed in <7 mo.
2 Chronic myelogenous leukemia in blast crisis.

Thirty-six patients, two to 56 years of age (average of 23 years) received marrow grafts for acute myelogenous leukemia, and 34 patients, five to 22 years of age (average of 11 years) for acute lymphoblastic leukemia. Relevant to evaluating this approach is the clinical condition of these patients at the time of grafting. All patients received transplants at a time when conventional and experimental chemotherapy was failing. The duration of disease from diagnosis averaged 24 months in patients with acute lymphoblastic leukemia, spanning an average of three relapses, and in acute myelogenous leukemia, it averaged 10 months, with 15 patients not achieving a remission with chemotherapy. Overall, 64 of the 70 patients were in relapse, 68 had previously been transfused with red cells or platelets (or both), and 22 were infected at the time of transplantation.

Two patients died in less than 10 days, and five did not show engraftment. Sixty-three obtained functional grafts demonstrated by rapidly rising peripheral counts, histologic evidence of a graft, and, when possible, cytogenetic analysis and red-cell or white-cell antigen or enzyme studies. In 46 of these 63 patients (73 per cent) graft-versus-host disease developed, ranging from an erythematous skin rash lasting only several days to the fatal syndrome of a desquamating erythematous skin rash, gross liver-function abnormalities and profuse diarrhea. There was no difference in the incidence of graft-versus-host disease in the two disorders — 21 of 31 patients with acute lymphoblastic and 25 of 32 patients with acute myelogenous leukemia.

The overall survival data for this group of patients are shown in Figure 2. Although the median survival for patients with the two types of leukemia remains short, the five-year period is characterized by marked improvement in supportive care of patients and more effective conditioning regimens. Analysis of the results according to the year of transplantation demonstrates the progress now evident in two respects: the prolongation of survival beyond the first 50 days; and the increasing number of long-term survivors. Thus, the percentage of patients surviving beyond 50 days has increased from less than 50 per cent in those receiving transplants between 1969 and 1971 to 100 per cent in those with transplants in the first six months of 1974.

Relapse was the basic cause of failure in 15 patients, four with acute myelogenous and 11 with acute lymphoblastic leukemia. Included are four patients (two in each group) whose leukemic cell population was so refractory that serial marrow aspirates demonstrated persistence of blast cells. Such refractoriness suggests a spectrum of degrees of reduction of the leukemic cell load. One could anticipate, therefore, that a substantial fraction of the patients might retain a malignant cell population large enough for a putative antileukemic effect of a marrow graft to do much good. In fact, we have observed four patients in whom leukemia recurred in seven to 23 weeks after marrow engraftment, and in whom cytogenetic evidence showed that the recurrence was composed of cells derived from the original host leukemia. Furthermore, the more recent aggressive conditioning regimens appear to have modified the relapse rate. Of the first six patients with acute lymphoblastic leukemia prepared with total-body irradiation alone, five had evidence of recurrence (including a child who died primarily of bilateral interstitial pneumonia and had extramedullary microscopic evidence of leukemia). With the subsequent addition of high-dose chemotherapy to the conditioning regimen, only six of 29 patients with acute lymphoblastic leukemia have shown a recurrence. As the median survival increases, however, more cases of recurrence may also become evident, although relapse beyond seven months has occurred in only one patient.

Nineteen of the 70 patients remain in complete remission beyond three months, nine for one to four years after transplantation. From the data presented, indications are that such a remission rate is increasing (Fig. 2). In many patients with acute myelogenous leukemia and adult acute lymphoblastic leukemia, and after relapse in acute leukemia of any kind, long-term unmaintained remissions are not possible with available chemotherapy. The results with marrow transplantation, far from ideal, are nonetheless encouraging and offer a therapeutic opportunity for the patient with a suitable donor whose leukemia by virtue of type or relapse augurs a predictably short prognosis.

The results of marrow grafting for the blastic crisis of
chronic myelogenous leukemia cannot yet be evaluated. Two patients died early of infection, and one with a graft is in remission after four months (Table 3).

Current Results in Miscellaneous Conditions

Three other applications of marrow grafting have long been recognized: radiation accidents; solid malignant tumors that are particularly sensitive to chemotherapy and radiotherapy; and genetic disorders such as thalassemia and sickle-cell disease.

Apart from transplants after radiation accidents, there are no published reports of long-term survival after allogeneic transplants for the disease categories listed. In these disorders either the transplantations have been performed before the recognition of the importance of HLA and mixed-leukocyte-culture matching, patients having succumbed to overwhelming infections in the early post-grafting period, or there has been no evidence of engraftment.

Within our center allogeneic marrow grafting has been carried out in single patients with neuroblastoma, malignant histiocytosis, and Hodgkin’s disease. All succumbed within 40 days of transplantation, two from overwhelming sepsis and one from viral pneumonia.

A major factor limiting the total eradication of a disseminated malignant neoplasm by current available chemotherapy and radiotherapy is irreversible damage to the marrow. Transplantation of marrow should remove this barrier and would permit the administration of much larger doses of these agents. Neuroblastoma, lymphosarcoma, Hodgkin’s disease and oat-cell carcinoma are examples of tumors that appear to be particularly sensitive to chemotherapy and to radiotherapy, and in such neoplasms the application of marrow transplantation may enable potentially curable doses to be given.

Two approaches are feasible: the infusion of the patient’s own normal marrow aspirated and stored before chemotherapy and radiotherapy (autologous marrow infusion); or the use of marrow from a major-histocompatibility-complex-matched donor. In the late 1950’s there were several case reports of remissions with use of autologous marrow infusion after high doses of chemotherapy or radiotherapy or both. Death of most patients from bacterial sepsis and the doubt whether marrow recovery in the long-term survivors was in any way related to the marrow infusion led to a general loss of interest in this technic. The development of methods for long-term storage of marrow at -180°C in dimethyl sulfoxide, better chemotherapy agents, and more effective supportive care of patients have renewed interest in this form of therapy, which, like identical twin transplants, does not carry the risk of rejection or graft-versus-host disease. Currently, we are storing marrow from patients with chronic myelogenous leukemia early in their disease. When blast crisis occurs, the patient will be treated with intensive chemotherapy and radiotherapy followed by return of the stored marrow, with the intent of restoring the chronic disease. Preliminary results indicate feasibility.

Current Problems

Success or Failure of Marrow Engraftment and Marrow-Cell Rejection

A review of the literature of human marrow transplantation before 1967 showed a high incidence of complete failure of engraftment. Failure of initial allogeneic engraftment is no longer a major problem. Excluding five patients who died too soon to be evaluated, 33 of 34 grafts
in patients with aplastic anemia were successfully established, and 63 of 68 in acute leukemia were successful. The quantity of marrow infused ranged from 1.1 to 10.9 x 10^8 per kilogram of recipient body weight (Table 4). Despite this range of one order of magnitude, there was no correlation between marrow dose and success or failure of engraftment nor of nadir of white cell count or time to recovery above 1000 per cubic millimeter. Although there has been concern about the dose of marrow cells required for engraftment, 116 precise determination of this number seems to be neither practical nor necessary.

Experiments in canine littermates matched at the major histocompatibility complex have shown that prior exposure to transudation of whole blood from the marrow donor may jeopardize the success of a subsequent marrow graft even in this "compatible" donor-recipient combination. 50, 51 Data similar to those in dogs have been reported in irradiated mice 115 and also in mice treated with cyclophosphamide. 19 Presumably, rejection was due to immunization of the recipient to histocompatibility antigens on platelets and leukocytes. With blood transusions from random donors or from family members other than the marrow donor, immunization of the recipient and rejection of the graft might be expected only when the marrow donor and the transfusion donors share "minor" histocompatibility antigens not present in the recipient. The results of allogeneic marrow grafting for the treatment of aplastic anemia have shown that patients given transfusions from family members have a high rate of failure of marrow engraftment or of marrow-graft rejection. 100 The two patients who had not been transfused before grafting had prompt engraftment and are among the long-term survivors. One patient who rejected his graft had had transfusions from both parents, which should have exposed him to the risk of sensitization to all family "minor" transplantation antigens that he did not inherit. Although Mathé et al. 15 had earlier reported an apparent harmful effect of transfusions before grafting in patients with leukemia, we have not observed graft rejection in our patients with acute leukemia, and most of the failures of engraftment occurred in the earlier patients. More aggressive modern chemotherapy is one explanation for this difference as well as the difference between acute leukemia and aplastic anemia.

At present no reliable laboratory tests are available to determine which patient is sensitized against his HLA-

matched marrow donor although research on this problem is in progress. 116, 117 Recent data using DLA-incompatible, unrelated donor recipient pairs of dogs indicate that the present state can be abrogated by a combination of procarbazine and rabbit antidog antithymocyte serum before total-body irradiation resulting in successful marrow engraftment in most cases. 95 We have initiated a randomized study in patients with aplastic anemia to determine the role of pretreatment with procarbazine and antithymocyte globulin. Initial results have shown that the regimen is well tolerated and that successful engraftment is possible.

**Graft-versus-Host Disease**

The distinction between illness due to the active immunologic assault of donor lymphoid cells against host target organs and the consequences of this assault, delayed organ function and infection, is indeed subtle and, in this discussion, both are considered a part of graft-versus-host disease. For unknown reasons, the principal target organs of graft-versus-host disease in both animals and man are skin, gastrointestinal tract and liver. 11, 28 Despite the use of sibling donors matched at the major histocompatibility complex and despite post-grafting immunosuppression, graft-versus-host disease has occurred in approximately 70 per cent of patients with successful marrow grafts. Evidently, compatibility or incompatibility for histocompatibility regions other than the major histocompatibility complex are important determinants of the graft-versus-host disease. There have been too few successful marrow transplantations between siblings not matched at the major histocompatibility complex to know the frequency of graft-versus-host disease in this situation, but, from studies in animals as well as from the results of marrow grafting in immunodeficient children, 49 it seems reasonable to expect that graft-versus-host disease (and graft rejection) will be major problems. We described a marrow transplant involving a one-haplotype mismatch. 118 Graft-versus-host disease was severe but not more severe than that seen in some transplants matched at the major histocompatibility complex.

**Clinical graft-versus-host disease.** The proposed clinical staging of the disease is shown in Table 5. The initial organ

involved in almost all cases is the skin. Biopsy is mandatory for diagnosis since not all rashes in these patients are due to graft-versus-host disease. Hepatic and intestinal involvement usually appears several days after the rash. Intestinal involvement is mainly in the form of diarrhea but may progress to abdominal pain and ileus. Liver disease is manifested by rises in bilirubin (mainly conjugated). Serum glutamic oxaloacetate transaminase is usually in the range of 150 to 750 IU. Rises in alkaline phosphatase are also observed especially in chronic graft-versus-host disease. Intestinal and hepatic abnormalities are not unique to this situation. Therefore, alterations in function of these organs should be attributed to graft-versus-host disease only when its involvement of the skin is clearly established or when there is biopsy confirmation in gut or liver. Fever, wasting and a decreased performance status are also regularly seen with severe involvement. Although fever may be a manifestation of graft-versus-host disease per se, it is most commonly due to an associated infection, often an occult viral infection.

We and others have attempted to classify the overall severity of clinical graft-versus-host disease on a grading system ranging from 0 to 1V (Table 6). Currently, analysis of survival among our patients suggests that patients can be grouped in two ways: those without clinically evident graft-versus-host disease (Grade 0) and those with graft-versus-host disease involving skin (Grade 1) show a survival of 55 per cent, whereas patients with Grades II to IV have a survival of only 15 per cent. Its strong association with infection indicates that graft-versus-host disease itself is a critical factor contributing to the poor immunologic reactivity, debility and compromised mucosal barriers in narrow-graft recipients. The grading system may become more meaningful as advances are made in the treatment of graft-versus-host disease and accompanying infections.

Chronic graft-versus-host disease characterized by a more indolent clinical course, with involvement of skin, liver and intestinal tract, has been observed in three long-term survivors. This picture may appear after complete or partial resolution of acute graft-versus-host disease. Whether the chronic form is the result of an immunologic attack of donor lymphoid cells against host tissue or of deficient immunologic reactivity of the graft, with accompanying opportunistic infections, or of a combination of both is not well understood at present.

Histologic criteria. Table 7 summarizes the proposed histopathologic staging of graft-versus-host disease based on scale ranging from + to + + + +. Hepatic involvement was characterized by degeneration and eosinophilic necrosis of parenchymal cells and degeneration and necrosis of the epithelium of small bile ducts. Because the effect on parenchymal cells was variable whereas small bile ducts were consistently involved, the grading was correlated with the percentage of pathologically altered small bile ducts.

Serial biopsies of the skin are easily obtained, but biopsies of the gut and liver cannot be done regularly and the histopathologic stage may therefore require revision. Histopathologic staging varied between organs and did not always correlate with the clinical grade except for mild or severe graft-versus-host disease.

Prevention and treatment. From the animal studies as well as from the clinical narrow-grafting experience it has become clear that some form of immunosuppressive therapy must be used after grafting to diminish or prevent graft-versus-host disease. The literature on this topic has recently been reviewed. To be effective, treatment with immunosuppressive agents must be started before graft-versus-host disease has become apparent. Of the many agents studied, methotrexate and cyclophosphamide have been found to be useful. Methotrexate was found to ameliorate graft-versus-host disease in mice, dogs and monkeys when given immediately after grafting. Studies in dogs have shown that methotrexate was most effective when continued for a long time (three months), and stable long-term chimerism (measured in years) was achieved in some DL-A incompatible recipients. Cyclophosphamide had some effect in mice, rats and monkeys, but was ineffective in dogs. Studies using cytosine arabinoside, procarbazine, 6-mercaptopurine, and antilymphocyte serum in the immediate post-grafting period have been disappointing.
Prevention of graft-versus-host disease has been attempted with use of antilymphocyte serum given just before grafting in rodents, dogs, and monkeys, with only slight prolongation of survival.

Our current post-grafting regimen in human patients consists of methotrexate, 15 mg per square meter on the first day and 10 mg per square meter on the third, sixth and 11th days and weekly thereafter for the first 100 days. Santos et al. have used cyclophosphamide, 7.5 mg per kilogram for five doses on alternate days, beginning on the first day after marrow grafting, followed by doses at irregular intervals. The frequency of fatal graft-versus-host disease in patients given a marrow graft from an HL-A-matched sibling and no post-grafting immunosuppression is unknown. Despite post-grafting immunosuppression with either methotrexate or cyclophosphamide, severe and fatal graft-versus-host disease has been observed in 10 to 20 per cent of human marrow-graft recipients.

Surprisingly enough, only a few studies have been reported in which established graft-versus-host disease was treated either with cytostatic agents or with antilymphocyte serum. For the most part, these studies were negative—i.e., the agents used failed to influence the course of events or the authors failed to document sustained chimerism. A review of these studies has been presented recently. An exception was the study by Owens and Santos, who inoculated (C57BL/6 X DBA 2) F1, hybrid mice with BALB/c spleen cells and were able to suppress clinically established graft-versus-host disease by cyclophosphamide. Cyclophosphamide was used to treat established graft-versus-host disease in a patient given a graft from an HL-A-matched sibling and was ineffective.

On the basis of encouraging studies in the canine model we have recently started using antilymphocyte globulin for treatment of human patients with graft-versus-host disease. With this therapy, 12 of 19 patients showed complete resolution of the graft-versus-host disease, live showed improvement of most organ systems involved, and two showed no changes except for improvement in skin lesions. Six of the 19 became long-term survivors. Five of the six are alive now between 525 and 865 days after grafting, and one died on the 346th day with chronic respiratory failure. Of the remaining 13 patients, 11 died of interstitial pneumonitis of predominantly viral origin, and two died with fungal and bacterial infections. These findings demonstrated the partial effectiveness of antilymphocyte globulin in reversing human graft-versus-host disease. This treatment of established graft-versus-host disease certainly does not present the solution of the problem, but it appears to have modified the grim outlook in a hopeful way. It is obvious, however, that continued animal and clinical research efforts have to be directed to a better understanding of the nature and control of graft-versus-host disease.

Albumin-gradient cell-separation techniques have been used in an attempt to eliminate immunocompetent cells from the marrow inoculum while retaining the hemopoietic stem cell. Proof, however, that this approach is useful in modifying graft-versus-host disease in grafts between random bred non-rodent animals is missing. The technic has been applied in a number of human transplantations. The result was either failure of engraftment or death from graft-versus-host disease when histoincompatible marrow was used. Aside from the technical problems, a number of theoretical reasons would argue against the efficacy of "stem-cell" separation technics. Even if it should be possible to separate completely lymphoid cells from stem cells, it is likely that the recipient still might be susceptible to the late form of graft-versus-host disease, which is presumably caused by a subsequent regeneration of reactive lymphoid cells derived from the "common" stem cell. If there is not a "common" stem cell giving rise to lymphoid cells, successful separation would create a recipient who is severely deficient in immune function and thus might succumb to infection. At present, therefore, stem-cell separation does not appear to be a promising approach.

Infection after Engraftment

Leukopenia, immunoincompetence and graft-versus-host disease have, as their principal consequence, infection, which is the usual proximate cause of death. These complications may overlap in time and clinical manifestation, but it is possible to discern time periods in which one or the other underlying cause predominates.

The infectious hazards of agranulocytosis are maximally apparent during the two to three weeks immediately after transplantation. In a series of 71 allogeneic marrow-transplant recipients who survived for at least 30 days, and who achieved engraftment, the median number of days with a granulocyte count of < 100 per cubic millimeter was 11, and that of patients with a count of < 500 was 18. The pattern of infection in agranulocytic patients has been well delineated, mostly in patients with acute leukemia, and infectious-disease experience in marrow-transplant patients during the immediate post-grafting period conforms closely to this pattern. Bacterial and candidal infections are particularly frequent and serious in agranulocytic patients. Gram-negative bacteremia is a common event. There is convincing evidence that antibiotic therapy is less effective in curing infectious disease in patients lacking granulocytes and that the apparent complete resolution of an infectious process may be insecure unless adequate granulocytes are present. Organisms usually considered of low virulence acquire enhanced consequence in the absence of granulocytes. The frequency of systemic candidiasis is difficult to assess since technics for its detection are of low sensitivity. Mucosal infections due to candida, however, are common. Bacterial infection appropriately treated rarely jeopardizes the achievement of successful engraftment, even in patients infected at the time the facilitation procedure is initiated, but it does cause considerable morbidity. Of 47 patients surveyed in a recent review, only two died from bacterial disease in the first 21 days, but in 22 bacteremia developed. Aside from the role of granulocyte transfusion the recently improved survival prospects of infected agranulocytic patients owe much to the development of new and more po-
tent antibiotics properly administered.

Because of decreased immune reactivity in these patients, it is not surprising that the incidence of infection, particularly viral disease, is increased during the first 100 days after transplantation. Perhaps the most troublesome single infectious complication is that of interstitial pneumonia. The syndrome has occurred at any time during the first four months after transplantation, but has its usual onset after the establishment of a functioning marrow graft. The overall incidence among 114 marrow-graft recipients in Seattle over the time period from 1969, through June, 1973, is 28 per cent. However, in the 24 identical-twin transplants in this series, the condition was documented in only three patients (13 per cent). Furthermore, as previously discussed, some allogeneic marrow recipients died without achieving effective hematopoietic function (or after marrow-graft rejection) in the period before the risk of interstitial pneumonia is very great. If these are excluded, and we consider only patients who achieved functional allogeneic transplants, the incidence of this syndrome is closer to 50 per cent. Mortality among this group of patients, death being primarily due to respiratory insufficiency from progressive pulmonary infiltration, is distressingly high at between 50 to 60 per cent. Whereas all groups of allogeneic marrow-graft recipients have contracted this syndrome, both the statistics on incidence and particularly those on mortality are worse in patients with grades II to IV graft-versus-host disease. In this connection, an apparent increase in incidence of interstitial pneumonia in marrow-transplant recipients has been reported in Seattle. However, it remains to be established whether this observation reflects a genuine increase in the attack rate or a manifestation of the enhanced chronicity of severe and moderate graft-versus-host disease (producing a longer period of maximum risk) resulting from the introduction of new methods of support and immunosuppressive treatment discussed above.

From the standpoint of cause about half the patients dying with interstitial pneumonia have unambiguous evidence of disseminated cytomegalovirus in the form of characteristic inclusion bodies on histologic examination of the lungs and other organs, as well as isolation of the organism in culture. A total of six histologically proved cases of Pneumocystis carinii has been noted at autopsy, three of which were found in the presence of cytomegalovirus. In two patients lethal varicella-zoster pneumonia developed. No recognizable pathogens have been associated with the remainder of the fatal interstitial pneumonias, although these are histologically indistinguishable from those caused by cytomegalovirus and pneumocystis (except for the specific signs of these agents). Of marrow-graft recipients who gave clinical evidence of interstitial pneumonia and subsequently recovered, about half also had serologic or cultural (or both) evidence of cytomegalovirus infection. The cause in the other half remains obscure.

A retrospective review of cytomegalovirus infection and serologic responses among marrow-graft recipients provided the following observations: cultural and histologic data taken together indicated that a minimum of one third of these patients contract or activate latent cytomegalovirus infections during the first few months after engraftment; and patients with marked rises in complement-fixing antibody titer either had no clinical manifestations or recovered from transient interstitial pneumonia. Most of these patients excreted cytomegalovirus in urine. In contrast, patients with fatal cytomegalovirus pneumonia rarely demonstrated a noteworthy rise in complement-fixing antibody titer and have not, in our experience, excreted cytomegalovirus in urine at the time of the disseminated infection. The implications of these findings, as well as their precise relation to immune reconstitution and other factors that might affect the pattern of response to cytomegalovirus infection in transplant recipients, deserve more thorough prospective study. Finally, very little can be said about the clinical management of interstitial pneumonia and disseminated cytomegalovirus infection. All the severely infected patients have received antibiotics and pentamidine isethionate. Cytosine arabinoside, adenine arabinoside and corticosteroids have also been used but there is no clear evidence of benefit from any of these drugs at present.

In contrast to the problems associated with cytomegalovirus infection (and whatever additional and unknown agent or agents may account for interstitial pneumonia) the experience in Seattle with other opportunistic viral infections is relatively modest. Herpes simplex virus infections of the mouth and lips are frequent complications in the first few weeks after transplantation, but, with one exception, have subsided and healed without widespread dissemination. Later, cutaneous herpes zoster occurs occasionally over the period in which cytomegalovirus infections are seen. These lesions have frequently spread over several dermatomes before subsiding. Antibody responses to these viruses have been observed. The documented incidence of P. carinii pneumonia has been referred to and, perhaps surprisingly, is quite low. Antibody responses to this organism are very rare in our population of marrow-graft recipients, with only two documented cases, both of which were not in patients with proved P. carinii pneumonia.

**Immunologic Status of Long-Term Survivors**

**Immunologic reactivity of syngeneic marrow-transplant recipients (monozygotic twins).** Three patients treated with twin marrow grafts for hematologic neoplasia have been tested for immunologic reactivity. Absolute lymphocyte counts were above 1000 per cubic millimeter in all patients within one to three months after transplantation. No consistent changes in serum immunoglobulin levels were noted. Two of these patients — both of whom had received twin peripheral blood lymphocytes as well as marrow — exhibited normal primary and secondary antibody responses to bacteriophage 0x174 at six weeks and at one year after marrow transplantation. Two patients did not exhibit cutaneous delayed hypersensitivity reactions to the usual battery of skin tests, even though one of the donors was positive to candida and mumps. The third patient became positive to candida at one year. Two patients responded to dimethylchlorobenzene at one and two years. Lymphocytes from all three were stimulated in the test...
with mixed leukocyte culture by irradiated allogeneic cells and by phytohemagglutinin to an extent almost comparable to that observed with the normal twin's lymphocytes during the first few months after marrow transplantation. The three long-term syngeneic transplant survivors studied had no serious infections. Thus, the results suggest an impressive restoration of immunologic function in the three patients. It is assumed, of course, that the immunologic system tested is totally of donor type, although no markers are available. Efforts are under way to study the immunologic reactivity of twin marrow-transplant recipients early after marrow transplantation with additional measurements of immunologic function.

Immunologic reactivity of allogeneic marrow-transplant recipients (major-histocompatibility-complex-matched donors). The recovery of immune reactivity in allogeneic chimeras would be expected to be slower than that of syngeneic chimeras owing to at least three possible mechanisms: it has been hypothesized that lymphoid depletion occurs in allogeneic chimeras as a result of destruction of donor lymphoid cells during graft-versus-host disease; allogeneic chimeras have often been treated with immunosuppressive drugs after grafting, which not only delay or prevent graft-versus-host disease but also suppress the response of chimeric lymphocytes to other antigens; and the combination of toxic conditioning regimens, post-grafting immunosuppression and graft-versus-host disease causes gut damage leading to a malabsorption syndrome, which given enough time, can lead to immunodeficiency.128 In general, allogeneic rodent chimeras are less immunologically active than their syngeneic counterparts even if studied as late as 300 days after grafting (reviewed elsewhere).128,129 In a recent study, the immune system of random-bred canine chimeras was surveyed for periods up to eight years after grafting.127 After a prolonged period of decreased immune reactivity lasting for 200 to 300 days after grafting, cellular and humoral immunity in these chimera returned to the normal range. Although there was a delayed rise in antibody titers during the primary immune response, long-term chimera showed normal peak titers and a normal qualitative and quantitative secondary antibody response. Animals were able to live in an unprotected environment without apparent increased occurrence of infection, supporting the conclusion that, after an initial phase of impaired immune function, these canine chimera regained normal immune reactivity.

In an initial study we described evaluation of immunologic reactivity in 10 human recipients of allogeneic marrow observed for five to 20 months after graftment.130 Five patients had hematologic neoplasia, and five aplastic anemia. Serum IgG, IgA and IgM levels declined in all recipients and then returned to normal by the 100th day. Absolute lymphocyte counts were above 1000 per cubic millimeter in all patients within one to three months after grafting. The recipients showed a markedly decreased antibody response to bacteria culture OX174. In contrast, several of these recipients acquired cytomegalovirus or herpes zoster infections from which they recovered, and they developed good antibody titers against these agents. Testing in mixed leukocyte culture showed that recipients of allogeneic grafts had a wide range of responsiveness, but clear stimulation was observed on nearly all occasions even within the first month of grafting. Despite this in vitro activity, the allogeneic recipients, with one exception, could not be sensitized to dinitrochlorobenzene when tested between 28 and 305 days after grafting. We concluded that recipients of allogeneic grafts showed a long-lasting immunologic deficiency that points out the necessity for vigilance in early detection and treatment of infection and the need for additional measures to restore immunologic competence in these patients.

Malignant Transformation of Donor Cells

A mechanism of leukemic relapse that was not anticipated was the possibility of malignant transformation of the engrafted marrow. Nevertheless, there is unambiguous evidence that this event has occurred twice in leukemic marrow-graft recipients. Two female patients with childhood acute lymphoblastic leukemia received total-body irradiation as their only cytoreduction in preparation for engraftment, followed by allogeneic marrow infusion from histocompatible male siblings. Both escaped the serious complications that follow marrow transplantation and appeared to achieve normal marrow status, only to suffer a florid leukemic relapse 69 and 135 days after engraftment. In both cases careful cytogenetic study of a large number of metaphase chromosomes, and in the second case, fluorescent staining for y chromatin in interphase nuclei, indicated that the recurrent leukemia was composed of male cells and was therefore of donor origin.128,129 There are only four other patients in our series who are strictly comparable to these two—that is, children with acute lymphoblastic leukemia prepared only with total-body irradiation. Three of these have also shown leukemic relapse, but in no case was an opportunity presented to determine the host or donor origin of the recurrent leukemia. The one leukemia-free patient in this group is our longest survivor at four years after grafting.

What caused the malignant transformation of the marrow graft? Several explanations have been discussed. It has been suggested that leukemia, at least in some cases, could be a disease of "regulation" such that any marrow in a leukemic host will become leukemic. Another theory advanced involves a cell-fusion event between donor and host cells followed by a loss of extra chromosomal material or "diploidization" with retention of the y chromosome. Still another suggestion is that immunodepression in the marrow-graft recipients could conceivably lead to a breakdown in the putative immune surveillance defenses against spontaneously arising malignant cell clones in the regenerating engrafted tissue. Furthermore, it should be noted that graft-versus-host reactions are themselves leukemogenic, at least in mice.130,131 Against the last two proposals is our failure to observe malignant transformation of marrow grafts in non-leukemic recipients. In addition, leukemogenesis mediated by graft-versus-host disease in mice appears to involve activation of endogenous C-type murine leukemia viruses.132 This point raises a final and perhaps most plausible hypothesis—specifically, that a leukemogenic virus or similar etiologic agent
resident in a recipient infected and transformed the transplanted marrow. Ionizing radiation will induce production of occult C-type leukemia viruses in some experimental animal systems. Moreover, oncovirus infections can be transmitted by fragments of cellular DNA containing an integrated DNA provirus, at least in some systems. Thus, one need not postulate the presence of recognizable whole-virus particles, but rather could envision transmission through the agency of subviral or other oncogenic subcellular material released from the degenerating host leukemic-cell population.

This list may well not exhaust all the possibilities underlying marrow-graft transformation, but it is in the absence of information on the ultimate mechanism, there are a number of questions of immediate consequence. The most important of these is the frequency and prevalence of leukemic transformation. The existence of a mechanism for the frequent induction of neoplasia in new populations of cells in the course of acute leukemia and related diseases might potentially threaten the ultimate success of intensive intermittent-therapy programs dependent upon the stepwise destruction of the tumor-cell population. At present, however, there is no conclusive evidence that induction of malignant transformation in new clones of cells does occur with noteworthy frequency outside of the two cases discussed here and the observation of apparent reintroduction of new tumor clones in certain late relapses of African Burkitt's lymphoma.

Adoptive Immunotherapy

The data on allogeneic marrow transplantation for hematologic neoplasia permit no conclusion about the existence or absence of an antileukemic effect of graft-versus-host disease as anticipated from animal studies. The principal evidence that graft-versus-host disease, whether or not clinically detectable, did exert an antileukemic effect stems from the observation that leukemia recurred more frequently in recipients of twin marrow than in recipients of allogeneic marrow — in which the potential for graft-versus-host disease existed. Analysis of data on the patients whose leukemia cleared from the marrow and who survived for more than 60 days reveals that 13 out of 22 such patients exhibited recurrent leukemia after twin marrow grafts whereas leukemia recurred in only 15 out of 49 patients treated with an allogeneic graft. It must be emphasized, however, that clinically detectable graft-versus-host disease does not correlate with presence or absence of recurrence of leukemia. Most importantly, clinically detectable graft-versus-host disease is not essential for long-term, complete remissions. Of nine long-term survivors free of acute lymphoblastic leukemia, seven never had clinically evident graft-versus-host disease, and neither did five of nine patients whose leukemia relapsed. Of the long-term survivors free of acute myelogenous leukemia six of 10 did have graft-versus-host disease, but so did two patients whose leukemia recurred. Thus, it is not possible to recognize an antileukemic effect of graft-versus-host disease from the data currently available.

Nature of "Tolerance"

In a stable long-term chimera, the immunologically competent foreign graft does not mount a harmful reaction against its host. The most common explanation is that the lymphoid cell clones that would have been reactive against host alloantigens have been made "tolerant" — i.e., specifically non-reactive. Another possibility is that the reactive cell clones have been eliminated in the course of an immunologic interaction. Alternatively, a form of immunologic enhancement may be involved, by which a factor in the chimeric individual's serum can protect against cellular immune reactions. We studied nine canine irradiation chimeras between 173 days and 7.5 years after transplantation of allogeneic marrow. The lymphocyte populations were foreign to their hosts and, therefore, theoretically capable of mounting a graft-versus-host reaction. Lymphocytes from the chimeric dogs were found to inhibit colony formation by their "own" fibroblasts, whereas lymphocytes from other chimeras or from normal dogs did not (the test used was the colony-inhibition assay). Serum from the chimeras specifically abrogated this inhibitory effect. These initial results suggested that the immunologic "tolerance" of the chimeric dog was mediated in vivo by blocking serum substances. Subsequently, similar findings were reported in rodent radiation chimeras, and in mice made tolerant by neonatal injections of allogeneic lymphocytes and in tetraparental mice.

More recently we studied nine canine irradiation chimeras and their DL-A-matched marrow donors between 545 and 1226 days after marrow grafting, using a microcytotoxicity or cell-inhibition assay. Before testing, marrow donors were immunized against their chimeras by repeated skin grafts, which they rejected. Skin fibroblasts from chimeras and their donors were tested for cell inhibition by exposure to sera and lymphocytes from chimeras, donors and normal dogs. Lymphocytes from sensitized marrow donors inhibited fibroblasts from their chimeras (eight of nine dogs); cell inhibition was abrogated by chimeric serum in only three of eight cases. Only one chimera showed consistent cell inhibition of its "own" fibroblasts, and the serum did not block cell inhibition. The remaining eight chimeras did not show consistent cell inhibition. In conclusion, the cell-inhibition assay is able to detect immunity across "minor" histocompatibility barriers in dogs. Results in chimeras suggest that serum blocking factors are not a prerequisite for maintenance of stable graft-host "tolerance" in DL-A-matched recipients. Similar findings were made in a subsequent study, in which 16 canine marrow-graft recipients were studied sequentially between 50 and 450 days after grafting.

Studies are now in progress involving the use of additional test systems and involving sequential studies of individual patients starting very early after the graft in an attempt to elucidate the complex problem of the "tolerant" state in the human marrow-graft recipient.
Marrow Transplantation from Unrelated Donors

It is obvious from the clinical experiences cited above that a multitude of problems remain to be solved when marrow donor and recipient are siblings matched at the major histocompatibility complex. At the same time, since less than half the patients will have matched siblings, efforts must be directed toward identifying unrelated persons who are perfect matches at the major histocompatibility complex for the patient. With computer technology, and with a large panel of donors, matching for the serologically detected loci can now be accomplished. Rapid advances in the ability to detect and evaluate lymphocyte-detected loci are occurring at present. Thus, we can expect in the near future to be able to identify unrelated donors matched at the major histocompatibility complex, either living donors or cadaver donors whose marrow has been stored. When this goal is achieved, it is important to realize that the unrelated donor matched at the major histocompatibility complex will be no better than the sibling similarly matched. The patient will still encounter the same spectrum of problems described above for the patient with a matched sibling. Hence, it is important to continue to try to solve these clinical and immunologic problems, especially since the vast majority of patients with matched siblings are not now being considered for marrow transplantation.

Discussion

It seems likely that in the near future marrow transplantation will be attempted as therapy for any variety of malignant neoplasia that is sensitive to irradiation or chemotherapy and for non-malignant disorders of the marrow such as thalassemia and sickle-cell disease. At present each new patient with acute leukemia or aplastic anemia should undergo histocompatibility testing along with the members of the family. If the patient has a sibling matched at the major histocompatibility complex, transfusion of blood products should be minimized, and transfusion from family members should be avoided. Marrow grafting can be planned at an appropriate time, perhaps immediately for patients with severe aplastic anemia or acute myelogenous leukemia but only after failure of conventional therapy for patients with mild aplastic anemia and acute lymphoblastic leukemia. Proper selection of the type of patient and the time of grafting raises too many questions to be enumerated here. For example, are the extremely refractory leukemias, described above, the result of prior intensive chemotherapy, and could this problem be avoided by earlier marrow grafting?

Allogeneic marrow grafting in man is still an exceedingly complex and difficult endeavor. Therefore, certain supportive facilities should be considered as mandatory for any center undertaking a marrow-transplantation program, including means of providing the large numbers of platelets and granulocytes that may be required, facilities for the proper administration of total-body irradiation, protection against infection, and bacteriologic monitoring. Laboratory capability should include histocompatibility typing, mixed leukocyte culture and other immunologic studies, production of antithymocyte globulin, cyto- genetics and blood genetic markers. The marrow-graft team, including physicians, nurses and technicians, should have experience in transplantation biology and medicine with a successful program of animal transplantation using the techniques to be applied to man. In this setting the patient should have the maximum opportunity to benefit.

Noteworthy advances in the knowledge of the cause and pathogenesis of human diseases may be expected as a corollary of marrow-transplantation studies. Examples already at hand are the demonstration, by the fact of successful engraftment, that the marrow microenvironment is normal in most patients with aplastic anemia and a demonstration that in vivo malignant transformation of normal human cells can occur in acute lymphoblastic leukemia. Marrow transplantation will also provide insight into many aspects of transplantation biology and tumor immunology. Despite the many discouraging complexities associated with marrow transplantation, some degree of satisfaction may be derived from the fact that knowledge of normal and abnormal immunology and physiology is being increased during endeavors to provide new therapeutic approaches for the patient with otherwise fatal disease.

We are indebted to Dr. Eloise Giblett, who carried out the blood genetic marker studies, and to the entire nursing staff of the Division of Oncology for their management of these patients.

Acute Graft-Versus-Host Disease Following Bone Marrow Transplantation in Humans: Prognostic Factors

M.M. Borit for the Advisory Committee of the International Bone Marrow Transplant Registry

ACUTE GRAFT-V-HOST DISEASE (GVHD) is a major cause of treatment failure following allogeneic bone marrow transplantation in humans. Acute GVHD is a formidable problem even when donors and recipients are perfectly matched as determined by HLA serotyping and by mixed leukocyte culture tests. In this setting moderate to severe acute GVHD occurs in 30% to 70% of patients and is the primary or contributing cause of death in 15% to 40% in most series. In vitro depletion of donor marrow of T cells pretransplant appears to reduce the risk of GVHD. In general, this strategy has not resulted in improved survival experience, however, due to a reduced probability of stable engraftment and, in leukemia patients, an increased probability of recurrent leukemia.

This study was undertaken by the International Bone Marrow Transplant Registry in an effort to identify variables associated with the risk of acute GVHD. In particular, we wished to identify variables that could be manipulated by the referring physician or

transplant team to reduce the likelihood of this serious complication.

PATIENTS AND METHODS

Data were analyzed from 2,036 consecutive recipients of HLA-identical sibling transplants for leukemia or aplastic anemia who survived at least 31 days with evidence of engraftment and were thus at risk of developing GVHD. Recipients of T cell-depleted bone marrow were not included with the 2,036 patients because there are no generally accepted standards to evaluate the efficacy of T cell removal. The data were provided by 106 bone marrow transplant teams worldwide. GVHD scores were dichotomized into none or mild (grades I to II) v moderate to severe (grades III to IV).

Initially, 33 variables were tested in univariate analyses for associations with the incidence of acute GVHD. Subsequently, variables having an association with a P value ≤ 0.10 in the univariate tests were entered into a multiple logistic equation. In multivariate analyses no significant difference was found in the incidence of GVHD among 661 patients with acute myelogenous leukemia, 509 with acute lymphoblastic leukemia, 369 with chronic myelogenous leukemia, and 390 with severe aplastic anemia. The status of leukemia did not influence the risk of GVHD. Therefore, the four disease groups were combined for the study. Further justification for pooling the data was that no unaccounted for center effects were detected. All P values are based on the results of multivariate analyses.

RESULTS

The incidence of GVHD was 45% (918/2,036), the case fatality rate was 48% (442/918), and GVHD was a primary or contributory cause of death in 22% (442/2,036) of the patients.

The use of alloimmune (via prior pregnancies or transfusions) female donors for male recipients had a significantly higher (relative risk, 2.9; P < .0001) incidence of GVHD than other sex match combinations. Similarly, using nonalloimmune female donors for male hosts was associated with a higher (relative risk, 2.0; P < .001) risk of GVHD than other sex match combinations. These findings suggest that the H-Y male antigen is a target for graft-vs-host reactions and that prior sensitization of female donors to H-Y amplifies the effect.

Transplantation of older patients and/or donors was associated with an increased (relative risk, 1.6; P < .001) incidence of GVHD. The age gradient was modest, however, ranging from 39% in the youngest quartile of patients to 52% in the oldest quartile. Further, the age effect was markedly influenced by the inclusion of alloimmune female-to-male transplants, most of which involved older donors and hosts. Age was no longer a significant risk factor (P > .30) when these 119 transplants were excluded from the analysis.

The incidence of acute GVHD was 65% among the small group of 46 patients who received no prophylaxis against GVHD. This was significantly higher (relative risk, 2.2; P < .01) than the incidence of 44% (542/1,235) in patients receiving methotrexate as prophylaxis against GVHD and the 46% (324/710) incidence in patients receiving prophylactic cyclosporine.

Patients not given trimethoprim sulfamethoxazole in the peritransplant period had a higher incidence of GVHD (50%) than the 44% incidence for those given the drug (relative risk, 1.3; P < .04). Patients whose pretransplant performance rating was less than 90% had a higher incidence of GVHD (49%) than the rate of 44% in those whose performance rating was 90% to 100% (relative risk, 1.2; P < .04).

The occurrence of moderate-to-severe acute GVHD was significantly higher (relative risk, 2.1; P < .0001) among patients given more rather than fewer transfusions posttransplant. It is uncertain, however, whether using large numbers of posttransplant transfusions was the cause of GVHD or a consequence of it.

The estimated probability of GVHD was 16% when none of the adverse factors identified in these studies was present. The probability was 87% to 95% when all of the adverse risk factors were present, with a cumulative relative risk of 5.4 to 5.9.

These studies identified seven factors that had significant associations with the risk of acute GVHD; several of these can be manipu-
lated to reduce the risk. The results should prove helpful in estimating the risk of GVHD for an individual patient. The results also should be of help in designing randomized clinical trials testing different methods to prevent GVHD. For example, if not stratified for the risk factors identified in this study, the rates of GVHD in each arm could vary from 16% to >85% by chance alone.

Received 17 March 1987: accepted for publication 16 June 1987

Summary. Acute graft-versus-host disease (GvHD) is an important complication of bone marrow transplantation in humans. Risk factors are imprecisely defined and controversial. We analysed data from 2036 recipients of HLA-identical sibling transplants for leukaemia or aplastic anaemia to identify risk factors for GvHD. Analyses indicate that grading of GvHD can be reproducibly divided into absent or mild versus moderate to severe: 2-year actuarial probability was 54% (95% confidence interval 32–56%) for absent or mild and 46% (44–48%) for moderate to severe. Factors predictive of development of moderate to severe GvHD include donor/recipient sex-match (female—male greater than others, relative risk 2–0. P<0.001). This risk was markedly increased if female donors for male recipients were previously pregnant or transfused (relative risk 2·1, P<0.0001). Older patients were at increased risk of GvHD (relative risk 1·6, P<0·001), but the age gradient was modest, even the youngest patients had a substantial risk of GvHD. If parous or transfused female—male transplants were excluded, age was not a significant risk factor. Cyclosporine or methotrexate were equally effective at preventing GvHD and were superior to no prophylaxis (relative risk 2·3, P<0·01). These data should be useful in estimating the risk of acute GvHD in an individual patient and in designing clinical trials to investigate methods to modify or prevent GvHD.

Graft-versus-host disease (GvHD) is an important complication of bone marrow transplantation in animals and humans (van Bekkum, 1985; Elkins, 1971; Möller, 1985; Sullivan, 1983). GvHD is caused by donor immune cells which probably react against disparate histocompatibility antigens in the recipient. Two forms of GvHD have been described: acute and chronic; these disorders are distinct in timing and clinical features.

Acute GvHD of moderate or greater intensity occurs in 20–80% of recipients of HLA-identical sibling bone marrow transplants. For example, at one institution using similar regimens over a period of years the reported incidence of acute GvHD in various randomized and nonrandomized trials has ranged from 21% to 23% in some studies (Doney et al. 1981a, b; Sanders et al. 1981; Springmeyer et al. 1984; Sullivan et al. 1986) to 70–79% in others (Deeg et al. 1983; Kingemann et al. 1986; Storb, 1983). At another institution the incidence in different sero-ranges from 33% to 34% (Bacchetti et al. 1978; Bräune et al. 1982) to 67–74% (Santos et al. 1983; Tutschka et al. 1980). The reason for this variability in incidence within and between institutions is uncertain and probably reflects several factors including patient selection, differences in diagnosis or grading of GvHD, differences in prophylactic and therapeutic measures, and variability in reporting the cause of treatment failure. One
additional important aspect relates to the inherent statistical variability associated with analyses of relatively small patient series.

Acute GvHD is a major cause of treatment failure following bone marrow transplantation. It is therefore of considerable import to accurately determine risk factors for developing acute GvHD in order to: (1) identify patients at high risk so that special precautions may be taken; (2) identify patients at low risk so that less intense immunosuppressive prophylaxis post-transplant may be given; and (3) to aid in donor selection if more than one is available. To evaluate risk factors for GvHD, we used multivariate statistical techniques to analyse data from 2036 patients reported to the International Bone Marrow Transplant Registry (IBMTR).

METHODS

Included in this analysis were 661 patients with acute myelogenous leukaemia (AML), 589 with acute lymphoblastic leukaemia (ALL), 396 with chronic myelogenous leukaemia (CML) and 390 with severe aplastic anaemia who received bone marrow transplants between 1 January 1978 and 30 June 1985. All patients received transplants from allogeneic HLA-identical sibling donors and survived ≥ 21 d with evidence of engraftment. 106 transplant teams worldwide reported their consecutive transplant experience. Data were analysed as of 31 January 1986: minimum follow-up was 7 months, maximum follow-up 7 years. During this interval, 909 additional leukaemia and severe aplastic anaemia patients were reported to the IBMTR, but were excluded from this study: 12 receiving fetal cells or tissues; 79 receiving bone marrow from genetically identical twins; 442 receiving bone marrow from donors other than HLA identical siblings; 98 dying < 21 d post-transplant who could not be evaluated for acute GvHD; 64 surviving ≥ 21 d without evidence of engraftment; and 214 recipients of bone marrow that was treated in vitro to deplete T cells. The latter were excluded at this time for several reasons. This approach is new and more than 15 different techniques are in use with resultant small group sizes. Further there are no widely accepted criteria to measure the efficiency of T cell removal and evaluation of its effect on the incidence and severity of acute GvHD depends on whether the technique was successful.

For purposes of this investigation, potential risk factors were grouped into three categories: recipient variables, transplant variables and post-transplant variables. A partial list is presented in Table I.

GvHD was evaluated by previously reported, prospectively defined criteria recommended by the IBMTR (Advisory Committee, 1975). Briefly, involvement of skin, liver and gastrointestinal tract were scored absent, mild, moderate, moderately severe or severe and an overall score was generated.

Thirty-three potential prognostic variables were studied. The association between each factor and acute GvHD was tested using χ², Wilcoxon rank sum or t tests. Factors found to be associated with acute GvHD with a P value ≤ 0.10 in these univariate tests were examined for the presence of interactions with a two-way analysis of variance test. The resulting factors and the significant interactions (P < 0.05) were included in a stepwise multivariate logistic model. From the logistic analysis, we derived the probability of acute GvHD for a patient with a single adverse risk factor or a specific profile of adverse risk factors. The relative risk associated with a single risk factor or profile was computed as the probability of GvHD for patients with that risk factor or profile divided by the probability of GvHD for patients with none of the adverse risk factors. The rates of GvHD among diseases (42% in ALL, 43% in severe aplastic anaemia, 45% in AML and 53% in CML) were not significantly different then all significant risk factors were entered in a forward stepwise multiple logistic regression analysis. To evaluate whether any single disease affected the conclusion, a jackknife approach (Mosteller & Tukey, 1977) was used to determine if the inferences about the risk factors would be affected by exclusion of any of the four disease categories. That is, all the same significant risk factors were tested when the analysis was repeated on each of the subsamples that had one of the disease categories excluded. Since the results passed this test for internal consistency over disease category, the results with the most statistical power—combining all four diseases—are pre-

RESULTS

Analysis of GvHD grading
Before determining factors predictive of acute GvHD, it was necessary to validate reporting criteria from participating centres. This was performed as follows. A hypothetical index profile was selected consisting of patients with the following features: acute leukaemia. HLA-identical sibling donor, pretransplant conditioning with cyclophosphamide (< 173 mg/kg body weight), total body radiation (8-12 Gy) and posttransplant immune suppression with methotrexate or cyclosporine to prevent GvHD. GvHD data for 684 patients who fulfilled these criteria from 69 of the 106 centres of varying size were compared. The incidence of no or mild GvHD was relatively consistent, 57% with a 95% confidence interval of 52-62% within this group. The distribution of patients with no versus mild GvHD varied somewhat between 22 centres that reported 10 or more patients. When we compared GvHD scores among 47 teams that reported fewer than 10 with the 22 teams that reported 10 or more patients, we found that absent or mild scores were assigned in 57% by both the smaller and larger centres. Since no significant distinction was detected between no or mild GvHD, these two groups were combined in the analyses.

Likewise, the incidence of moderate to severe acute GvHD was relatively consistent in the 69 centres: 43% with a 95% confidence interval of 38-48%. Within this group, the distribution of cases with moderate versus moderately severe versus severe acute GvHD varied but there was no consistent difference based on geographic location or centre size. Because of the relative consistency of GvHD reporting, we divided the analysis of GvHD into none or mild versus moderate to severe GvHD.

Risk of GvHD. The incidence of moderate to severe acute GvHD was 45 ± 2% (95% confidence interval) (918/2036) and the actuarial probability at 6 months was 46 ± 2%. 48% (442/918) of patients who developed moderate to severe acute GvHD died with this complication. Overall, GvHD was a primary or contributory cause of death in 22% (442/2036) of the patients in this study. Variables significantly associated with the risk of GvHD are shown in Table II.

Sex and sex match. Neither recipient nor donor sex was significantly associated with GvHD. The incidence of GvHD in male recipients was 48 ± 3% versus 41 ± 3% in female recipients. Similarly, GvHD in recipients of cells from male donors was 47 ± 3% versus 44 ± 3% in recipients of cells from female donors.

Female—male grafts had a higher incidence of GvHD (53 ± 4%) than the three other types of matches (42 ± 2%); none of the latter differed significantly from one another. Because prior pregnancies or transfusions might affect the likelihood of cells from female donors to cause GvHD, we investigated the incidence of GvHD in recipients of transplants from females with or without prior pregnancies or transfusions. This variable had no statistically significant effect on the risk of GvHD when the recipient was female: 39 ± 9% versus 34 ± 6%, respectively. When the female donor, was not previously pregnant or transfused, female-
presented. Differences in the risk of GvHD between treatment centres that could not be accounted for by recorded information were tested in two ways in logistic analysis after adjusting for the known risk factors. First, we compared the group of patients transplanted in the seven largest centres with the group from the smaller centres. Second, we compared rates of acute GvHD in patients from each of the seven largest centres with the smaller centres. The actuarial incidence of acute GvHD was computed using standard life table methods.

**STUDY GROUP**

Recipient variables. Data from 2036 recipients of HLA-identical bone marrow transplants were analysed. There were 1192 males and 844 females; median age was 21 years (range <1–59). 777 (47%) of 1646 patients with leukaemia were transplanted in first complete remission or chronic phase. 20% in second complete remission and 33% with more advanced disease. In patients with acute leukaemia, CNS leukaemia was present pretransplant in 7% and 9% had one or more chromosome abnormalities at the time of diagnosis. Coexisting diseases were present in 11% of patients. Median performance score (Karolinsky et al. 1948) pretransplant was 100% (range 10–100). Median interval from diagnosis to transplant was 9 months (range <1–195). 58% of transplants were performed within 1 year and 76% within 2 years of diagnosis. Median number of pretransplant transfusions was 14 (range 0–99); patients with CML received the fewest transfusions (median <1), those with ALL, an intermediate number (median 10), and those with aplastic anaemia (median 20) and AML (median 25) the most (P < 0.0001). 32% of patients with CML had a splenectomy prior to transplantation.

Transplant variables. Donors were male in 1111 cases and female in 925. Median donor age was 22 years (range <1–62). 1065 transplants were sex matched (male = male, 33%; female = female, 20%) and 971 sex mismatched (male = female, 22%; female = male, 26%). Among female donors, 231 had been pregnant or had received transfusions; 517 had not; and information regarding parity or transfusions was either not available or not reported for 177. 68% of transplants were ABO identical and 32% were incompatible; of these 325 were mismatched with regard to graft rejection (e.g. A = O) and 285 with regard to GvHD (e.g. O = A). Most (1816) patients were prepared for transplantation with chemotherapy (cyclophosphamide, cytarabine, daunorubicin, vincristine and others) and radiation; 213 received chemotherapy alone and seven radiation alone. Most patients who received chemotherapy alone had severe aplastic anaemia. Doses of radiation ranged from 3 to 16 Gy given in 1-20 fractions at dose rates of 1-3 to 99 cGy/min using either 1r or X-irradiation. Radiation fields included total body with or without lung shielding for 1695 patients and total lymphoid, total nodal, or thoraco-abdominal radiation for 128 patients. Median dose of unmanipulated bone marrow cells transplanted was 3.1 × 10⁹/kg (range 0.2–18.8). Oral antimicrobials were given pretransplant for decontamination of the gastrointestinal tract in 76% of the patients.

Post-transplant variables. Post-transplant prophylaxis of GvHD consisted of methotrexate in 1235 patients and cyclosporine in 710. Both methotrexate and cyclosporine were given to 29 patients. 16 received antithymocyte globulin, corticosteroids, cyclophosphamide or other agents and 46 received no prophylactic treatment for GvHD. Median number of post-transplant transfusions was 18 (range O–99); only 15 (0.7%) patients received unirradiated transfusions post-transplant and these patients were analysed separately. Most patients (60%) were managed in conventional isolation, or in laminar airflow environments (38%); 2% were not isolated. Trimethoprim–sulfamethoxazole for prophylaxis of Pneumocystis carinii and/or bacterial infections was used in 72% of patients.

* Allo refers to female donors with previous pregnancies or transfusions; Not Allo refers to female donors who had not been pregnant or transfused.
† It is not clear whether the association between large numbers of post-transplant transfusions and an increased incidence of acute graft-versus-host disease represents a causal relationship or is the effect of existing graft-versus-host disease.
Risk Factors for Acute GvHD

Figure 2. Multivariate cumulative relative risk (numbers in parentheses) and cumulative percent probability of moderate to severe acute graft-versus-host disease. When one of the significant adverse risk factors identified in this study was present, a risk of 1.0 was used. First adverse risk factor = alloimmune female—male transplant; second = no prophylaxis against graft-versus-host disease; third = older patients; fourth = trimethoprim—sulfamethoxazole not given; fifth = lower pretransplant performance ratings; sixth = larger number of post-transplant transfusions.

patients with severe aplastic anaemia, prior splenectomy, presence of infection in the week prior to transplantation, bone marrow cell dose, use of unirradiated transfusions post-transplant (note: only 15 patients were available for study), use of pretransplant decontamination of the gastrointestinal tract and conventional versus laminar airflow isolation. No 'centre effect' was detected.

DISCUSSION

Moderate to severe acute GvHD occurred in 45 ± 2% of the 2036 patients receiving bone marrow transplants from HLA identical siblings. The strongest predictive factor having an adverse effect on the risk of GvHD was the use of previously pregnant or transfused female donors for male recipients. The risk of GvHD also was significantly increased when female donors who had not been pregnant or transfused were used for male recipients in comparison with other sex-match combinations. The IBMTR previously reported that female—male transplants were associated with an increased risk of GvHD in 48 patients with severe combined immunodeficiency disease (Bor tin & Rimm, 1977). Female—male transplants also had an increased incidence of GvHD in 264 patients with leukaemia reported by Zwaan & Hermans (1982). Some but not all experimental data in mouse (Lengerova & Chutna, 1959; Uphoff, 1975) using nulliparous or multiparous donors support the finding that the risk of GvHD is increased in female—male transplants.
The relationship between donor/recipient sex and sex-matching with GVHD is controversial. For example, in several reports the incidence of GVHD was elevated when female donors were used irrespective of the sex of the recipient (Atkinson et al. 1986; Borton et al. 1981; Ellenbein et al. 1983; Gluckman et al. 1981). Neither sex of the donor nor recipient was associated with the risk of GVHD in this study. In other studies, both female—male and male—female sex-mismatched transplants had an increased incidence of GVHD (Bross et al. 1984; Storb et al. 1977, 1984). In this study the risk was highest in female—male transplants (53 ± 4%) and significantly lower in the other sex-match combinations: female—female (39 ± 5%) male—male (44 ± 4%) and male—female (42 ± 5%). Because of the finding that use of female donors who were parous or transfused was associated with a high incidence of GVHD in male (but not female) recipients, we wished to examine whether the sex of the progeny of parous females or sex of their blood donor(s) affected the likelihood of GVHD, but these data were not available.

The relationship between age and acute GVHD is complex and controversial. We and others reported that recipient and/or donor age correlates directly with the risk of GVHD (Bordin et al. 1981; Gluckman et al. 1981; Ringden & Nilsson, 1985; Storb et al. 1977, 1983; Weiden, 1980; Zwaan & Hermans, 1982). In the present study we again found a direct correlation between age and the risk of GVHD (P < 0.001). This relationship was biased, however, by inclusion of the 119 males receiving transplants from previously pregnant or transfused female donors, almost all of whom were in the older age group. Patient age was not significant when this group was excluded from analysis.

It has been suggested that GVHD is infrequent in very young patients (Ramsay et al. 1982). This notion is not supported by our data. For example, the incidence of moderate to severe acute GVHD was 33% in patients 0–6–6–6 years of age. Age did, however, have a substantial impact on mortality from GVHD: GVHD was a primary or contributory cause of death in 26% of individuals in the youngest quartile who developed GVHD versus 44% of individuals in the oldest quartile with GVHD (P < 0.0001).

The relative efficacy of cyclosporine and methotrexate in preventing GVHD is controversial. In non-randomized and randomized studies the risk of GVHD was significantly increased with cyclosporine in some (Barrett et al. 1982; Deeg et al. 1983; Speck et al. 1983) but not all reports. No significant difference between the efficacy of cyclosporine and methotrexate on the risk of GVHD was detected in this study. A detailed analysis of individuals receiving T-cell depleted transplants, a combination of methotrexate and cyclosporine, or methotrexate or cyclosporine combined with corticosteroids will be published elsewhere.

There is controversy as to whether methotrexate is superior to no prophylaxis (Lazarus et al. 1984, Sullivan et al. 1986). In this study the incidence of GVHD was significantly increased in patients given no prophylaxis versus those given methotrexate or cyclosporine.

Three variables were noted to have a marginal association with the risk of GVHD: use of prophylactic trimethoprim–sulfamethoxazole, pretransplant performance status and number of post-transplant transfusions. In animals, intestinal decontamination or modification of the intestinal flora is associated with a decreased risk of GVHD (van Bekkum et al. 1974). We found that the risk of GVHD was somewhat reduced in patients given trimethoprim–sulfamethoxazole pretransplant (44 ± 3% versus 50 ± 4%, P < 0.04). The explanation for this difference is unknown. Interestingly, patients who received other antibiotics for the purpose of intestinal decontamination had the same risk of GVHD as patients not receiving decontamination. Thus it is unlikely that differences in the intestinal microbial flora are responsible for the decreased risk of GVHD observed in patients receiving trimethoprim–sulfamethoxazole.

Patients who had the highest performance ratings immediately prior to transplantation had a somewhat lower risk of GVHD compared to patients whose performance ratings were less than 50% (44 ± 3% versus 49 ± 5%, P < 0.04).

The association between the number of transfusions administered post-transplant and the risk of GVHD is difficult to interpret. It is unclear whether the association was cause or effect. Although unirradiated transfusions of whole blood or blood components such as platelets or granulocytes are capable of causing lethal GVHD in immunocompromised patients (von Frieder et al. 1982; Nikoskelainen et al. 1983; Weiden, 1984), essentially all patients received only irradiated transfusions post-transplant. Intravenous administration of spleen cells irradiated with 10 Gy is associated with an increased risk of GVHD in immunosuppressed rodents (Bennet & Hand, 1978). Thus, it is possible that the number of irradiated post-transplant transfusions correlated directly with the risk of acute GVHD because radioresistant cells capable of inducing GVHD in immunosuppressed patients are present in irradiated blood products. Another possible explanation relates to the observation that transfusions are correlated with an increased risk of CMV infection (Weiner et al. 1986; Winston et al. 1980) which, in some animal models and man, has been associated with an increased risk of GVHD (Grundy et al. 1985). On the other hand, GVHD has been reported to activate latent CMV infections (Dowling et al. 1977). The incidence of CMV interstitial pneumonitis was 14 ± 2% in patients with moderate to severe acute GVHD versus 6 ± 1% in patients with no or mild acute GVHD (P < 0.0001). It is also possible that the critical clinical status of patients with moderate to severe acute GVHD necessitated large numbers of transfusions and that the correlation was the result of GVHD rather than its cause. Additional studies, including the dose of radiation to the blood and the precise relationship between the onset of GVHD and timing of transfusions, are needed to resolve this question.

Several factors reported to be associated with the risk of GVHD in smaller series of patients were not confirmed in this study. Storb et al. (1983) found a reduced risk of GVHD in severe aplastic anemia patients who were maintained in a protective environment: the same team found no association in other studies (Anasetti et al. 1986; Buckner et al. 1978; Storb et al. 1986). We found no significant difference in the incidence of GVHD among patients maintained in laminar airflow isolation versus conventional isolation.

There is debate whether different diseases are associated
with different risks of developing GvHD. Bross et al (1984) reported that the risk of GvHD was highest in patients with acute lymphoblastic leukaemia in comparison with those with other diagnoses. An editorial (1984) suggested that the incidence of GvHD is highest in severe aplastic anaemia. We found no differences in multivariate analysis.

Most data suggest that ABO incompatibility is not a risk factor for GvHD (Buckner et al. 1978; Gale et al. 1977; Hershko et al. 1980). In contrast, major and minor ABO mismatches were reported to be associated with GvHD by Bacigalupo et al (1985) in 109 transplanted patients. No significant associations were found between major and minor ABO mismatches and GvHD in the present study.

In animal models, the incidence and severity of GvHD is increased when total body radiation rather than chemotherapy is used for pretransplant conditioning (Elkins. 1971). Also, different doses, schedules and fields of radiation were reported to produce different rates of GvHD in animals (Gottlieb et al. 1980; Slavin et al. 1978). We found no significant difference in the incidence of GvHD with different conditioning regimens.

Data from animal models support the concept that the number of cells transplanted correlates directly with the incidence of GvHD (van Bekkum. 1983). In patients with AML transplanted in first remission, the IBMTR (Bortin et al. 1983) found a trend toward an inverse correlation between bone marrow cell dose and the risk of GvHD. Ringden & Nilsson (1985) found a significant (P<0.01) inverse relationship between cell dose and the risk of GvHD. Atkinson et al (1986) found no effect of cell dose. numbers of T cells or T cell subsets transplanted and the risk of GvHD. In this study there was no significant effect of cell dose on the risk of GvHD.

The reason for the discrepancies between the findings of this study and others is unclear. In some instances other reports were based on relatively small sample sizes of less than 300 patients. In other cases, failure to identify significant risk factors. even in randomized clinical trials, may have been due to small sample sizes with substantial type II (β) errors. often in excess of 80%. Certainly, one important aspect of this study is the use of pooled data from more than 2000 consecutive transplants reported by more than 100 teams. It is unlikely that several of the positive and negative associations reported here could have been identified in smaller databases.

The data presented in this study indicate that GvHD remains a major problem following bone marrow transplantation from HLA-identical siblings. Although the risk of GvHD may be reduced by T-cell depletion of donor bone marrow in vitro (for review, see Gale, 1987), this approach is associated with other problems such as an increased risk of graft rejection and leukaemia relapse (Gale & Reirner. 1986). Other approaches such as the combination of methotrexate and cyclosporine or either drug combined with corticosteroids may also be useful.

In this study we identified several prognostic factors, some of which can be manipulated in a favourable direction. These results should be useful in estimating the risk of GvHD in individuals with a specific profile of risk factors. The data also should prove useful in developing future approaches and in designing prospective clinical trials testing alternative methods to prevent GvHD. For example, if the randomization is not stratified for the prognostic variables identified here, it would be possible to observe rates of moderate to severe acute GvHD of 16% to >85% by chance alone in either or both arms.

ACKNOWLEDGMENTS

The authors thank D'Etta Koser, Sharon Gargul and the Swiss Jacobsen for help with data analysis, and Karen Wilkowsky for help in preperation of the manuscript.

Major Complications of Marrow Harvesting for Transplantation

M. M. BORTIN for the Advisory Committee of the International Bone Marrow Transplant Registry (IBMTR) and C. D. BUCKNER for the Seattle Bone Marrow Transplant Team (SMTT)

Medical College of Wisconsin, Milwaukee, WI 53226, USA & Fred Hutchinson Research Center, Seattle, WA 98104, USA

Complications to bone marrow donors were analyzed for 2027 transplants reported to the International Bone Marrow Transplant Registry and for 1263 transplants performed in Seattle. Thus, a total of 3290 donor risk episodes were available for study. The incidence of major, i.e., life-threatening complications in the combined series was 0.27%. Neither death nor permanent residua occurred in any of the donors.

Marrow transplantation is increasingly performed as a therapeutic modality. Donors usually have been HLA identical siblings but improving results have encouraged extension of the donor pool to include less than perfectly matched family members (1) and fully matched unrelated donors (2). It can be anticipated that there will be a further increase in marrow transplantation in the next several years and this will result in a further intensification of the search for acceptable donors.

The decision to perform a marrow transplant involves weighing the risks and benefits to the patient, as well as the risks to the donor. There have been numerous reports presenting risk-benefit ratios as they affect the marrow recipient, but there is essentially no literature describing the risks to the donor.

The purpose of this paper is to present the major, i.e., life-threatening complications that have occurred to marrow transplant donors as reported to the International Bone Marrow Transplant Registry (IBMTR) together with those
that have occurred in donors aspirated by the Seattle Marrow Transplant Team (SMTT). More detailed reports describing less serious complications and statistics relating to the procedure will be forthcoming from the IBMTR and the SMTT.

MATERIALS AND METHODS

From its inception in 1970 through June 30, 1983, reports of 2248 allogeneic or syngeneic transplants have been submitted to the IBMTR by 99 bone marrow transplant centers, worldwide. In this report we have excluded from the IBMTR analysis reports of 176 fetal tissue or thymic epithelial transplants, 10 bone marrow transplants in which the response to the question regarding donor complications was not completed and, to avoid duplication, 35 bone marrow transplants reported to the IBMTR by the SMTT. Thus, there were 2027 instances in the IBMTR series in which bone marrow donors were at risk of complications attendant to the procedure.

The hospital records of 1160 allogeneic or syngeneic donors of marrow in Seattle were reviewed and the complications of 1263 separate donations analyzed. This report includes the majority, but not all, of the donors aspirated by the SMTT. Only records of donors aspirated at the transplant center were analyzed, including all marrow aspirations at the USPHS Hospital (1969–73), Providence Medical Center (1973–75) and the Swedish Hospital Medical Center (1975–Dec 31, 1982). The only exclusions from Seattle were procedures performed at other hospitals and patients aspirated for autologous transplantation.

When a donor gave marrow on two or more occasions, each instance was considered separately for risk of complications. Thus, from both series there was a total of 3290 bone marrow donations, each representing an individual risk episode. Marrow aspirations almost always were performed from the posterior iliac crests (3). In addition, the anterior iliac crests often were aspirated and occasionally the sternum. Almost all patients had general or spinal anesthesia; caudal blocks were used infrequently.

RESULTS

The IBMTR series includes three episodes of life-threatening marrow donor complications. A brief description of each such complication is presented below:

IBMTR ID 184, a 10-yr-old boy had marrow aspirated from the posterior iliac crests under general anesthesia. He developed fever and blood cultures revealed Enterobacter species. He was treated with gentamycin. Recovery was prompt and complete.

IBMTR ID 1358, a 60-yr-old female underwent marrow aspiration from the posterior iliac crests under general anesthesia. She developed a femoral vein thrombosis at the site of an indwelling femoral vein catheter. Treatment with streptokinase was complicated by a small retroperitoneal hemorrhage that was identified on CAT scan. Transfusions were not required and recovery was complete without sequelae.

IBMTR ID 1765, a 53-yr-old female developed a shortness of breath shortly after marrow aspiration. A roentgenogram of the chest was compatible with a small pulmonary embolus with atelectasis. She was treated with heparin and oral anticoagulants. The response was prompt and recovery was complete within 2 wk.

The following life-threatening events occurred in the SMTT experience:

SMTT UPN 50, a 19-yr-old male underwent marrow aspirations under general anesthesia from the anterior and posterior iliac crests. On extubation, he was noted to have bronchospasm and a chest X-ray was compatible with aspiration pneumonitis. He was treated with prednisone and antibiotics and discharged after 5 days with a normal chest X-ray.

SMTT UPN 561, a 26-yr-old female received preoperative medication consisting of morphine 10 mg and scopolamine
0.4 mg IM. One h later, she was given Valium 5 mg IV followed in 5 min by instillation of Pontocaine 12 mg intrathecally followed by Valium 5 mg IV. Thirty min later, shortly after commencement of the marrow aspiration procedure, the patient suffered a cardiopulmonary arrest which responded to external cardiac massage and the administration of epinephrine and Decadron. There were no sequelae. Marrow aspiration was carried out 24 h later under general anesthesia without complication.

**SMTT UPN 1085**, a 4-yr-old male underwent marrow aspirations from the posterior iliac crests under general anesthesia with Halothane. Ten min into the procedure, he developed sinus tachycardia, then developed ventricular tachycardia. The procedure was halted, the patient was turned and a blow was administered to the precordium. He reverted to normal sinus rhythm with intermittent ventricular irregularities which responded to Lidocaine. Subsequent electro- and echocardiograms were normal and there were no sequelae.

**SMTT UPN 1493**, a 43-yr-old man was evaluated on August 31, 1981 as a potential marrow donor. He was found to have hypertension with a blood pressure of 160/110 mm Hg and placed on Lopressor and diuretics. On September 17, 1981 he was admitted for marrow aspiration and his blood pressure was 150/100 mm Hg. The following day, he underwent multiple marrow aspirations from the anterior and posterior iliac crests and the sternum under general anesthesia without complications. On February 1, 1982 he was readmitted for a second marrow donation and underwent marrow aspirations from the anterior and posterior iliac crests without problems. His blood pressure prior to and during the procedure was in the normal range. On the evening of discharge, he developed paresis of the left side of his body. A CAT scan was consistent with a cerebral infarction with a right middle cerebral distribution. Electroencephalogram showed temporal slowing and an echogram showed stenosis of the carotid bifurcation on the right. In March of 1982, he underwent a carotid endarterectomy and at the time of this writing, July 1983, he has made an almost complete recovery.

**SMTT UPN 1641**, a 44-yr-old man developed tenderness over the posterior iliac crests 24 h after the procedure. He was treated empirically with Dicloxicillin and, when cultures of the aspiration sites revealed *Enterobacter cloacae*, with Trimethoprim-Sulfamethoxazole. He was discharged from the hospital but because of persistent infection he was subsequently readmitted for 10 days to receive intravenous antibiotics. In addition, he required incision and drainage of the infected area and had an uneventful outcome.

**SMTT UPN 1900**, a 60-yr-old man underwent marrow aspirations from the anterior and posterior iliac crests under spinal anesthesia. He was noted to be febrile on return to the ward and one of four blood cultures was positive for *Klebsiella pneumonia*. He was treated with intravenous antibiotics for 2 wk and discharged without sequelae. Intensive studies failed to reveal a source for the bacteremia.

**DISCUSSION**

Life-threatening complications occurred in 3 of 2027 IBMTR donations and 6 of
1263 donations in the SMTT experience for an overall incidence of 0.27%. There was no threat to life in 99.73% of the marrow donations. Although essentially all donors had pain and soreness at the aspiration sites for several hours to several days following the procedure, pain that persisted for a week or more occurred in less than 0.5% of the donations. Other consequences of marrow donation included anemia of sufficient magnitude to require transfusions in a few instances, one case of a broken aspiration needle that required surgical removal, and a few transient episodes of hypotension, atrial arrhythmia or laryngospasm.

Five of the life-threatening complications reported here (non-fatal cardiac arrest, pulmonary embolus, aspiration pneumonitis, ventricular tachycardia and cerebral infarction) probably could be attributed to use of a general anesthetic. The occurrence of these life-threatening complications associated with general anesthesia, while rare, was anticipated from experience accumulated in healthy individuals undergoing surgical procedures (4). Although no deaths occurred in either the IBMTR or SMTT series, the authors are aware of a fatality in an older donor at a transplant center that has not reported any of their cases to the IBMTR. While the probability of an anesthetic death is exceedingly small in healthy individuals of any age, the risk is highest in the elderly (4). It should be noted that less than 1% of all donors in the IBMTR and SMTT series were over 60 yr of age.

The potential for fatal complications resulting from marrow aspiration per se is remote and probably limited to the consequences of sepsisemia or infection at the aspiration sites as occurred in three cases reported here.

These data demonstrate that marrow donation for transplantation is an exceedingly safe procedure but with finite and definable risks. Information on donor complications should continue to be accumulated carefully and disseminated widely.

ACKNOWLEDGMENTS

We thank Ms. P. Minks, Ms. D. Schaefer and Ms. D. Waldock for their help in preparation of the manuscript and data collection. We gratefully acknowledge the contribution of donor data for the IBMTR series by the transplant centers shown below.

Cognitive, educational, psychosocial adjustment and quality of life of children who survive hematopoietic SCT and their siblings

M Barrera and E Atenafu

Department of Psychology, Population Health Sciences, The Hospital for Sick Children, Toronto, Ontario, Canada

Our objective was to compare cognitive, educational and psychosocial outcomes, and quality of life (QOL) of pediatric hematopoietic SCT (HSCT) survivors with those of their siblings, 2 years post-HSCT. Forty-six HSCT survivors, with age ranging from 3 to 16 years, and 33 siblings, with age ranging from 3 to 20 years, participated. Standardized tests were performed and questionnaires were completed by the participating children and their mothers. Survivors’ full, verbal and performance IQ scores did not differ significantly from those of their siblings. Survivors, however, had significantly higher perceptual organization scores than their siblings. Siblings’ mean scores on spelling were significantly higher than those of survivors, but arithmetic and reading scores were not. Siblings had significantly more internalizing problems than survivors. Siblings’ physical QOL scores were significantly better than those of survivors. Finally, child age, maternal depression scores and age, and family cohesion were related to cognitive and educational differences. A history of cranial radiation and a diagnosis of neuroblastoma or Hodgkin’s lymphoma in survivors were related to the difference in internalizing scores. Except for some deficits in educational outcomes and physical QOL, survivors’ cognitive and psychological outcomes at 2 years post-HSCT were similar to those of their siblings. Family and clinical factors were identified as critical for these outcomes.

Bone Marrow Transplantation (2008) 42, 15-21; doi:10.1038/bmt.2008.84; published online 31 March 2008

Keywords: cognitive; educational; psychosocial outcomes; children; HSCT

Introduction

Children and adolescents who undergo hematopoietic SCT (HSCT) may be vulnerable to cognitive, educational, perceptual motor skills and psychosocial deficits resulting from the treatment and disease. Although early retrospective studies have reported cognitive and academic deficits in survivors of pediatric BMT, particularly if they received cranial radiation at a younger age, more recent prospective studies have found that, in general, survivors of HSCT perform well, cognitively and educationally, or even improve some of their performance 2 years post-HSCT compared with their pre-HSCT performance. Moreover, some child characteristics (older age at transplant) and familial factors (older maternal age and less maternal depression symptoms) seem to be associated with better outcomes. It is less clear how survivors’ outcomes compare to those of their healthy siblings, who are exposed to the family crisis precipitated by the diagnosis of a life-threatening illness such as cancer, the intense treatment that culminates in a transplant and related complications. This study addresses this gap.

Survivors of childhood cancer have been compared with their close-in-age siblings in cognitive, educational, quality of life (QOL) and psychosocial outcomes with variable results. Indeed, some studies have found that survivors have more cognitive and educational deficits than their siblings. Other studies have found no differences between survivors of childhood cancer and their healthy siblings in behavioral, educational and social problems, as well as feelings of distress, guilt and psychosomatic symptoms. In contrast, in an early study, siblings of childhood cancer survivors showed more distress than the survivors in perceived social isolation; or survivors performed like their siblings in psychological adjustment but did significantly worse than their siblings in educational outcomes. A recent study examining post-traumatic stress found that siblings reported more symptoms of post-traumatic stress than did childhood cancer survivors. In another recent study, siblings and survivors of leukemia did not differ in behavioral problems but siblings displayed more social and academic difficulties. Clearly, the current inconclusive evidence comparing children with cancer with their siblings provides little direction as to whether survivors of HSCT will be worse off than their siblings.

To date, to our knowledge, there are no published studies that compare the comprehensive outcomes of pediatric cancer survivors and their healthy siblings.
HSCT survivors with those of their siblings. The only comparative study of siblings in this population examined the psychosocial outcomes of donor and non-donor siblings of children who undergo HSCT, but did not compare them with the ill child. Donors were reported to have significantly more anxiety than non-donors but non-
donors were reported to have more problems at school. HSCT inflicts added stress on children and families already overburdened with a wide range of medical, psychosocial and financial stresses related to the diagnosis of cancer or other blood disorders and unsuccessful treatment. Considering this and the aggressiveness of the HSCT procedure, one may expect that the outcomes for survivors and siblings may be worse than the outcomes for childhood cancer survivors who do not undergo an HSCT. Augmenting the knowledge of the long-term cognitive, educational, psychosocial and overall QOL outcomes of survivors will help clinicians and families to make decisions regarding comprehensive care and future planning.

Thus, the main objective of this study was to compare cognitive, educational, perceptual motor skills, and psychosocial outcomes and QOL of HSCT survivors with their close-in-age siblings at 2 years post-HSCT. The secondary objective was to examine clinical, familial and child factors that may be associated with the differences, if any, between the groups. To examine related factors, we used a conceptual model to explore the potential factors that could explain any of the differences between the outcomes for survivors and siblings, which was similar to that used in earlier studies of children who were diagnosed with cancer, their parents and the longitudinal sample of survivors of HSCT. Briefly, this multivariable model proposes that individual psychological outcomes after a major health crisis, such as undergoing HSCT, will be influenced by personal (e.g., age and gender), clinical (e.g., diagnosis, time since diagnosis and conditioning protocol) and familial factors.

Given the added medical demands for the ill child with this procedure and the great deal of attention they receive, we predicted that survivors will show better psychosocial outcomes than their siblings, but will still show deficits in cognitive and educational outcomes and physical QOL. Given our previous findings that familial factors contributed to the survivors' cognitive and educational outcomes, and that both survivors and siblings have different experiences within the same family, it is likely that, when differences exist, familial factors such as maternal depression scores will be associated with poorer outcomes in survivors. This study was part of a major project investigating the psychosocial and educational outcomes in a family after pediatric HSCT.

Materials and methods

Participants and recruitment
Potential survivor participants for this investigation were children over the age of 3 years who participated in the longitudinal study of the larger project and had complete data at 2 years post-HSCT. All the families that had eligible siblings agreed to participate in the longitudinal study but not all ill children survived 2 years post-HSCT. Complete data were obtained for 46 survivors and 33 siblings. The inclusion criteria for siblings were as follows: age within 2 years of the target child's age and presenting with no major health problems. Only one sibling per family participated and five of the siblings were donors. Comparisons related to being a donor, however, were not the focus of this investigation. Table 1 presents clinical and demographic characteristics of the survivors and siblings. Briefly, mean age of participating survivors was 10.13 years (s.d. = 4.4, range 2–16), whereas that of siblings was 10.96 years (s.d. = 3.62, range 3–20). Majority of survivors were diagnosed with other leukemia types (i.e., AML and CML), neuroblastoma and ALL. Other diagnoses included hematological disorders and Hodgkin's lymphoma. The majority of survivors (68%) underwent an autologous transplant (48% related). Seventy-four percent experienced no cranial radiation before or during conditioning. The mean time since diagnosis at pre-HSCT was 19.9 months (s.d. = 19.5). Most children came from a two-parent European-descent family and a middle-class socio-economic background. The majority of parents had undergone at least part of college or university education.

Procedure
After approval from the Research Ethics Board was obtained, an invitation letter was sent to all eligible families describing the study and inviting them to participate in the study, with the last assessment at 2 years post-transplant. Informed consent and assent were obtained at the initial assessment for the survivors. Assent or consent of siblings was obtained at their participation 2 years post-HSCT. Families were scheduled for two assessment sessions, one for the sibling and one for the survivor, to complete the cognitive, educational and visual motor performance tests and behavioral questionnaires. The mother was the primary parent during the HSCT and the one who completed the questionnaires about the survivor's and sibling's behavior and QOL, and about her own as well.

Outcome measures

General Intelligence was measured using the Wechsler Intelligence Scale for Children Third Edition (WISC-III). The Wechsler scales are well normed, producing IQ estimates labeled as verbal (VIQ), which includes information, similarities, arithmetic, vocabulary and comprehension subtests), performance (PIQ, which includes picture completion, coding, picture arrangement, block design and object assembly) and full scale (FIQ). Using the WISC-III subtests, including two supplementary subtests (digit span and symbol search), we derived specific factor-based cognitive indices: freedom from distractibility (which includes arithmetic and digit span), processing speed (which includes coding and symbol search) and perceptual organization (PO; which includes picture completion, picture arrangement, block design and object assembly) and verbal comprehension (which includes all the subtests of the verbal scale except arithmetic and digit span). The latter index was not used because it tests basically the same constructs as VIQ. Average reliability estimates for the IQ

Measures of related factors

The Family Adaptability and Cohesion Evaluation Scale (FACES-III) and the Beck Depression Inventory (BDI) were used as the measures of family cohesion and maternal distress, respectively, as potential related factors. These measures were chosen because they are brief and widely used in families with a history of childhood chronic illness or cancer and could be completed by a parent with minimal burden. FACES-III is a 20-item scale with two dimensions of family relations: adaptation and cohesion. Test–retest reliability over a 4- to 5-week period was r = 0.80 for adaptability, and r = 0.83 for cohesion, with high discriminative validity. In this study, the cohesion score was used as a measure of family functioning. The BDI is a self-administered 21-item questionnaire designed to measure depressive symptomatology. The BDI has been found to be highly sensitive in measuring changes in depressive symptoms and severity. Concurrent validity of the BDI with most other self-report measures of depression has been consistently high. Both measures were completed by the mother.

Clinical and demographic factors

Information on the child’s disease and treatment was obtained from the medical chart and confirmed by parental report. The clinical variables considered in this study were as follows: diagnosis type (ALL, other leukemias, neuroblastoma, Hodgkin’s lymphoma and hematological disorders), time since diagnosis (stratified into less than 30, between 30 and 36, and more than 36 months), history of radiation treatment (no radiation, total body radiation (TBR) only, and combined cranial radiation therapy (CRT) and TBR) and radiation group (<300 cGy or >1200 cGy). The child characteristics included in this study were as follows: child’s age at pre-HSCT and gender. Maternal age and education were also considered, with the latter as an index of socioeconomic status.
Statistical analysis

Initially, descriptive statistics were calculated for the outcome measures and related variables. Because of the small sample size and missing data for some of the variables (see Table 2), all the outcome measures were tested for normality using the Kolmogorov–Smirnov test. The majority of the variables did not violate the assumption of normality. However, because the FIQ and VIQ scores were not normally distributed, they were tested using both parametric and non-parametric tests in the comparisons between survivors and siblings. These results were similar, hence only the parametric results are reported. Paired t-tests were conducted to compare survivor and sibling scores on all measures (cognitive, visual motor, educational, psychosocial and QOL). When there was a significant difference between survivors and siblings, we examined what factors may have accounted for the difference. Thus, the following analyses were conducted to select and reduce potential predictors of differences. To avoid collinearity, a pair-wise assessment of associations between predictors was examined. That is, χ²-tests within categorical predictors, analysis of variance for continuous and categorical and Pearson correlations for continuous variables were conducted. The variables found to have high potential collinearity were not included together in a multivariable model. Covariates significant at the 20% level in the bivariate analyses were included in the full multivariable, generalized linear regression model. History of radiation was chosen over radiation group based on these preliminary analyses. Generalized linear regression models were then constructed to examine the effects of the potential factors associated with the differences between survivors and siblings. These analyses were conducted using SAS software version 9.1 (SAS Institute Inc., Cary, NC, USA).

Results

Differences in outcome measures between survivors and siblings

Cognitive and visual motor outcomes. Mean FIQ, PIQ and VIQ scores of survivors did not differ significantly from the corresponding mean scores of their siblings. Although survivors' mean PIQ scores were higher than those of their siblings, this difference did not reach significance (t(31) = 1.70, P = 0.10). Analysis of the cognitive indices indicated that the mean for PO was significantly higher for survivors than the mean for siblings (t(31) = 2.14, P = 0.04). Both PO scores, however, were within the normal range. Moreover, the VMI mean standard scores for survivors and siblings did not differ significantly.

Educational outcomes. Siblings' mean scores for spelling were significantly higher than those of survivors (t(25) = 2.06, P < 0.05), with the siblings' scores being more than 7 points higher. The mean scores for arithmetic and reading were in the same direction but did not reach significance.

Psychological adjustment. The mean score for total CBCL, and externalizing scores, did not differ significantly between survivors and siblings but the difference between their mean internalizing scores was significant, with the siblings scoring 4 points higher than the survivors, suggesting more internalizing problems (t(32) = -2.66, P < 0.02). However, as a group, the mean internalizing score for survivors and siblings were within the normal range.

Quality of life. The mean physical QOL summary score for survivors was significantly below the mean for siblings, suggesting more physical difficulties in survivors 2 years post-HSCT (t(31) = -4.31, P < 0.0001), with a difference of 10 points. The mean psychosocial QOL summary scores did not differ significantly between the groups.

Factors associated with the differences between survivors and siblings

To further understand the differences found between the survivors and siblings in the cognitive index of PO, the
educational outcome, spelling, psychological adjustment, measured by internalizing scores, and physical QOL, next we examined potential clinical factors (diagnosis, history of radiation, time since diagnosis, type of transplant), child characteristics (age) and family factors (maternal age and depression scores, family cohesion) that might be related to these differences. Preliminary analyses indicated that none of the clinical variables were associated with the difference between siblings and survivors in PO, which reflected better scores for the survivors than the siblings. Two familial factors, maternal age and family cohesion, were identified in preliminary analyses, using parametric and nonparametric statistics, as associated with the difference between the groups in PO and included in the regression model. The model was significant ($R^2 = 0.60$, $F_{2,14} = 9.30$, $P = 0.0036$), with maternal age ($F_{1,14} = 13.79$, $P = 0.02$) and family cohesion ($F_{1,14} = 8.92$, $P = 0.011$) being associated to the difference, in spite of the small sample that had family cohesion data. These results indicate that the older the mothers, the higher the differences in favor of the survivor. Moreover, the difference was greater in more cohesive families.

For the difference in spelling, which reflected better outcomes for siblings than for survivors, the regression model ($R^2 = 0.47$, $F_{2,22} = 9.83$, $P < 0.0001$) included two factors: child age ($F_{1,22} = 8.76$, $P = 0.007$) and maternal depression ($F_{1,22} = 4.54$, $P = 0.04$), suggesting that the difference in spelling scores was smaller with older survivors and when maternal depression scores were low.

For the difference in internalizing scores, which reflected more internalizing problems for siblings than for survivors, the significant model ($R^2 = 0.51$, $F_{4,20} = 4.59$, $P = 0.0026$) included history of cranial radiation ($F_{2,20} = 3.35$, $P = 0.05$) and diagnosis ($F_{5,20} = 3.04$, $P = 0.03$). This analysis suggests that the difference was smaller if the survivors had combined CRT and TBR or a diagnosis of neuroblastoma or Hodgkin’s lymphoma. Finally, none of the variables tested (personal, clinical and familial) were associated with the difference between survivors and siblings in physical QOL, suggesting that this difference is primarily a result of disease and HSCT treatment.

Discussion

Contrary to predictions, survivors of HSCT performed as well in global and specific cognitive outcomes as their siblings but better than their siblings in PO. As predicted, they showed some deficits in educational outcomes and physical QOL. Moreover, their psychosocial QOL was rated as good as that of their siblings and, as a group, they presented with less internalizing problems than their siblings. These encouraging results support the previous longitudinal outcomes in this population, which showed improvement on PIQ and stable overall cognitive performance during the first 2 years post-HSCT, outcomes that were equivalent to or better than the normative values. It was surprising, however, that survivors were in fact doing better than their siblings on the specific index of PO, which measures specific ability to think in terms of visual images and manipulate them with fluency. This ability is associated with persistence and alertness, and perhaps reflects the survivors’ experiences during the hospitalization and recovery period. During this period, survivors usually spend a substantial amount of time playing video games, which can enhance the skills measured by the PO index.

It was not a surprising finding that two familial factors, maternal age and family cohesion, were associated with the difference in scores in favor of the survivors. This result suggests that the children experienced different environments, one that may have resulted in greater individual attention in favor of the survivors because of their medical condition. This finding, however, is limited by the small sample size. Another familial factor, maternal depression scores, was associated with the difference in spelling. Thus, if mothers had high depression scores, survivors had lower spelling scores than their siblings, suggesting that survivors’ attention and memory for writing might have been influenced by changes in maternal mood.

It was not surprising, however, to see that the difference in spelling was smaller for older groups, as older children are more likely to have learned spelling patterns before HSCT. Thus, the findings of this study align with the previous longitudinal educational outcomes suggest that a younger age at HSCT and indices of poor maternal psychological well being (measured by depression scores) may be risk factors for their educational outcomes. Consequently, these findings highlight the importance of early school attendance for learning the fine details of written language before HSCT, and identifying an area of intervention focus for schooling children during the first 2 years post-HSCT. Moreover, these findings also suggest that family support and counseling pre- and post-HSCT may result in indirect positive effects on cognitive and educational outcomes.

Although, compared with their siblings, survivors, as a group, did not present with internalizing difficulties, it was interesting to see that survivors with a history of cranial radiation or a diagnosis of neuroblastoma or Hodgkin’s lymphoma were likely to have high internalizing scores as their siblings. This finding raises the possibility that survivors with a history of cranial radiation, and those who survive neuroblastoma and Hodgkin’s lymphoma, are potentially at risk for internalizing problems. It is important to stress that neither survivors nor siblings, as a group, had mean internalizing scores in the clinical range. This attests to children’s resilience to the effects of traumatic medical experiences. Still, the fact that siblings in general tended to have more internalizing problems (anxiety, depression and social withdrawal) than survivors supports some earlier findings. Recent reports on post-traumatic stress symptoms in siblings of children with cancer, and suggests that some siblings, in fact, were reported to have internalizing scores in the clinical range.

It was not surprising to find poorer physical QOL in survivors compared with siblings, given their previous disease and aggressive treatment. It was interesting to see, however, that in spite of these physical limitations, psychosocially they were rated to be doing at least as well as their siblings. Finally, none of the additional personal...
and familial factors examined in this study were associated with the group difference in physical QOL, which suggests that this difference was directly a result of the disease and treatment, particularly, undergoing HSCT. In spite of the physical problems, however, survivors remain cognitively and emotionally resilient and continue to live, what appear to be, well-adjusted lives. The fact that our results show lesser deficits than reported previously may also reflect current less-aggressive protocol treatments, for example, reduced cranial radiation for ALL patients.

This study has several limitations. A small sample and missing data resulted in reduced statistical power and limited the contribution of this study. Having a small sample size is not unusual in research with this medically vulnerable population faced with poor health, many stressors and high mortality rates.3 Comparing the outcomes of these survivors with those of their siblings is an asset as it controls for both environmental and genetic variance. Conversely, having the mother complete reports on both survivors and siblings limits the data on questionnaires to maternal perspective. The study was also limited by the availability of siblings as not all the survivors have a sibling close in age to complete the assessment measures. Although there are suggestions that being a sibling donor may make a difference in the sibling outcomes, comparisons of sibling donors and non-donors could not be made due to the small sample size of donors (five). Future studies should compare these outcomes among these groups of siblings and survivors. Despite these limitations, the outcomes of this comprehensive comparative study are unique, as they illustrate the resilience of survivors and the impact of pediatric HSCT within the family.

In conclusion, 2 years post-HSCT survivors' PO and psychological adjustment seem to be at least as good as those of their siblings, but their physical QOL and educational outcomes showed some deficits. Child characteristics, such as age, but mainly familial factors (maternal age and depression and family cohesion) seem to be associated with the difference in cognitive and educational outcomes between survivors of HSCT and their siblings. Conversely, clinical factors—history of cranial radiation and type of diagnosis—seem to be associated with psychological adjustment differences. These findings provide new knowledge for corroboration by future researchers. Finally, these findings have important implications for comprehensive family care, particularly in light of the important positive association of the outcomes with maternal well being and age.

References

Indeed, our study of prospective EBV monitoring was initiated because of a case similar to the one described by Wondergem et al. Our patient was a 32-year-old man with severe aplastic anemia who received horse antithymocyte globulin (ATG) with no response at 3 months and was then treated with rabbit antithymocyte globulin. Two weeks later, rapidly progressive massive lymphadenopathy developed in the neck, axillary, and mediastinal areas, requiring endotracheal intubation. Axillary lymph node biopsy revealed EBV lymphoproliferation, accompanied by an EBV viral load of 870,000 copies per 10⁶ mononuclear cells in the blood. Cyclosporine was discontinued and the patient received one cycle of cyclophosphamide, doxorubicin, vincristine, prednisone plus rituximab (CHOP-R) with a rapid decrease in node size and in peripheral blood EBV copy numbers. He went on to unrelated hematopoietic stem cell transplantation for his aplastic anemia and 4 years later he is doing well with no further evidence of EBV disease.

Notwithstanding, EBV-lymphoproliferative disease after immunosuppression for aplastic anemia is very rare and its occurrence has been limited to case reports. We have now monitored EBV reactivations in more than 150 courses of immunosuppressive therapy with no additional cases of EBV disease, despite very high viral loads and prolonged periods of EBV polymerase chain reaction (PCR) positivity. In the past 18 months we have monitored EBV viral loads in patients who received rabbit ATG as initial therapy; higher viral loads were again observed in patients treated with the rabbit ATG on top of similar levels to what was reported in the manuscript when rabbit ATG was administered as a second course only compared with those who received horse ATG. Therefore, the EBV viral load cannot be interpreted in isolation as cut-off values that are predictive or diagnostic of disease have not been established. Rather than mandate routine testing for what we believe is a rare event, we would instead prefer to stress awareness of the potential for EBV reactivation and disease, with intervention only when there is clinical suspicion due to rising lactate dehydrogenase (LDH), lymphadenopathy, clinical deterioration in association with a high EBV viral load, and confirmatory lymph-node histology.

To the editor:

Physical and not mental health is impaired in very long-term survivors after HSCT compared with their respective donors: a paired analysis

Bhushan and colleagues recently published a comprehensive analysis on late mortality after allogeneic hematopoietic stem cell transplantation (HSCT), providing interesting data about the functional status of 547 recipients and 319 siblings. At the time of this Collaborative Bone Marrow Transplant Survivor Study, patients and donors had a median age of 41.5 and 44 years, respectively, and a median time of 8.6 years after HSCT. By questionnaire, long-term survivors reported significantly more difficulties in integration back into society after HSCT, in holding down employment, or in obtaining or retaining health insurance compared with their siblings. These results provided additional information to the relatively scarce and partially conflicting reports on functional status in the long-term recipients of HSCT surviving more than 10 years.2,3

In order to obtain a comprehensive overview on physical and mental health in very long-term survivors after HSCT, we invited 44 recipients and their respective HLA-identical sibling donors to take part in a prospective study at the University Hospital of Basel. Both the recipients and their donors were controlled at the same time point, in pairs, and were given a complete clinical and biologic examination. Each answered a Short Form 36 (SF-36) Health Survey, which provides the generic health status measure using 36 items assessing 8 different concepts (Table 1). Three of the concepts provide a score for physical health, 3 for mental health, and 2 for general health status. These 8 concepts are summarized in 2 global tests, one for physical and one for mental health. Norm-based scores were used, in which 50 represents the mean score, and 10 the standard deviation for the general population. The median age of the recipients and donors at the time of the study was 44.3 years (24-63) and 43.4 years (22-61), respectively, with a median time of 17.5 years (range, 11-26 years) after HSCT. Four patients received an HSCT for aplastic anemia and 40 for hematologic malignancies. All patients received bone marrow as stem cell source and total body irradiation was part of the conditioning in 39 patients (89%). Acute graft-versus-host disease (GVHD) was observed in 31 (70%), and chronic GVHD in 22 (50%) patients.

In a paired comparison, recipients showed a significantly lower rank of the norm-based scores for all questions related to physical well-being, except for role limitation, but no difference in the mental health scores compared with their respective donors (Table 1). This is confirmed by the global test for physical (P = .001) and mental (P = .831) health. Physical health was significantly lower in patients with extensive chronic GVHD (P = .05), in females (P = .024), in recipients older than 25 years at HSCT (P = .024) or older than 42 years at study evaluation (P = .05). None of these factors had a impact on mental health.

health status (MCS, \( P > .10 \)). In summary, our data extend the findings reported by Balzar et al.\(^{2}\) on the functional health status in long-term survivors, validating the finding that the physical health status of very long-term survivors after HSCT can be impaired, while mental health status remains preserved.

Revised criteria for the myeloproliferative disorders: too much too soon?

We would like to raise several concerns about the updated World Health Organization diagnostic criteria for polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF), as proposed by Tegfæ et al.\(^{1}\)

First, while the authors explain that the new criteria are not absolutely comprehensive, they never state the exact purpose of this revision. As a purpose of diagnostic criteria is to guide diagnosis and clinical management, the authors should demonstrate that the revised criteria are validated by data from previous studies. For example, while the discovery of the JAK2V617F mutation is of paramount importance, it has not changed our ability to discriminate between the different disorders and has not changed therapeutic recommendations, although it may in the future. Without these supporting data, these criteria produce significant ambiguity for physicians attempting to decipher their clinical relevance.

Second, the new criteria emphasize differences in bone marrow morphology among the myeloproliferative disorders. But, it appears that the vast majority of this work has been done with small groups of patients in retrospective and unblinded settings, which may facilitate biases and misinterpretations. In addition, the references supporting these morphologic criteria primarily focus on the work of one of the authors. We have concerns about the general applicability of these guidelines to centers that lack the necessary hemopathology expertise. Is there sufficient confidence that evaluation of megakaryocyte morphology and fibrosis is widely reproducible among the various observers who will be attempting to make these distinctions? This concern is shared by others.\(^{2,3}\) We also question whether morphologic assessment can reliably differentiate between primary and secondary causes of myelofibrosis, such as seen in primary pulmonary hypertension, a common cause of secondary myelofibrosis. Rather that stating that "the histologic differences among the entities outlined here are recognized by experienced hemopathologists," the authors should provide objective evidence of the validity, utility, consistency, and reproducibility of the proposed criteria.

Third, the morphologic criteria have never been applied to patients with congenital polycythemia due to Von Hippel-Lindau or EPO receptor gene mutations. In our experience with these disorders, many of these patients had their narrow morphology interpreted as consistent with PV.\(^{4,5}\)

In addition, there is a major mistake in Tefëfi et al.'s Table 1, which summarizes the 2001 criteria; contrary to what is stated in the table, dominantly inherited polycythemia due to a truncated erythropoietin receptor is always associated with a low erythropoietin level.

In summary, we feel that before using the revised criteria as a diagnostic guide, these issues need to be further evaluated in large-scale, prospective studies, such as those being undertaken by the Myeloproliferative Disorders Research Consortium.

Differential Characterization of the "Reticulum Cell" in Lymphoreticular Neoplasms

LUNG T. YAM, M.D., MEHDI TAVASSOLI, M.D., AND PETER JACOBS, M.D.

From the Divisions of Hematology and Clinical Pathology, Scripps Clinic and Research Foundation, La Jolla, California, and the Department of Hematology, University of Cape Town, Cape Town, South Africa.

ABSTRACT

Yam, Lung T., Tavassoli, Mehdi, and Jacobs, Peter: Differential characterization of the "reticulum cell" in lymphoreticular neoplasms. Am J Clin Pathol. 64: 171–179, 1975. The term "reticulum cell" is confusing, having been applied to the cells involved in many hematopoietic neoplasms, such as reticulum-cell sarcoma, histiocytic medullary reticulosis, leukemic reticuloendotheliosis, and monocytic or histiocytic leukemias. In histologic sections, even the cells from poorly differentiated extramedullary lesions of chloroma or myeloblastic leukemia have been called "reticulum cells." A combined morphologic and cytochemical approach has been used to study "reticulum cells" in smears and tissue sections of neoplasms involving "histiocytes" or "reticulum cells." The cytochemical markers are: chloracetate esterase for neutrophilic granulocytes; nonspecific esterase and fluoride-resistant esterase for monocytes and histiocytes (phagocytes); tartrate-resistant acid phosphatase for the reticulum cells of leukemic reticuloendotheliosis; pyronin for the lymphatic reticulum cells (germinal center cells). The morphology of these cells is very well appreciated in smears, and the locations of these marked cells in tissue sections are easily recognized. The use of cytochemical and immunochemical methods and functional studies, in addition to simple morphology, may be useful in subclassification of lymphoreticular neoplasms. (Key words: Reticulum cell; Lymphoreticular neoplasms; Malignant lymphoma; Leukemic reticuloendotheliosis; monocytic leukemia.)

THE NEOPLASTIC DISEASES of the reticuloendothelial system comprise a variety of clinical entities. Many of these diseases have distinct clinical features and different natural histories, necessitating different therapeutic approaches. Morphologic examination of tissue sections and smears is the cornerstone of diagnosis and classification of these disorders, thereby dictating the therapeutic approach and prognosis of the disease. The inadequacy of morphologic examination based on hematoxylin–eosin-stained sections or Wright–Giemsu stained smears has long been evident by virtue of the controversies and difficulties surrounding the interpretation of the cell type involved.
A noncommittal term often used by morphologists dealing with cells involved in these disorders is "reticulum cell." It has been used to indicate a poorly differentiated cell when proper identification by conventional methods has escaped the morphologist. For example, when highly undifferentiated granulocytic neoplasms manifest as a solid tumor, it is not uncommon to have an erroneous histologic diagnosis of "reticulum-cell sarcoma."12-14 In the classic "reticulum-cell sarcoma" or malignant lymphoma of the histiocytic type, the neoplastic cell involved has been considered to be a reticulum cell by some and a histiocyte by others.10,17,18 In this situation, "reticulum cell" is synonymous with "histiocyte." In acute monocytic leukemia of the Schilling type, the cells are often called "monocytes," although others have considered these cells to be histiocytes, and the disease to be histiocytic leukemia. Here, the monocytes and their precursors are considered to be histiocytes.5,6 "Histiocytic leukemia," however, has also denoted "leukemic reticuloendotheliosis."15,16 In acute monocyctic leukemia of the Naegeli type, both myelocytic and monocytic cells proliferate, and it may be very difficult to distinguish these two types of cells accurately. In other instances, the reticulum cells are thought to be related to endothelial cells, as in leukemic reticuloendotheliosis, to plasma cells (plasmacytoid reticulum cells), or to lymphocytes (lymphatic reticulum cells).18 In some malignant lymphomas, it is not uncommon to find coexistence of many large "histiocytes" and the smaller, poorly differentiated lymphocytes, rendering it difficult to differentiate between histiocytic lymphoma and lymphocytic lymphoma. These problems demonstrate that the so-called "reticulum cells" are various in nature. A more precise definition for these cells is needed.

Previous studies have demonstrated that it is possible to identify many of the cells of the hemopoietic system both on smears and in tissue sections through the use of chemical markers.2-4,7,8,10,12,15 The present study was undertaken to study several diseases involving "reticulum cells," poorly differentiated hemopoietic cells, and "histiocytes" and to establish definite criteria for cells involved in these "reticulum-cell" diseases.

Materials and Methods

Cases studied included: histiocytic lymphoma 10; poorly differentiated lymphocytic lymphoma 10; acute myelomonocytic leukemia 10; leukemic reticuloendotheliosis 10; and one case of a patient with Sjogren's syndrome and histiocytic lymphoma (immunoblastic sarcoma). Ten patients with acute granulocytic leukemia and five patients with well-differentiated lymphocytic lymphoma were also included as controls for granulocytes and lymphocytes. The diagnoses of histiocytic and lymphocytic lymphomas were made according to the histologic criteria of Rappaport.17 The diagnosis of leukemic reticuloendotheliosis was established by identifying the typical clinical features and characteristic cytologic and histologic changes.21 The diagnoses of acute monocyctic or granulocytic leukemia were based upon the clinical pictures and the presence of leukemic cells in blood and marrow.

The tissues of 56 patients with definite neoplastic involvement were studied. In the malignant lymphomas, available tissues were lymph nodes obtained by biopsy and spleens obtained by splenectomy. In leukemic reticuloendotheliosis, the blood, marrow and spleens were studied. In acute leukemias, the tissues studied were blood and marrow in every patient and autopsy material of marrow, spleen, lymph nodes and liver from five.
Cytologic materials, including smears of blood and marrow and imprints of lymph nodes and spleens, were stained with Wright–Giemsa, methyl green–pyronin, and for acid phosphatase, tartrate-resistant acid phosphatase, nonspecific esterase, chloracetate esterase, and fluoride-resistant esterase (15 mg. NaF per 10 ml. incubation medium).\textsuperscript{12,20} Smears made from lymphocyte cultures stimulated with phytohemagglutinin (PHA) were also prepared and studied in a similar fashion.

Frozen sections of spleen and lymph node tissues were prepared and were stained with hematoxylin–eosin, and for acid phosphatase, tartrate-resistant acid phosphatase, nonspecific esterase, and fluoride-resistant esterase.\textsuperscript{13} After the cryostat sections had been made, tissues were further embedded in paraffin, sectioned at 6 microns, and stained with hematoxylin–eosin, reticulin stain, and methyl green–pyronin.

Several types of cells are defined on smears with Wright–Giemsa stain, and on paraffin-embedded sections stained with hematoxylin–eosin (Figs. 1–8). Detailed descriptions of these cells are listed in the appendix. The terminology used here is solely for the purpose of this communication. These terms have been used, or are being used, in the hematologic literature, but may be subject to evolutionary change.\textsuperscript{15}

Results

Cytometric Characteristics of the Cell Types

The cytometric characteristics of the various types of cells are listed in Table 1.

The lymphatic reticulum cells of Moeschlin (germinal center cells), immunoblasts, typical and atypical lymphocytes, and lymphoblasts all share common cytometric features. They lack chloracetate esterase activity but have weak to moderate acid phosphatase activity and minimal nonspecific esterase, fluoride-resistant esterase and tartrate-resistant acid phosphatase activities. The cytometric characteristics of these cells are similar to those of the PHA-stimulated lymphocytes.

Both histiocytes and monocytes contain strong activity of acid phosphatase and nonspecific esterase. The histiocytes have strong activity of fluoride-resistant esterase. Moreover, they are larger than the monocytes, and often contain phagocytosed material. A few histiocytes particularly the epithelioid variant, do have tartrate-resistant acid phosphatase activity. By contrast, the monocyte and its precursors do not show significant activity of fluoride-resistant esterase or tartrate-resistant acid phosphatase. The immature monocytes are moderately positive for methyl green–pyronin stain.

The immature granulocytes are characterized by having chloroacetate esterase activity but negligible activity of tartrate-resistant acid phosphatase, nonspecific esterase and fluoride-resistant esterase. They have variable pyroninophilia.

The hairy cells or neoplastic reticulum cells of leukemic reticuloendotheliosis are characterized by a strong tartrate-resistant acid phosphatase activity. They differ from the histiocytes with tartrate-resistant acid phosphatase activity by lacking significant nonspecific esterase and fluoride-resistant esterase activity.

Cell Types Involved in the "Reticulum-cell" Neoplasms

The types of cells involved in the various "reticulum-cell" neoplasms are listed in Table 2.

In malignant lymphoma of the histiocytic type (reticulum-cell sarcoma), we interpret the predominant cell type as a lymphatic reticulum cell (Figs. 1–4). Lymphoblasts, atypical lymphocytes, and
histiocytes (Figs. 3 and 4) are present in small and variable numbers, ranging from 5 to 20% in most cases. In cases with a pleomorphic histologic feature, the lymphatic reticulum cells are bizarre, varying considerably in size, nuclear contour, and cytoplasmic basophilia. In cases with a mixed histiocytic-lymphocytic histologic picture, the imprints show increased numbers of lymphoblasts and lymphocytes or histiocytes interspersed with the lymphatic reticulum cells.

In the poorly differentiated lymphocytic lymphomas, the predominant cells are the lymphoblast and the atypical lymphocyte (Fig. 6a and b), although some lymphatic reticulum cells, typical small lymphocytes, and phagocytic histiocytes are also present.

In the well-differentiated lymphocytic
Figs. 1–8. Top, 1–4; center, 5a, b, 6a, b; bottom, 7a, b, 8a, b.

Fig. 1. Paraffin-embedded section of lymph node from a patient with histiocytic lymphoma, showing the characteristic "histiocytes" (arrows) with prominent nuclei. Note that many smaller lymphocytes with pyknotic nuclei are also present. Hematoxylin and eosin, ×1,400.

Fig. 2. Lymph node imprint from the same patient as in Figure 1, showing the characteristic "histiocytes" or lymphatic reticulum cells (coarse arrows) with prominent nuclei. These cells have deep blue cytoplasm and an intense cytoplasmic stain with methyl green–pyronin. The cell in the right lower corner (fine arrow) is probably a lymphoblast, and may be identical to the cell indicated by the fine arrow in Figure 1. Wright–Giemsa, ×1,400.

Fig. 3. Paraffin-embedded section of lymph node from a patient with histiocytic lymphoma, showing histiocytes with and without phagocytosis (arrows). Hematoxylin and eosin. ×1,400.

Fig. 4. Lymph node imprint from the same patient as in Figure 3, showing one histiocyte (arrow) and several lymphatic reticulum cells. Wright–Giemsa, ×1,400.

Fig. 5. Lymph node section (5a, hematoxylin and eosin) and imprint (5b, Wright–Giemsa) from a patient with immunoblastic sarcoma, showing the typical large immunoblasts, mature plasma, and transitional forms (arrows) ×1,400.

Fig. 6. Two types of "lymphosarcoma cell": one with a huge nucleolus and prominent nucleolar membrane (6a, blood) and the other with a notched nucleus (6b, lymph node imprint). The lymphoblast simulates the cell in 6a but has a smaller nucleolus. Wright–Giemsa, ×1,400.

Fig. 7. Myeloblasts from a patient with acute granulocytic leukemia (7a) and monoblasts from a patient with monocytic leukemia (7b). Wright–Giemsa, ×1,400.

Fig. 8. Bone marrow section (8a, hematoxylin and eosin) and smear (8b, Wright–Giemsa), from a patient with leukemic reticuloendotheliosis, showing the typical hairy cells. ×1,400.

Lymphomas, typical lymphocytes are seen on smears and imprints, and small, pyknotic lymphocytes are seen on sections. Atypical lymphocytes with folded or lobulated nuclei are uncommon in these cases.

In the one case of histiocytic lymphoma associated with Sjögren’s syndrome (immunoblastic sarcoma), the predominant cells are immunoblasts and plasma cells (Fig. 6a and b). Some lymphatic reticulum cells, atypical and typical lymphocytes, and histiocytes with epithelioid features are also present.

In the acute leukemias, the granulocytes and their precursors predominate in cases of acute granulocytic leukemia, although some monocytes are also present (Fig. 7a): the monocytes and their precursors are the predominating cells in acute monocytic leukemia (Fig. 7b), but variable numbers of immature granulocytes are also present. Histiocytes with strong nonspecific esterase activity and fluoride-resistant esterase are not found in the blood smears from these patients.

In leukemic reticuloendotheliosis, hairy cells are present in the blood, marrow, spleen and lymph nodes (Fig. 8). This cell is pathognomonic of the disease.

Discussion

Morphologic examination of several cell types in the reticuloendothelial system, e.g., monocytes, immature lymphocytes, histiocytes, and stem cells, lacks definite criteria needed for accurate cell identification. This is particularly true when the cell type is relatively immature—thereby lacking even the usual morphologic characteristics. The problem is further compounded in neoplastic disorders of the reticuloendothelial system by abnor-
malities resulting from the neoplastic nature of cell proliferation. Thus, the term “reticulum cell” has been used to connote several different types of cells. The confusion in defining the “reticulum cell” has created much difficulty in dealing with the “reticulum-cell” neoplasms.

Cytochemical markers provide an additional dimension to morphologic identification. Cells of the same size, shape, and cytoplasmic-nuclear ratio, in addition to possessing similar folded nuclei, may differ in their origins and natures. Enzymatic differences indicated by cytochemistry provide clues to the exact natures of these cells. Furthermore, some cells, easily identified on a smear or imprint, may appear quite different in sections. Here, sometimes, the cytochemical marker can provide essential evidence that the two are the same.

The present study indicates that the cytochemical markers, as used herein, can be helpful in defining the cell types often considered “reticulum cells.” The monocytes predominate in acute monocytic leukemia. They are phagocytic, and are characterized by strong activity of nonspecific esterase. The histiocytes are phagocytic and are unique in having strong activity of a fluoride-resistant esterase. They are present in small numbers in tissue but have not been found in blood, even in pathologic conditions. The immature granulocytes seen predominately in acute granulocytic leukemia have strong activity of chloracetate esterase but very weak or no activity for nonspecific esterase. The hairy cells are pathognomonic for leukemic reticuloendotheliosis. They have a hairy appearance, strong tartrate-resistant acid phosphatase activity, and, usually, insignificant activity of esterases. The lymphatic reticulum cells that predominate in cases of “histiocytic lymphoma” are morphologically similar to the lymphatic reticulum cells (germinal center cell) of
Moeschlin and to the completely transformed lymphocytes stimulated by PHA. They do not have phagocytic activity. The lymphoblasts and atypical lymphocytes are seen often in poorly differentiated lymphocytic lymphomas. They have no positive cytochemical markers and may require the use of surface markers and other immunochemical methods for accurate identification and classification.

We have used the term “lymphatic reticulum cell” to describe the “reticulum cells” or “histiocytes” that are predominant in malignant lymphoma of the histiocytic variety included in this study. These cells are considered to be lymphocytic in origin because they resemble activated lymphocytes, both morphologically and cytochemically. Transitional forms between these cells and the lymphoblasts occur often. Thus, an analogy can be made between the lymphocytes of malignant lymphomas and the lymphocytes cultured in the presence of PHA. Morphologically, the lymphatic reticulum cells closely resemble the lymphocytes transformed in the presence of PHA, whereas the lymphoblasts and atypical lymphocytes seen in poorly differentiated lymphomas resemble partially transformed cells. The lymphocytes in well-differentiated lymphocytic lymphoma resemble lymphocytes that are unstimulated or poorly stimulated in the presence of PHA. In malignant lymphomas, the lymphatic reticulum cells are seen predominantly in “histiocytic” lymphoma; the lymphoblasts and the atypical lymphocytes in poorly differentiated lymphocytic lymphoma; and the typical lymphocytes in well-differentiated lymphocytic lymphoma. In lymphocyte cultures stimulated with PHA, the unstimulated or partially stimulated cells predominate at days 1 and 2, while fully transformed cells are present on day 3 and thereafter. In addition, the extent of stimulation of the lymphocytes is directly proportional to the concentration of the PHA added to the culture medium. It is possible that the malignant lymphomas, be they well-differentiated, poorly differentiated or histiocytic, represent a cellular response to a continuous stimulation by some as yet unidentified antigens; different “antigens” may result in various extents of cellular response. Thus, a milder and shorter stimulation would give rise to a less profound cellular reaction, as in the well-differentiated lymphoma; while a

| Table 2. Cell Types Involved in the Lymphoreticular Neoplasms |
| --- | --- | --- |
| Disease | Major Cell Types | Minor Cell Types |
| Malignant lymphoma, histiocytic | Lymphatic reticulum cells | Lymphoblast, atypical and typical lymphocytes, histiocytes |
| Poorly differentiated lymphocytic | Lymphoblasts, atypical lymphocytes | Lymphatic reticulum cells, typical lymphocytes |
| Well differentiated lymphocytic | Typical lymphocytes | Atypical lymphocytes |
| “Immunoblastic sarcoma” | Immunoblasts, plasma cells | Histioocytes (epithelioid cells) lymphatic reticulum cells, typical and atypical lymphocytes |
| Leukemic reticuloendotheliosis | Neoplastic reticulum cells (hairy cells) | — |
| Acute monocytic leukemia | Monocytes, monoblasts | Immature granulocytes |
| Acute granulocytic leukemia | Immature granulocytes | Monocytes |
stronger and prolonged stimulation would result in a more profound cellular reaction, as in the poorly differentiated or the "histiocytic" lymphomas.

This study indicates that a combined morphologic and cytochemical approach can improve the identification and definition of the cells of the various lymphoreticular neoplasms. With the addition of immunohistochemical methods and by the use of functional criteria for the cells, it is possible to provide objective means to identify the various types of cells, and thereby to classify with improved precision this perplexing group of "reticulum-cell" neoplasms. We then may be in a better position to investigate such problems as etiology and pathogenesis of these diseases.

Acknowledgments. Drs. P. V. Sacks and R. K. Brynes helped in obtaining material for this study; Drs. R. McMillan, H. E. Finkel, R. J. Lukes, and W. H. Crosby offered helpful criticism.

APPENDIX

Lymphatic Reticulum Cell (Germinal Center Cell): In smears or imprints, this cell is about 20 μ in diameter (range: 16–27 μ). Its nucleus is large (12–16 μ) and round, often with fine or moderately coarse nuclear chromatin. Most of these cells contain one or several prominent nucleoli with distinct nuclear membrane. The cytoplasm is abundant, deep blue in color, and may be vacuolated. Cytologically, this cell may be indistinguishable from the phagocytized, reticuloendothelial cells. In tissue sections, the nucleus of this cell is round or oval, and some nuclei are indented, with irregular outlines. This nuclear membrane tends to be distinct and often thick. The nucleus is vesicular, and nucleoli are promi-
Nucleoli are often surrounded by a clear zone of parachromatin, variably containing a few threads of darkly-staining chromatin. Cytoplasm may appear pale, amphophilic or basophilic, and stains strongly with methyl green-pyronin reaction. This cell is often seen as the "histiocyte" in the reactive center of the malpighian follicle of the spleen and the germinal center of the lymph node. It is recognized as the "histiocyte" in the malignant lymphoma of the histiocytic variety (Figs. 1 and 2).

Histiocyte (Phagocyte): In smears or imprints, this cell is 30μ in diameter (25–40μ). It has a relatively small nucleus and abundant cytoplasm which is pale to greyish and often contains phagocytosed material. The cytoplasm margin is indistinct. The nucleus is round, oval or lobulated, with a fine chromatin network and occasionally one or two small nucleoli. Occasionally, binucleated cells are seen. In tissue sections, the histiocytes are characterized by large amounts of pale eosinophilic or clear cytoplasm, often containing phagocytosed material. The cytoplasm appears to flow between adjacent lymphoid cells. The nucleus is often round, oval or reniform, and is larger than that of a monocyte. It has a heavily and variably folded nuclear membrane. Nucleoli are relatively numerous or prominent, and chromatin is coarse, being present in moderate amount. When the hematoxylin–eosin-stained sections are not optimally stained, it may be difficult to distinguish the lymphatic reticulum cells from the phagocytic histiocytes (Figs. 3 and 4).

Immunoblast (Plasmoblast): In smears or imprints, this cell varies considerably in size and in morphology. The typical cell is large, 7μ in diameter (range: 14–22μ). The cytoplasm is abundant and is deep blue with a purple hue. The nucleus may or may not be eccentrically located in the cell, and contains one or two large bluish nucleoli with prominent perinuclear membrane. The chromatin network is characterized by large vesicular clumping. In tissue sections, these cells are characterized by large vesicular nuclei containing prominent nucleoli which are often seen in close relation to the nuclear envelope. Cytoplasm is present in moderate amount and is basophilic, often with a purple hue (Fig. 5a and b).

Lymphoblast and Atypical Lymphocytes: In smears or imprints, the lymphoblast is about 14μ in diameter (range: 12–18μ), with a large nucleus and a narrow rim of deep blue cytoplasm. The nucleus is round, often containing one or two pale nucleoli. The chromatin network is fine. The atypical lymphocytes or "lymphosarcoma cells" are usually larger than the normal lymphocytes and have more cytoplasm. Some have a very prominent nucleolus. Others often show marked nuclear variation, and have notched or folded nuclei, with or without nucleoli. The chromatin pattern is coarse and clumped. Histologically, these cells are the poorly differentiated lymphocytes, most often seen in the poorly differentiated lymphocytic lymphomas (Fig. 6a and b).

Immature Granulocytes: These include the myeloblasts, promyelocytes and myelocytes. The morphology of these cells on smears is well known and is not described here. In tissue sections, these cells have a wide rim of cytoplasm, and moderate nuclear pleomorphism with round, oval or lobulated nuclei. Nucleoli may be seen in the more primitive forms (Fig. 7a).

Monoocyte and Monoblast: In smears, the monocyte is 12–16μ in diameter. It has a round or indented nucleus with a lacy chromatin pattern. The cytoplasm is sky blue or greyish blue, often vacuolated and occasionally containing small azurophilic granules. The monoblast has a blue rim of cytoplasm, a large nucleus and one or several prominent nucleoli. In tissue sections, the monocyte has moderate amounts of pale eosinophilic or clear cytoplasm. Its nucleus is often oval or reniform with a delicate, lace-like chromatin pattern and a uniformly thin, sharply outlined nuclear membrane. Nucleoli are generally small and inconspicuous in the mature cell, but are large and prominent in the more immature forms. Phagocytosed material is occasionally present (Fig. 7b).

Hairy Cell or Reticulum Cell of Leukemic Reticuloendotheliosis: In smears or imprints, this cell is 14μ (10–20μ) in diameter. The cytoplasm is abundant, pale blue, and the cytoplasmic borders are shaggy. The nucleus is round, oval or indented, with a fine chromatin network, inconspicuous nucleoli and very distinct nuclear membrane. In wet preparations, these cells have a characteristic shaggy appearance. In histologic sections, they have abundant pale staining on water-clear cytoplasm. Their nuclei are oval or indented with fine nuclear chromatin (Fig. 8a and b).
Rapid Communication

A Clinical Evaluation of the International Lymphoma Study Group
Classification of Non-Hodgkin's Lymphoma

By The Non-Hodgkin's Lymphoma Classification Project

The recognition of several new types of non-Hodgkin’s lymphomas (NHL) in recent years has led to proposals for changing lymphoma classifications, including a new proposal put forth by the International Lymphoma Study Group (ILSG). However, the clinical significance of the new entities and the practical utility of this new proposal have not been studied. Therefore, we performed a clinical evaluation of the ILSG classification. A cohort of 1,403 cases of NHL was organized at nine study sites around the world and consisted of consecutive patients seen between 1988 and 1990 who were previously untreated. A detailed protocol for histologic and clinical analysis was followed at each site, and immunologic characterization as to T- or B-cell phenotype was required. Five expert hematopathologists visited the sites and each classified each case using the ILSG classification. A consensus diagnosis was also reached in each case, and each expert rereviewed a 20% random sample of the cases. Clinical correlations and survival analyses were then performed. A diagnosis of NHL was confirmed in 1,379 (98.2%) of the cases. The most common lymphoma types were diffuse large B-cell lymphoma (31%) and follicular lymphoma (22%), whereas the new entities comprised 21% of the cases. Diagnostic accuracy was at least 85% for most of the major lymphoma types, and reproducibility of the diagnosis was 85%. Immunophenotyping improved the diagnostic accuracy by 10% to 45% for a number of the major types. The clinical features of the new entities were distinctive. Both the histologic types and the patient characteristics as defined by the International Prognostic Index predicted for patient survival. In conclusion, we found that the ILSG classification can be readily applied and identifies clinically distinctive types of NHL. However, for clinical application, prognostic factors as defined by the International Prognostic Index must be combined with the histologic diagnosis for appropriate diagnostic and clinical decisions.

© 1997 by The American Society of Hematology.

Because of the increasing incidence of non-Hodgkin’s lymphomas (NHL), with approximately 53,000 new cases occurring annually in the United States,1,2 the diagnosis and classification of these disorders is an increasingly important clinical issue. The classification of NHL has evolved steadily throughout the twentieth century. An early system proposed by Gall and Mallory3 used the terms giant follicular lymphoma, lymphosarcoma, and reticulum cell sarcoma, but proved too imprecise for clinical application. In the 1950s, Rappaport et al4 recognized the importance of the growth pattern in some types of NHL and used patterns in addition to cell size and shape, as the basis of a new and clinically relevant classification. In the 1970s, recognition that NHLs were tumors of the immune system and were derived from T or B cells led to the immunologically based classifications of Lukes and Collins,5 and later Lennert and associates (Kiel classification).6-9 In an attempt to unify terminology and improve the effectiveness of communication between pathologists and clinicians, the Working Formulation was proposed in 1982.10 Over the next two decades, however, the Kiel classification dominated clinical practice in Europe, whereas the Working Formulation became the main classification system used in North America.

In the last two decades, increased understanding of the immune system and the genetic abnormalities associated with NHL have led to the identification of several previously unrecognized types of lymphoma. These include mantle cell lymphoma18-20 monocytoid B-cell lymphoma,21-23 extranodal lymphoma of mucosa-associated lymphoid tissue (MALT),24-28 splenic marginal zone lymphoma,29-31 primary mediastinal large B-cell lymphoma,32-34 and a variety of T-cell lymphomas,35-38 including anaplastic large cell lymphoma.18-20 The recognition of these new and supposedly clinically relevant types of NHL has led to proposals for changing lymphoma classifications. Modifications of the existing classifications, and a new proposal by the International Lymphoma Study Group (ILSG)39 incorporating some aspects of the Kiel classification and Working Formulation, have been put forward. However, the clinical significance of the new lymphoma entities and the practical utility and clinical relevance of this new proposal needed to be tested.

The histologic diagnosis of specific subtypes of NHL is widely believed to be imprecise. Previous studies have identified high rates of diagnostic discrepancy between different pathologists (interobserver variability) and for the same pathologist (reproducibility) when reviewing the same case at different times.34-38 This inaccuracy in diagnosis has made treatment decisions difficult. In the past two decades, the widespread use of immunophenotyping has led to increased insight into the diagnosis and classification of tumors of the immune system. However, the value of immunophenotyping in the day-to-day practice of lymphoma diagnosis and clinical care has not been clearly shown.

With this background, we set out to perform a retrospective clinical evaluation of the newly proposed ILSG classification.40 Although the ILSG classification is a proposal for classifying all lymphoid neoplasms (Table 1), our study was tailored to the NHL subset of this classification.

Abbreviations: CLL, chronic lymphocytic leukemia; MALT, mucosa-associated lymphoid tissue.

* Follicular lymphomas are designated as such and were graded according to the Revised European American classification.†

† Composite lymphomas consisted of two distinctly different cytologic subtypes of lymphoma.

Data from Harris et al. 1986.

---

designed to only assess the ILSG classification of NHL. Specific goals of our study were the following: (1) to evaluate the ability of hematopathologists to apply the ILSG classification to a retrospective group of cases collected at sites around the world; (2) to determine the role of immunophenotyping and clinical data in the diagnosis of the various entities; (3) to determine the clinical importance of immunophenotyping; (4) to determine the intraobserver and interobserver reproducibility of diagnosis of the various entities; (5) to determine clinical correlations for the various entities, including clinical features at presentation and survival outcomes; and (6) to determine whether certain entities can be grouped for prognostic or therapeutic purposes.

### PATIENTS AND METHODS

Nine institutions in eight countries were chosen to provide up to 200 consecutive cases of previously untreated NHL that were representative of the geographic region during the time between January 1, 1988 and December 31, 1990. The first 200 cases at each site that fulfilled the following criteria were selected for the study.

In all cases, tissue biopsy samples that were adequate for diagnosis and classification were required, and all diagnostic pathology materials obtained before initial therapy, including positive bone marrow (BM) specimens, were included in the pathology review. Immunologic characterization as to B- or T-cell origin, by whatever means in use at the institution, was also required in all cases. Leukemias were excluded from the study unless a tissue biopsy, other than BM, was performed before therapy. Clinical characteristics, treatment data, and some follow-up information were also required in all cases. The nine study sites, which provided a total of 1,403 cases, are shown in Table 2.

The clinical information for each case was abstracted from the medical record by a clinician or data manager and recorded on a standardized form for direct computerized data entry. These data included coded patient and site identifiers; patient sex, ethnic origin, and date of birth; the date and site of the diagnostic biopsy; and a tabulation of nodal and extranodal sites of involvement and Ann Arbor stage at the time of initial diagnosis. Laboratory data were recorded, including the serum lactate dehydrogenase level, absolute lymphocyte count, presence of circulating lymphoma cells, presence of a monoclonal serum Ig, and a history of immunodeficiency and viral (human T-cell lymphoma virus-1 [HTLV-1], human immunodeficiency virus [HIV]) status. Also recorded were the performance status and maximum diameter of the largest tumor mass. The initial therapy and therapeutic response, details of remission, progression, or relapse, and subsequent therapies and follow-up were tabulated in each case. For this report, all cases with clinical data were included regardless of the specific therapies given. In 73 of the cases, sufficient data was not available for the clinical and survival analyses.

At each institution, the pathology slides and reports for each case were carefully reviewed by a designated site pathologist. The original stained slides and immunostains were organized for review, and additional sections, immunostains, and other studies were performed if deemed necessary by the site pathologist. The results of the immunologic studies for each case, as well as any available cytogenetic or molecular genetic data, were recorded on a standardized form for direct computerized data entry. Five expert hematopathologists then traveled as a group to each of the nine sites to review and classify

ILSG CLASSIFICATION FOR NHL

Each case in each of the three major classifications. The site visits occurred over a period of 8 months beginning in June 1995. All expert pathologists used a standard Nikon Labophot-2 microscope (Nikon, Inc., Melville, NY), including a 10X plan achromat objective (high-power field = 0.159 mm²). The diagnostic categories in each of the three classifications were used according to published criteria. More specific criteria were developed for some of the entities with Nancy L. Harris providing consultation regarding the ILSG classification. The criteria of Masa and Beart were used to grade follicular lymphomas in the ILSG classification.

At each site, the diagnostic slides were reviewed and classified independently by each expert hematopathologist. The initial classification was based on examination of the hematoxylin-eosin and Giemsa stained slides with only the following clinical information from the time of initial diagnosis: patient age and sex, site of the biopsy, and the major site of disease (ie, diagnosis 1). After recording a diagnosis in each classification, the expert was then presented with the immunophenotypic profile, along with any available cytogentic and molecular genetic data, and the immunohistology and/or flow cytometry report. After review, a second diagnosis was rendered in each classification (ie, diagnosis 2). Then, the expert was presented with all of the pretreatment and clinical information and a third diagnosis was made in each classification (ie, diagnosis 3). No previous diagnosis could be changed based on information subsequently revealed.

If a case was considered subclassifiable in any of the classifications, the expert was required to give a reason, ie, inadequate material, poor slide preparation, additional phenotyping needed, additional information needed, or other reasons. The expert was allowed to change the phenotype of a case if he interpreted the immunohistology and/or phenotype data differently than the site pathologist. For some diagnostic categories, a research protocol was also completed by the expert pathologists. All of this information was recorded on standardized forms for direct computerized data entry. Approximately 40 to 50 cases were reviewed by each pathologist each day.

In addition to the independent diagnoses rendered by each of the five expert pathologists, a consensus diagnosis was also reached in each case. A consensus was considered to have been reached if at least four of the five expert pathologists agreed on the third diagnosis (diagnosis 3) in the ILSG classification. A diagnosis of follicular lymphoma of any grade was considered an agreement, and a diagnosis of peripheral T-cell lymphoma of any type was also considered an agreement. In these latter two categories, agreement by three of the five expert pathologists with regard to the specific type was considered the consensus diagnosis. If there was no agreement with regard to the type, the case was arbitrated by D. Weisenberger based on the individual diagnoses and the research protocol. All other cases without a consensus diagnosis were jointly reviewed on a multi-headed microscope and discussed by the five expert pathologists and the site pathologist in a consensus conference at the end of each day, and an attempt was made to reach a consensus of at least four expert pathologists in each case. If additional sections, immunohistology, molecular studies, or other information was required, a diagnostic algorithm was developed by the group and the additional materials were obtained, if possible, and reviewed at a subsequent consensus conference at the site. If the additional materials could not be obtained during the site visit, the required materials and information were subsequently sent to D. Weisenberger who arbitrated the case based on the algorithm.

At the end of each site visit, after all cases had been reviewed, each expert pathologist reviewed 20% of the cases. The cases for review were randomly selected by the statistician. These cases were classified a second time by each expert, without knowledge of his initial interpretation, using all available pathology materials and pretreatment clinical information. Cases in which a consensus diagnosis had not yet been reached were excluded from the review.

Completed clinical and pathology forms were reviewed and edited to detect any inconsistencies, and additional information and/or classification was obtained when needed. After completion of the editing, the clinical and pathology data forms were entered into a computer for data analysis. The International Prognostic Index was used to stratify patients within the various disease entities. Treatment outcome was measured using failure-free survival and overall survival. Failure-free survival was defined as the time from diagnosis to the first occurrence of progression, relapse after response or death from any cause. Follow-up of patients not experiencing one of these events was censored at their date of last contact. Overall survival was measured from diagnosis to death from any cause, with surviving patient follow-up censored at the last contact date. Estimates of failure-free survival and overall survival distribution were calculated using the method of Kaplan and Meier. Time to event distributions were compared using the log-rank test.

RESULTS

Twenty-five of the 1,403 cases (1.8%) were found to have a diagnosis other than NHL and, thus, were excluded from further analysis. The types of NHL found in the remaining 1,378 cases are presented in Table 3. Approximately 31% of the cases were forms of diffuse large B-cell lymphoma and approximately 22% of the cases were types of follicular lymphoma. All types of T-cell processes, including natural killer (NK) cell disorders, made up only 12% of the cases. Small lymphocytic lymphoma was observed in 6.7% of the cases, a higher percentage than is sometimes appreciated.

The major newly recognized types of lymphoma that occurred most frequently were marginal zone B-cell lymphoma of MALT type (7.6%), mantle cell lymphoma (6.0%), pri-
large B-cell, and the T-cell lymphomas, immunophenotyping was helpful in many cases in reaching the correct diagnosis and improved the diagnostic accuracy by some 10% to 45%. For many of these cases, the initial diagnosis based on histology only was unclassifiable malignant lymphoma. Immunophenotyping allowed the classification of such cases into specific categories. Detailed clinical data was helpful in distinguishing primary mediastinal large B-cell lymphoma from the other diffuse large B-cell lymphomas, because there were no characteristic histologic or immunologic differences between these two categories.

The expert pathologists' review of a 20% sample of the cases at each site showed that they could reproducibly make a diagnosis of NHL (Table 5). Overall, the review diagnoses agreed exactly with the pathologist's initial diagnosis 3 or the consensus diagnosis (including the grading of follicular lymphoma) in 85% of the cases (range, 82% to 89%). Because the consensus diagnosis for all of these cases was reached before the time of the review, the consensus process may have influenced the assessment of some cases at review. Therefore, the pathologists were allowed to agree with either their original diagnosis 3 or the consensus diagnosis at the time of review. For an additional 9% of the cases, the review diagnosis was nearly the same as the original diagnosis (ie, follicular, grade 1, v follicular, grade 2; or, follicular, grade 3, v follicular, grade 3, plus diffuse large B-cell). Thus, for 94% of the cases reviewed (range, 92% to 97%), the expert pathologists made a diagnosis consistent with either their original diagnosis 3 or the consensus diagnosis. In only 6% of the cases (range, 3% to 8%) the pathologist's review diagnosis would likely have led to a different approach to therapy than the original diagnosis.

The clinical characteristics of the more common types of lymphomas are presented in Table 6. It is important to recognize that, although the average results vary between the various types, there was considerable overlap between the types for any particular characteristic. The newly recognized types of lymphoma appear to be distinctive. Marginal zone B-cell lymphomas of MALT type was characterized by a high frequency of localized extranodal disease and a prolonged survival, whereas nodal marginal zone (monocytoid) B-cell lymphoma more often presented with advanced-stage disease and had a worse survival. Mantle cell lymphoma had high grade B-cell, Burkitt-like.

a striking male predominance, a high frequency of advanced-stage disease with marrow involvement, and the lowest 5-year survival of any type of lymphoma. Primary mediastinal large B-cell lymphoma occurred more frequently in young females and was often of low stage, but the survival was no different from that of other diffuse large B-cell lymphomas. Anaplastic large T/null-cell lymphoma occurred mainly in young patients and had a surprisingly high 5-year survival when compared to other lymphomas with large cell histology or a T-cell phenotype. This was not due to inactivation of a high proportion of patients with only skin involvement, a group that represented just 6% of these patients.

The average overall survival by histologic type allowed for division of the NHLs into four broad groupings (Fig 1). Those with a 5-year overall survival of greater than 70% included follicular lymphoma, marginal zone B-cell lymphoma of MALT type, and anaplastic large T/null-cell lymphoma. Lymphomas within a 50% to 70% 5-year overall survival included small lymphocytic, lymphoplasmacytoid, and nodal marginal zone B-cell lymphomas. Lymphomas with a 30% to 40% 5-year overall survival included diffuse large B-cell lymphoma, primary mediastinal large B-cell lymphoma, and the high-grade B-cell Burkitt-like and Burkitt lymphomas. Lymphomas with less than a 30% 5-year overall survival included peripheral T-cell lymphoma, precursor T-lymphoblastic lymphoma, and mantle cell lymphoma.

Whereas the histologic diagnosis of a specific type of lymphoma provides clinically important information, equally important prognostic information was obtained from the clinical characteristics of the individual patients. We found considerable variation within any particular histologic type for both overall survival and failure-free survival based on patient clinical characteristics using the International Prognostic Index (Table 7). For example, patients with follicular lymphoma had significantly different outcomes depending on their clinical prognostic characteristics (Fig 2). Moreover, patients with follicular lymphoma with a high (unfavorable) prognostic index had a far worse overall and failure-free survival (ie, 17% and 6%) than patients with a diffuse large B-cell lymphoma and a low (favorable) prognostic index (ie, 73% and 63%). In contrast, the histologic diagnosis of anaplastic large cell lymphoma was important because it was associated with a surprisingly good survival, even with a high prognostic index. In contrast, patients with mantle cell lymphoma had a relatively poor outcome despite apparently good clinical characteristics. The prognostic index also did not predict survival in precursor T-lymphoblastic lymphoma, although the number of cases was small.

**DISCUSSION**

This study shows that, using the definitions proposed in the ILSG classification, it is possible to accurately identify most of the major types of NHL. The major types recognized by this classification are also clinically distinctive, with the possible exception of high-grade B-cell Burkitt-like lymphoma, which appears to be very similar clinically to diffuse large B-cell lymphoma (Table 6). This classification was, in general, easily and accurately applied by the expert hematopathologists. In fact, this study suggests that when expert pathologists work from clear definitions, with the use of immunologic markers, the diagnosis of NHL can be made more accurately than had been thought. Previous studies, using morphology only, found that the diagnostic accuracy of specific types of NHL could not be made accurately 50% to 60% of the time. In contrast, we have shown that, when expert pathologists work from clear and agreed upon criteria, the diagnosis of NHL can be at least 85% accurate for most of the common types. However, the methods used to reach a consensus diagnosis in our study certainly had a positive influence on these agreement rates. Because treatment depends on the diagnosis, it must be made as accurately as possible. We believe that the diagnosis of NHL should always be made by a hematopathologist who is experienced in lymphoma classification.

Immunophenotyping added significantly to the accuracy of diagnosis of many of the lymphoma types, including mantle cell lymphoma, diffuse large B-cell lymphoma, and the T-cell lymphomas. However, immunophenotyping did not add significantly to the accuracy of diagnosis of some lymphomas, such as follicular lymphoma, small lymphocytic lymphoma, and marginal zone B-cell lymphoma of MALT...
Fig 1. NHLs with a 5-year overall survival of greater than 70% (A), 50% to 70% (B), 30% to 49% (C), and less than 30% (D); ALCCL, anaplastic large T/null-cell lymphoma; MZ, MALT, marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue; FL, follicular lymphoma; MZ, nodal, marginal zone B-cell lymphoma of nodal type; LP, lymphoplasmacytoid lymphoma; SL, small lymphocytic lymphoma; Med LBC, primary mediastinal large B-cell lymphoma; DLCL, diffuse large B-cell lymphoma; BCL, Burkitt-like lymphoma; T-LB, precursor T-lymphoblastic lymphoma; PTCL, peripheral T-cell lymphoma; MC, mantle cell lymphoma.

Abbreviations: PI, International Prognostic Index; OAS, overall survival; FFS, failure-free survival; CLL, chronic lymphocytic leukemia.

The table shows the survival rates for different histologic types of NHLs, grouped by the International Prognostic Index. Each type, all of which have very distinctive histologic features which usually facilitate the diagnosis without a need for immunologic data. For other types, such as the lymphoplasmacytoid, nodal marginal zone B-cell, and high-grade B-cell Burkitt-like lymphomas, imprecise histologic criteria and the lack of specific immunologic markers led to a diagnostic accuracy of only 53% to 65%. Further definition of these entities is clearly needed. Because the need for immunophenotyping cannot be predicted before biopsy, it is vital that each patient have tissue available for immunophenotyping and other special studies to facilitate proper patient care. In many cases, this will require communication between the oncologist, the surgeon, and the pathologist.

The 13 major types of NHL shown in Fig 1 made up over 90% of the cases in our study, with diffuse large B-cell lymphoma and follicular lymphoma comprising over 50% of the cases and the newly recognized entities comprising 21% of the cases (Table 3). The clinical features of the various lymphoma types were remarkably different, as were
the "poor prognosis" entities. Therefore, to make proper clinical decisions, it is necessary to consider both the histologic type and the various prognostic factors present in an individual patient. Any useful clinical grouping of the NHLs must take both types of information into account.

Although the ILSG classification could be accurately applied and appears to be useful clinically, there are a number of areas that could be improved. Changes in organization and terminology have been suggested by others. In addition, more specific criteria for some of the lymphoma types are clearly needed, such as the lymphoplasmacytoid, nodal marginal zone B-cell, and high-grade B-cell Burkitt-like lymphomas. The cellular origin of so-called "marginal zone" lymphomas, along with diagnostic criteria, also need to be elucidated. Subtyping of the diffuse large B-cell lymphomas into immunoblastic and nonimmunoblastic types may be useful, and the clinical and pathologic features of anaclastic large B-cell lymphomas need to be more carefully studied before combining it into the generic category of diffuse large B-cell lymphoma. Precise criteria for grading within the various lymphoma types are clearly needed, such as for the follicular lymphomas, mantle cell lymphomas, and marginal zone B-cell lymphomas of MALT type. Finally, the number of categories of peripheral T-cell lymphomas, for which the diagnostic criteria are imprecise and difficult to apply, seems excessive when there is little evidence to support subdividing for clinical purposes. Hopefully, these issues will be addressed by the working groups of the new World Health Organization classification project.

In conclusion, the ILSG classification was readily applied and identified clinically distinctive types of NHL. Immunophenotyping added significantly to the accuracy of diagnosis in certain major lymphoma types and was clinically important. For clinical application, however, prognostic factors as defined by the International Prognostic Index must be combined with the histologic classification for appropriate clinical decisions.

ACKNOWLEDGMENT

The study participants thank Dr. Saul A. Rosenberg for his advice regarding the study design and analysis.

APPENDIX

Study Participants: The pathologists and clinicians at each institution were, respectively, Wing C. Chan and James O. Armitage (Omaha, NE), Randy Gascoyne and Joseph Conners (Vancouver, Canada), Pauline Close and Peter Jacobs (Cape Town, South Africa), Andrew Norton and T. Andrew Lister (London, UK), Ennio Pedrinis and Franco Cavalli (Locarno, Switzerland), Françoise Berger and Bertrand Coller (Lyons, France), Faith Ho and Raymond Lian (Hong Kong), Germain Ott/Alfred Schaer and Wolfgang Hiddemann (Würzburg/Göttingen, Germany). The five visiting expert hematopathologists were Jacques Diebold (Paris, France), Kenneth A. MacLennan (Leeds, UK), H. Konrad Müller-Hermelink (Würzburg, Germany), Bharat N. Nathwani (Los Angeles, CA), and Dennis D. Weisenburger (Omaha, NE). Nancy L. Harris (Boston, MA) participated as a consultant regarding application of the International

LYMPHOMA — HISTOPATHOLOGY IN CHANGING CLINICAL PERSPECTIVE

Peter Jacobs
On behalf of the Non-Hodgkin's Lymphoma Classification Project

Background. Lymphoma management has traditionally been dominated by nodal histopathology. Unfortunately, many different classifications coexisted and frequent revisions have often obscured clinical correlations. Some improvement in understanding histogenesis followed the introduction of immunophenotyping, while a number of new entities have been described in the last decade. In addition, the whole question of lymphomagenesis is undergoing critical exploration. The use of cellular and molecular biological techniques is therefore shifting focus to the role of oncoproteins and the impact of mutation in the normally modulating suppressor genes.

To accommodate these advances the International Lymphoma Study Group has proposed the Revised European-American Lymphoma Classification. While this is an undoubted advance, it has met with persistent concerns regarding applicability to patient management.

Study setting. In determining the extent to which the latter reservation is valid, and at the same time directly testing the clinicopathological value of the new system, a group of acknowledged experts drawn from nine major academic centres worldwide analysed approximately 1 400 previously unreported cases, focusing on outcome. As part of that study 196 consecutive patients seen in Cape Town were separately examined.

Results. Findings here were similar to those of the overall experience, although distinct geographical differences emerged. Specifically in the follicular centre-cell lymphomas there was no difference in the 5-year failure-free survival rate, but these neoplasms accounted for 33% of lymphomas, which is similar to North America and London but contrasts with the 14% in the remaining six sites. Also, while mean survival for all types of peripheral T-cell lymphoma was 18% at 5 years, these accounted for 8% of lymphomas locally, as seen...
also in London and Hong Kong, but exceeding the 3-6% reported elsewhere.

Local experience, as in the other eight centres, documented good diagnostic concordance between trained haematopathologists when this classification was used by them all. Furthermore, unusual subtypes were generally well accommodated within this revised system. It should be noted that whilst histopathological features retain predictive value, they should not be considered the predominant factor. It was concluded that for management decisions to be appropriate, renewed and correct weighting must be assigned to other prognostic variables that include clinical features and markers of tumour biology.

Summary. This more enlightened prerequisite is the central goal that underlies optimal treatment outcome, since it determines stratification to appropriate and peer-reviewed protocols. It follows that review of histopathology needs to precede management of all newly diagnosed cases, preferably only by accredited multidisciplinary clinics. The previous anachronism of basking therapy on opinions of non-specialist pathologists, without appropriate review, is unwise. Furthermore, treatment by lone practitioners, or even single-specialty groups that lack the discipline to analyse their findings critically and regularly report their updated results, can no longer be considered standard of practice and should be discouraged. 

Historically, nodal architecture was used to divide these tumours into follicular lymphomas, lymphosarcomas, and reticulum-cell sarcomas. Unfortunately, this grouping was too vague to have predictive value with regard to outcome. Subsequently cytomorphology was combined with disturbances in architecture, seeking to give clinical relevance to the growth pattern. Much of that focus was changed when it was appreciated that these neoplasms originated from cells of the immune system. There followed a period of enormous confusion, since as many as 20 different classifications existed concurrently, precluding uniformity of patient entry into clinical trials, or even exchange of information between centres. Some semblance of organisation was imposed on this chaos by publication of the working formulation in 1982. Although intended as a means of interpreting data between systems, it became accepted as a classification in North America. In contrast, the Europeans favoured the system described by Karl Lennert.

This unsatisfactory state of affairs has been reassessed recently for a number of reasons. There was a growing appreciation that new and distinct variants existed. Immunophenotyping became more readily available, so that B- or T-cell origin could be determined routinely and impact of lineage could be explored as a separate variable. Cytogenetics, as in the leukaemias, was providing relevant prediction with regard to response to therapy and outcome, but was poorly accommodated in most routine reports. Furthermore, the shortcomings of older classifications were giving way to the more clinically based prognostic index.

In an attempt to redress persisting concerns, the International Lymphoma Study Group combined salient features from the working formulation with the Kiel approach to produce what is known as the Revised European-American Lymphoma (REAL) Classification. Despite this undoubted advance, some reservations have persisted, particularly among clinicians. Reservations have focused mainly on the undue weight given to histopathological features, the lack of reproducibility of diagnostic criteria between centres, or indeed even by the same pathologist, and the role that immunophenotyping should play in a practical approach to classifying, understanding and treating these neoplasms.

For these reasons an international multicentre study was undertaken to examine this new proposal. The objective was to assess its acceptability and value to practising pathologists, to explore any potential geographical differences that may exist, and specifically to determine whether it had clinical relevance. Accordingly, a collaborative effort was undertaken by clinical experts in nine areas throughout the world (Table I) working with local haematopathologists to evaluate the utility of the REAL Classification in contemporary management of patients with these lymphoproliferative disorders. In addition to publication of the global results, we now separately report the Cape Town experience.

Consultants were Saul Rosenberg at Palo Alto for study design and analysis, Nancy L. Harris for advice regarding the REAL Classification, James R. Anderson and Pascal Ray were statisticians, and the visiting pathologists were Jacques Diebold, Kenneth A. McMullan, H. Konrad Muller-Hermelink, Bharat Radwani and Dennis D. Weisenburger.

MATERIALS AND METHODS

Consecutive patients registered at Groote Schuur Hospital between 1 January 1988 and 1 December 1990 were identified from the records of the lymphoma clinic. The completeness of the database was confirmed by reference to the hospital central statistics department. Biopsy material, including referred slides and blocks registered in the Department of Anatomical Pathology at the University of Cape Town, was similarly scrutinised. Four hundred and twenty-six cases were identified, and after extracting pertinent clinical information, each was reviewed. Where treatment details or follow-up information was insufficient this was noted, but the case was excluded from further consideration. The lymph node and bone marrow biopsies of the remaining cases were reviewed and additional immunophenotyping was carried out where necessary. One hundred and ninety-six cases fully met the criteria for analysis (Table II). Criteria were that the tissue samples should be adequate and that all the relevant pathology materials should be available, including bone marrow aspiration and trephine biopsy samples, with immunological information being sufficient to assign the neoplasm confidently to B- or T-cell lineage. Patient characteristics, treatment data and follow-up information needed to be complete. Leukaemias were excluded.

The clinical material was compiled from review of the medical records, while histopathological preparations were reviewed by the designated site pathologist. Where necessary, additional sections were prepared and immunostains included. Other studies were performed in order that the material could be classified appropriately. Cytogenetic and molecular biological data, where available, were recorded on a standard data-capture sheet. Once compilation was complete five expert haematopathologists travelled to each of the nine centres over an 8-month period, beginning in June 1995, and spent a week reviewing all the collated information at each participating institution.

A standardised approach was used in which each of the experts first used haematoxylin and eosin- or Giemsa-stained sections to record a diagnosis when supplied only with patient age, sex, major site of disease and origin of the biopsy. The same exercise was then repeated, adding immunophenotyping together with any other cellular or molecular biological data. Finally, all available preclinical treatment information was integrated to establish a final diagnosis. At the end of each daily working session individual opinions were reviewed, with consensus defined as agreement between four of the five experts. When the site visit was complete, 20% of all the cases were randomly selected for re-review without reference to the original diagnosis.

Treatment outcomes were measured by overall and failure-free survival, with the latter defined as the time from diagnosis to first occurrence of progression, relapse after response, or

death from any cause. Follow-up of patients not experiencing one of these events was censored at the time of last contact. Estimates of survival were calculated using the method of Kaplan and Meier and time-to-event distributions were compared using the log-rank test.

RESULTS

In the multicentre study 1.8% of cases were excluded from analysis because the diagnosis was not that of lymphoma. No such errors were recognised in the Cape Town material.

Of the consecutive locally entered patients, 33% had follicular lymphomas, 29% had diffuse large B-cell lymphomas, 8% had peripheral T-cell lymphomas, and a further 8% had small lymphocytic lymphomas. The marginal variant of the mucosal-associated lymphoid tumours was 6%, while for the mediastinal diffuse large B-cell and anaplastic large B-cell lymphomas it was 5% each, and for the mantle-cell tumours it was 1%. Twelve per cent of patients had other less frequently encountered forms of lymphoid malignancy (Table III).

As in the parent study, diagnosis based only on histology was not significantly altered by inclusion of immunophenotype when the lymphomas were follicular. These stains improved diagnostic accuracy in three other subtypes. Consequently a further 14% of diffuse large B-cell cases and an additional 39% of anaplastic large-cell cases were identified, while in peripheral T-cell variants a 45% improved recognition was possible. It should be noted that when all additional clinical data were added this was only helpful in primary mediastinal diffuse large B-cell cases. Here diagnostic accuracy improved by 37%.

It is noteworthy that when 20% of the cases were re-reviewed, the original diagnosis was verified in 80-90% of cases, suggesting that REAL Classification is reproducible in experienced hands. It is unlikely that such inter- or intra-observer reproducibility will apply to the individual who is not specifically committed to the in-depth study of these tumours.

The overall and failure-free survival rates for the Cape Town groups were 48% and 36%, respectively (Fig. 1). For patients with follicular lymphomas the corresponding figures differ by grade, both for overall survival (Fig. 2) and for those free of relapse at 7 years (Fig. 3). For the diffuse large-cell, chronic lymphocytic and peripheral T-cell lymphoma patients, overall and failure-free survival are approximately the same and can be represented by one set of graphs (Fig. 4).

DISCUSSION

Results from this local study parallel experience from other centres in supporting use of the REAL Classification on the grounds that it is currently the most appropriate approach in identifying the major types of non-Hodgkin's lymphoma. Retrospectively it became clear that in 85% of the cases examined histopathology alone sufficed for reliable diagnosis;

While immunophenotyping was a requirement for entry, not all patients had cytogenetics performed; for completeness the data from the overall study are cited. The remaining 12% were other less frequently encountered forms of lymphoid malignancy.

* Marginal zone lymphoma: A = MALT type, B = nodal type.
† IPFI = International Prognostic Index.
this was particularly true in those cases with a follicular growth pattern. It should be emphasised that where possible an entire node together with capsule should be atraumatically removed and processed by an experienced pathologist using fixatives chosen both to maintain nuclear and cytoplasmic detail and at the same time to be appropriate for phenotyping. It is to be anticipated that many of these features will be consolidated into World Health Organisation recommendations in the immediate future.\textsuperscript{14}

Accuracy was enhanced by adding immunostains using monoclonal antibodies. Here, consensus diagnosis improved between 2\% and 14\% in mucosal-associated lymphoid tumours, small lymphocytic or chronic lymphocytic leukaemia, those with lymphoplasmacytoid differentiation, high-grade or large B-cell tumours, nodal marginal zone and mantle-cell neoplasms. The striking advantage of these additional preparations in defining lineage was seen in the T-cell variants, whether precursor, anaplastic large or peripheral T-cell types. In these latter subtypes this information approximately doubled the number correctly identified over those using only sections stained with haematoxylin and eosin. Unfortunately, the need for these preparations cannot be predicted at the time of diagnosis, so that suitable planning must be made for the material to be studied using appropriate methods at a later date. It is noteworthy that flow cytometry is being increasingly employed, and that multidisciplinary groups managing these patients typically rely on this technology, using fresh tissue to avoid problems of fixation and processing.

One of the striking features of this study is that it confirms previous concerns that arose shortly after publication of the REAL Classification and were strongly reflected in the Cape Town experience, namely the importance of integrating all available information within a prognostic index, with particular emphasis given to patient data. This point is most remarkably demonstrated in primary mediastinal large B-cell tumours. However, the value of careful attention to clinical features, many of which reflect disease biology, cannot be underestimated. Logically it must, therefore, be acknowledged that previous preoccupation with purely microscopic features is
no longer acceptable. Correct stratification of patients to appropriate treatment programmes needs to integrate biochemical markers that include lactic dehydrogenase and additional imaging in order to document tumour distribution and bulk.

Assuming that optimum treatment protocols are used, the Cape Town experience again mimics that of the multicentre analysis in recognising four survival patterns. Consequently, overall 5-year survival exceeded 70% in patients with anaplastic large-cell lymphoma, marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue, and the follicular lymphomas. A second group of these tumours occupied an intermediate position and comprised the nodal variant of marginal zone B-cell lymphomas, those with lymphoplasmacytoid differentiation and small lymphocytic lymphoma or its chronic leukemic equivalent. In the third category, where overall survival is approximately 50%, the majority of cases involved diffuse large B-cell neoplasms. In the remainder of cases this figure dropped to 30% and largely involved T-cell and mantle-cell lymphomas.

Although these results have improved over the last 5 years, they leave much to be desired. One area where new technology can be expected to improve outcome significantly is selection of treatment regimen based on inclusion of cellular and molecular biological data. In this context karyotyping or fluorescent in situ hybridisation that reveals the presence of chromosomal rearrangement or deletions is already proving valuable, both in diagnosis and in predicting results from conventional therapy. For example, the integration of such information into selection criteria for any particular treatment programme means that high-risk patients can rationally be assigned to intensive chemotherapy, often coupled with irradiation, and myeloprotection with haematopoietic stem-cell transplantation as first-line protocol management. A specific example will involve cases that at presentation have intermediate or high-risk features defined by the International Prognostic Index.7

A number of observations that emerge from the local study echo findings in other centres. The REAL Classification is therefore reproducible provided that the initial material is interpreted by an experienced pathologist, preferably one who is a regular participant in ongoing review workshops at international level. Secondly, cytomorphological and architectural features are no longer acceptable as the only criterion for diagnosis, with accuracy often being improved by inclusion of immunophenotyping and karyotypic analysis. Thirdly, there is growing acceptance that all relevant clinical information, including imaging and biochemical measurements, needs to be used in allocating patients to a risk category in the International Prognostic Index. Fourthly, and perhaps of particular relevance in developing countries, is the appreciation that work-up and management must be centred in multidisciplinary clinics that are at least nationally, and preferably internationally, accredited. This necessitates audit of every patient referred and peer-review of outcome in consecutively enrolled patients. Data accumulated in this way can be further monitored when it forms part of multicentre or collaborative studies.

In contrast, the previous practice of management by an occasional therapist, or even within a single-discipline practice, has shortcomings. These include over-treatment on the one hand, and failure to disclose the availability of innovative or investigational options on the other, which may lead to the equally unacceptable undertreatment. The clinical trials group of the South African Society of Medical Oncologists has taken a leadership role in this direction.8 Here ongoing local studies are being catalogued and efforts are being made to co-ordinate relevant approaches at national level with guidelines for conventional management, while concurrently advancing scientific standards through collaborative programmes. Issues that are suitable for such investigation include evaluation of topoisomerase inhibitors, high-dose chemoradiotherapy with myeloprotection using haematopoietic stem and progenitor cell transplants or anti-B-cell monoclonal antibodies. There are compelling advantages, particularly in the third world and as managed health care programmes permeate all levels of practice, for the small number of centres that have earned a reputation for excellence to be identified and designated as such. This step is needed to maintain standards, to disseminate information about what expectations exist with regard to treatment outcomes, and to provide a reliable base both for referral of new patients and to ensure that the guiding principles of interdisciplinary consultation are observed. Failure to act in this direction will fuel the downward spiral in understanding and therefore the correct contemporary management of patients with lymphoma.

CONCLUSION

In South Africa, as elsewhere in the world, the goal should be one of treating lymphoid malignancies with the intention of improving disease-free survival, or more directly, achieving the highest possible cure rate. The extent to which successful outcome is achieved depends on exacting diagnosis and stratification of patients to the most effective treatment option designed to capitalise on assignment-by-risk category, with appropriate weight being given to inclusion of clinical characteristics such as tumour progression and biology. The local experience, part of a much larger international study project, cogently argues for referring any patient with suspected lymphoma to an established multidisciplinary group without delay. In this way evaluation will be comprehensive and recommendations can be made about inclusion in peer-reviewed protocols.

Equally important is the obligation to monitor the response in each case objectively, so that appropriate changes to treatment can be made immediately there is any deviation from
anticipated outcome. Acceptance of these principles excludes the older practice of dabbling by occasional therapists, or even therapy given by single-discipline practices. These are largely curable neoplasms, and however unpalatable, there is no substitute for constant guidance — even supervision if appropriate — from the properly constituted and impartially functioning combined clinic.

I thank Fred Ulichnich and James Anderson, from the University of Omaha in Nebraska, for the separate statistical analyses of the cases from Cape Town; Patricia Marais and Gillian Ganz for help with the manuscript typing; and Christine Dölling for bibliographic assistance. Pauline Close, from the Department of Anatomical Pathology at the University of Cape Town, was the site pathologist. Carol Johnson, Radiation Oncologist, collated the clinical material. James O Armitage, Professor of Medicine, at the University of Nebraska Medical Centre, kindly reviewed the manuscript. These studies were supported by the Medical Research Council and the Cancer Association of South Africa.

Editorial

Proceedings of the 12th Biennial Congress – South African Lymphoma Study Group

1. Background

More than 30 years ago these intriguing tumours arising in the lymphoreticular system started to attract attention. This was because of their relatively frequent occurrence and ready accessibility of involved tissue for biopsy and serial study to complement clinical and radiological course. There resulted effective treatments that improved quality of life and with constant refinement became a model to test combined modality regimens leading to evidence that potential cure was possible in many cases.

To generate an environment conducive for participation in these advances by means of worldwide scientific, academic and intellectual collaboration on one hand and providing optimum care for our patients on the other there was created the South African Lymphoma Study Group. Since inception Professor James O. Armitage provided encouragement for the imperative and constant stimulation by keynote presentations so that over more than two decades the initial small meeting, sponsored by Bristol–Myers, consolidated and grew steadily. Now registered as a national body these firmly entrenched meetings take place every second year bringing together a wide spectrum of local and overseas delegates sharing the common goal of improving understanding and outcome in these neoplasms of the immune system.

Even in an under-resourced country the ever-spreading recognition of how important precise diagnosis and accurate staging is in standardising risk-stratified protocols remains the central theme of these endeavours. Accordingly an interactive format has been retained that allows debate throughout the entire age spectrum, cuts across disciplines and, in this way, provides for constructive interchange between basic science, clinical haematology and immunology. There has always, simultaneously, been full accommodation of important contributions from the pharmaceutical industry with full integration of paramedical professions – most notably our nurses.

Particular effort has always been made to introduce and disseminate new knowledge exemplified by the rapidly emerging role of monoclonal antibodies and a range of small molecules that provide opportunities to test more precisely focused therapeutic interventions. Improving technology that enables distinctive signatures to be assigned to individual tumours using microchip gene array analysis provided impetus. Consequently classification becomes more biologically centred thereby supplementing traditional cytomorphology and histopathology and so providing a rationale for considering these neoplasms as reflecting the immune system in disarray. This burgeoning molecular genetic approach has become the focal point for entry into innovative therapies that extend to the use of radioconjugates and vaccination strategies.

Introduction was provided by Lucille Wood and her associates in an extension of data reported as part of the lymphoma reclassification project that brought together investigators from different parts of the world under the chairmanship of Professor James O. Armitage. Apart from geographical differences this experience documented good diagnostic concordance between trained haematopathologists when the revised European-American classification was used. Furthermore, unusual subtypes were
generally well accommodated within the system. Additionally, this participation provided a powerful incentive to register patients at a multidisciplinary or combined lymphoma clinic and an interim report describes outcome in Hodgkin and other lymphomas from this privately based academic centre in 253 consecutive referrals. Diagnosis was based on the World Health Organisation guidelines, prognosis assigned by the international index and therapy risk-stratified with results subject to appropriate statistical methodology. None of these patients underwent transplantation. It was concluded that, approached in this way, benefit accrued from the all-important centre effect with the proviso that matching figures are unlikely to apply, particularly in the Third World, outside such disciplined circumstances. This reflection is relevant since it is the reasonable expectation from patients and referring physicians alike that, since lymphomas are potentially curable, such comprehensive management will be regarded as standard of care. It follows logically that late referral and prior therapy will adversely affect performance status and compromise lifespan - these alternatives are inappropriate and need to be strongly discouraged.

The curability of follicular lymphoma was the keynote address by Jim Armitage who made the point that these entities had been widely regarded as incurable. However, if the cure is defined as remission that continues indefinitely and the patient eventually dies of another disease some will fall into this category. Furthermore, those with grade III act much like diffuse large B-cell lymphoma where disease eradication is frequent. This is in contrast to more indolent subtypes where there is variable response to initial therapy and here a significant proportion go on to benefit from haematopoietic stem cell transplantation.

Beacopp as standard for high-risk hodgkin lymphoma received authoritative comment from Volker Diehl in that consolidation radiation should be reserved to manage partial responses after an adequate number of anthracycline containing chemotherapy regimens or with residual nodal lesions. Dose and time intensification with an escalated version of this regimen further reduces the need for irradiation with the caveat that CT PET imaging may well discriminate between scar or viable tumour tissue. Importantly, initial benefits do not appear to be of set by later side-effects but the definitive answer awaits longer observation. These results should influence current approach including primary care specialists.

Telomeres and telomerase in leukaemia and lymphoma was reviewed by Glenda Davison who outlined the role of these structures in stabilising chromosomes and so, interactively, regulate cellular lifespan. Imbalance of the system is associated with the development of haematologic malignancy and improved understanding a potential basis for therapy targeting the telomere-telomerase complex.

The role of haematopoietic stem cell transplantation is discussed by Matthew Seftel in two contexts. In Hodgkin lymphoma patients failing to achieve sustained complete remission from chemotherapy become eligible for autografting. Not all such interventions are effective and new approaches include tandem procedures incorporating reduced intensity allogeneic grafts where the rationale is an immunologically mediated anti-lymphoma effect. Contrarily, chronic lymphocytic leukaemia continues to benefit from new therapeutic interventions despite which disease recurrence in relapse remains a major concern. Here, while autografting appears to have little benefit, allogeneic transplantation has curative potential that requires balance with procedure related complications that may be reduced with non-myeloablative conditioning.

Aids-related non-hodgkin and hodgkin lymphoma is noted by Gerhard Sissolak to have a relationship between incidence and progression of immunodeficiency. This poses a particular problem in sub-Saharan Africa with the rapidly escalating pandemic of human immunodeficiency viral infections where there is a counterbalancing effect from administration of highly active retroviral therapy making possible wider use of effective chemotherapy regimens. A number of unanswered questions include concomitant or sequential administration of antiviral and anti-lymphoma treatments, impact of resource allocation in Third World countries and the role of coinfection with oncogenic agents including human herpes and Epstein-Barr viruses. Consideration is given to epidemiology, pathogenesis as well as clinical features and treatment modalities in this situation.

Fine needle aspiration biopsy and flow cytometry in the diagnosis of lymphoma is considered by Guillaume Swart and his associates to have value in distinguishing reactive from neoplastic lymphoid populations when compared to the established practice of excision biopsy and histopathology but requiring ongoing evaluation. The argument is advanced that flow cytometry is rapid and objective in quantitatively and qualitatively documenting cell
surface characteristics. The utility of this approach has not been widely recognized and this is particularly true in South Africa. To better define the role of this combined procedure a series of patients were prospectively evaluated leading to the conclusion that, used proactively in a collaborative multidisciplinary setting, it may be possible to limit surgical procedures to specific situations requiring data that is not available from this specific intervention.

Castleman’s disease, hodgkin lymphoma and retroviral therapy is reported by Chris Kenyon and his associates to have an interesting interrelationship with the immunologic reconstitution that follows commencement of highly active retroviral therapy in patients with acquired immunodeficiency disease. Attention is drawn to the presentation after starting treatment perhaps reflecting an aberrant response to antigens that include the human herpes virus suggesting that proactive inclusion of drugs effective against these agents may be appropriate.

Novel proteosome inhibitors as a therapeutic strategy in lymphoma is reviewed by Akin Abayomi drawing on precedent from preclinical experiments and studies in myeloma for the presence of ubiquitin-proteosome pathway in modulating intracellular neoplastic processes that are protein dependent and can be modulated by inhibitors of the system. This concept is given focus by considering the introduction of this class of agents into the treatment of lymphoreticular malignancy.

Summary and conclusions, on behalf of the organising committee, was presented by Jim Armitage, Lucille Wood and Peter Jacobs. Their view was that this meeting re-emphasised the continued value of the South African Lymphoma Study Group, particularly on this continent, for all serious students of these tumours to share a common forum for presentation of their experience and contrast this with outcome in the first world. Such an opportunity remains valuable at a time when sub-Saharan Africa is reeling under the impact of an ever-accelerating academic of the acquired immunodeficiency disease with quaint approaches to treatment finding expression and prominent voices! Against this background it is reassuring to see that the reputation of a local scientific community survives as reflected in two ways. On the one hand is the sound quality of work being carried out in this country. On the other, endorsement is at a huge enough level to again bring some of the world’s unquestioned authorities to share in this important imperative. These deliberations are recorded in the accompanying publications.

EDITORIAL

The South African Lymphoma Study Group came into being some 25 years ago to promote understanding of these tumours arising from the immune system at a time when they were also becoming increasingly recognised in this country. The impetus was found in a worldwide awareness of these entities and an early priority was to explore possible geographical differences. To foster such potentially relevant advances a scientific collaboration was established with Professor James O Armitage in Nebraska and that association has remained intact throughout subsequent years. Over time ever expanding interest, both locally and overseas, has led to the meeting being held, jointly, with other countries. These have included Israel, Belgium on two occasions, the United Kingdom and currently with Germany. A novel, and now distinctive, innovation has been to select a theme based on some particular characteristic having high profile at that time. This was exemplified, previously, by regarding these neoplasms as reflecting the immune system in disarray - a play on the recently developed technology of microchip gene array analysis. Another, and the current topic, is that of survivorship. Here, as treatment improved and survival lengthened, a surprising spectrum of underestimated and often overlooked side-effects have become recognised with the passage of time. These combine to have a varying and often adverse impact on quality of life. This phenomenon could be restated as an interrelationship between patient and the treating multidisciplinary team in seeking to maximise cure with optimal care. Appreciation of such enlightenment has altered focus to individualised management, rather than cases having purely statistical consideration. Of seminal importance is that this ethos accommodates personal choice on the basis of informed consent and balances often investigational regimens with ethical considerations.

One high profile intervention is that of immunohaematopoietic stem cell transplantation and the relative merits of autologous as opposed to allogeneic graft source still actively debated. Another, acute in the Third World, is resource distribution. Here, to help meet this need, the feasibility of duplicating traditional University Teaching Hospital facilities in the private sector was tested and found demonstrably realistic. Neither have the contributions of the pharmaceutical industry been neglected.
Accordingly the question before us this year was chosen to explore the extent to which new approaches, designed to circumvent anticipated side-effects, might be more effective and less toxic than past practices.

**Nomenclature** was the logical starting place where Jim Armitage set the tone by lucidly reviewing traditional approaches emphasising new diagnostic accuracy and subtyping within the broad scheme recently updated by the World Health Organisation giving focus to the peripheral T-cell variants. Integral to these established features is supplementation with additional immunophenotyping and, ever increasingly, both cytogentic and molecular methods. On such a basis signatures can be assigned not only to groups but individuals as the favoured approach for tailoring therapy. Guillaume Swart illustrated the role of fine needle aspiration biopsy as of value in separating benign from malignant lesions such as the breast or thyroid gland. In well trained hands the simple method can rapidly segregate these two distinctive pathophysiologic processes. However, when compared to the established practice of excision node biopsy, the additional information derived from histopathology, continues to undergo evaluation. The point was made that, particularly when tumours are atypical or polymorphic, confidence in distinguishing reactive populations is made more secure by use of simultaneous flow cytometry. With accumulating experience the need for surgical procedures can be reduced. This changing approach received emphasis from Ghulam Mufti discussing biological versus morphologic issues in the myelodysplastic syndromes – relevant since these entities may arise in the course of treated lymphoreticular malignancies. He made the point, elegantly, by stressing the increasing appreciation of contributions from unravelling mechanisms giving rise to genomic instability, cell cycle and immunotherapy using myeloid malignancies as the model.

**Pathogenesis** focused on the viruses where Diana Hardie showed how the presence of human gamma herpes viruses, causing persistent infection in the host, acquire genes from the recipient having the capacity to modify immune response as well as exerting oncogenic properties. Mervat Mattar outlined the causative association between hepatitis C virus and lymphoma in a proportion of non-Hodgkin variants drawing on her data from Egypt where high positivity rates in that population complicate management by necessary drug administration.
Glenda Davison noted that the immune system has the ability to control and destroy malignant cells well seen in the graft-versus-leukaemia effect evident when additional donor lymphocytes are infused following relapse from allogeneic transplantation.

Here dendritic cells are potent antigen presenters becoming activated after phagocytosis and processing foreign protein. During this process there is upregulation of MHC class II and other co-stimulatory antigens having the ability to recruit naive T cells. Recent evidence has shown that it is possible to load this population with tumour specific markers and so generate specific responses where that technology is promising in early clinical studies. Mahmoud Aljurf reviewed antigen and immune driven lymphoproliferative disorders with several of these possibly instigated by transformation of a polyclonal normal lymphocyte population to their monoclonal or neoplastic counterparts. The list of potential precipitating molecules continues to grow with the concurrent recognition that progression is a multistep process. During this transition, although clonal abnormalities may be recognised, some responsiveness to normal regulation of growth and differentiation persists so that the point of no return is hard to define. It is speculated that this may be the reason why similar morphologic or other subtypes occur concurrently in patients with profound immunosuppression.

Similarities are emerging in sub-Sahara where infection with the human immunodeficiency virus, leading to Acquired Immune Deficiency Syndrome, is rapidly gaining attention with its comparable profound defects in both innate and acquired arms often approaching that found in organ transplantation. This point was elaborated on in some detail by Gerhard Sissolak emphasising geographical differences based on a cohort of 512 consecutive individuals treated in a private academic centre. Very elegantly discussed by Hans Konrad Muller - Hermelink was the relationship of lymphoma in South Africa and, as he put it, the other world. This phenomenon was illuminated from his experience and large databases in treating and contrasting pathogenesis found in diffuse large cell lymphoma and Epstein-Barr viral related lymphoproliferations. Amplification of the need to establish worldwide cooperation in this area of research was given encouragement, particularly in the context of these meetings, by Volker Diehl who is a leading protagonist of information sharing.
desirable example as to just how much can be achieved with properly orchestrated national
efforts. His overview of advanced Hodgkin lymphoma in the context of ABVD and more recent
therapeutic options in fostering new international transatlantic studies was predictably insightful.
A point of some interest is that, in considering the management of these cases, principles emerge
that are pivotal to treat the underlying driving factor on the one hand and improve immune status
on the other. This may well be the mechanism incriminated by Alan Tooke in which a variety of
autoimmune disorders were shown to overlap with an increasing evolution to the malignant
counterpart of one or other lymphoma.

Clinical aspects are remarkably protean. Derek Miller reported that renal involvement is
probably more common than clinically suspected in most subtypes especially follicular and diffuse
large B-cell cases with autopsy studies showing upwards of 50% of cases with often-recognisable
features to be seen on CT scanning. Wide ranges of infiltrative patterns occur although most
typically in late stage disease and remain particularly useful in defining underlying pathology. An
important point is that reversibility is possible although some degree of chronic renal disease may
persist. Mark Sonderup explained how hepatic venous outflow obstruction gave rise to 3 distinct
categories with veno-occlusive syndrome at the level of the sinusoids and terminal - venules. In
contrast Budd - Chiari cases resulted from thrombosis in the hepatic veins with a timely reminder
that the former may complicate transplantation and the latter associated with thrombophilia.
Melvyn Letier described primary gastrointestinal lymphoproliferation most commonly found in the
stomach. Also highlighted were the mucosa-associated subtypes closely linked with Helicobacter
pylori with the observation that resolution may follow eradication of the organism. The small
intestine may often be silent for prolonged periods of time with recognition of these neoplasms
arising on the basis of overlooked gluten enteropathy. Central to many of these different organs
involved is demonstrating the extent of disease at diagnosis and, equally importantly, revealing
residual tumour as part of the staging and restaging program. The emerging role of positron
emission tomography combined with conventional CT scanning continues to be explored but there
was strong support from the academic faculty that functional as opposed to purely imaging needed
to be more widely accepted in this country. This point was convincingly presented by Vijay Dahya.
A hot topic was the management of cytopenia in those who are retroviral positive even before the emergence of the Acquired Immune Deficiency Syndrome and this is a rapidly escalating challenge as this viral epidemic relentlessly escalates.

Matthew Seftel stressed the importance of fever in neutropenic cancer patients as representing a medical emergency having a significant incidence of overwhelming infection and death. The spectrum of microbiological pathogens varies both temporarily and geographically so that universal recommendations for antimicrobial therapy are still challenging. Nonetheless unifying principles are clear with areas for resolution being the place of prophylactic antibiotics, safe treatment in an outpatient setting and empiric regimens. This section was completed by Christina Stephane defining the paediatric perspective where these tumours comprise 10% of childhood cancers and up to 17% in teenagers. Hodgkin lymphoma is seen in much younger ages in the developing countries with a male predominance and histologic subtypes varying between ethnic groups. A remarkable observation was that under 15 years the presence of Epstein-Barr viral markers were suggestively associated with favourable survival although interracial variation recognised. Disturbingly the non-Hodgkin variants increase with age and shift to a more aggressive variants. Particular effort is needed to identify effective low toxicity protocols, avoid radiotherapy and retain compliance. Across all of these important variables is the escalating frequency of late effects including infertility, impaired cognitive performance and emergence of secondary malignancies.

_Treatment_ is increasingly multimodality. This shift in concept and practice continues to move treatment away from the old and largely inflexible concept of Third World practices as regarding one regimen as appropriate for all! In its place is the use of prognostic factors to individualise regimens that will typically link agents having different mechanisms of action. Choices range from traditional cytotoxic drugs through rapid acceleration in the use of monoclonal antibodies to a changing perspective for bone marrow transplantation in one or other of its various forms. In the most traditional sense Vernon Louw elegantly summarised the current status for Waldenstroms macroglobulinaemia. Asim Belgaumi instructively used his database in very young children with Hodgkin lymphoma as a model to argue for causal infectious association.
consequences making the telling point that, while information is relatively restricted, differences are quite clear between developed countries and under resourced areas of the world.

Marcel Reiser presented pharmacodynamic studies on how rituximab could be escalated in the treatment of high-grade non-Hodgkin lymphomas. Constructively there was balance between the effects of increasing density, with or without intensity, of the conventional drug regimen against higher levels of monoclonal antibody with utility in elderly having poor prognosis. Along similar lines Andres Engert concisely used the powerful German Hodgkin Lymphoma Study Group database to update attendees on the relative merits of established chemotherapy programmes such as ABVD and more aggressive combinations exemplified by BEACOPP in both standard and escalated forms. Notable was the tour de force for using phenotype to introduce not only rituximab as a relatively new development in exploring toxin mediated selective immunotherapy. In keeping with the theme of the meeting to reflect on late effects of treatment and survivorship in this distinctive lymphoma.

Another monoclonal antibody of proven value in these tumours of the lymphoid system was the way Anders Österborg demonstrated the emerging role of alemtuzumab in targeted therapy. Along these lines immunotherapy appears to have considerable potential and the principles lucidly described by Said Dermime in both a mouse model showing effectiveness of the vaccine as well as leukaemia.

Not surprisingly bone marrow transplantation remains an important option with David Brittain discussing its role in relapsed Hodgkin lymphoma. Perspective - as counterpoint - emerged from the eastern Mediterranean and North Africa in the presentation by Mahmoud Aljurf. Jackie Thompson related her experience of myeloablative allografting for the low-grade lymphoid malignancies and thought-provoking presentation by Devan Moodley reported early but clear benefit in patients with multiple sclerosis having progressive disease.

Penultimately Mike Webber provided a timely reminder of how psychoneuroimmunological influences impact outcome in quality of life. The point was how ethics and changes in neuropsychiatric functions can be seen as a thread running through these practices often providing an anchor for accommodating to these different periods - important in the concept of survivorship.
Impressive was the discussion by Marc Blockman of how significant adverse drug events were an ever-present risk in almost all modern treatment programs. These important considerations were given strong emphasis by Tony Behrman who brought finality to our deliberations underlying the importance of ethics, ethical rules and illustrated these in the context of the modern day haematologist.

Summary and closure by Andres Engert emphasised the pride of place enjoyed by these intercontinental biennial meetings. They continue to bring together all serious students of the constantly expanding group of tumours arising from the immune system and do so at a time when sub-Saharan Africa is reeling under the impact of an ever-accelerating epidemic of the acquired immunodeficiency syndrome. The latter is, sadly, still a beneficiary of most unusual therapeutic approaches to treatment finding expression in prominent voices! Against this background it is reassuring to see that the reputation of the local scientific community survives as reflected in two ways. On the one hand the sound quality of work presented from the South African workers. On the other the endorsement that has again brought many eminent authorities from all over the world to participate in what is, unquestioned by any standards, a stellar faculty. This increasingly popular and highly effective forum achieved a degree of interaction that was rewarding for delegates and faculty alike. It is this ethos that has defined the recognised benefits of continuing with the alternate year symposia.

Despite tumultuous changes that range from the American presidency through worldwide financial collapse, to disasters in almost every country there is nevertheless an obligation felt by the organising committee to maintain this forum for the benefit of patients and the professional multidisciplinary teams alike. Accordingly in October of 2010 the South African Lymphoma Study Group will reconvene being hosted jointly with our colleagues from the Netherlands and participants from Belgium, Saudi Arabia and other parts of the world in what will be the 14th biennial Congress.

The initial announcement and further information is available by contacting Reyhanah Trevor:

Abstract #353

Chimeric Anti-CD20 Monoclonal Antibody (Rituximab;Mabthera) in Remission Induction and Maintenance Treatment of Relapsed or Resistant Follicular Non-B-Cell Lymphoma: Final Analysis of a Phase III Randomized Intergroup Clinical Trial

Diwakar V. Van Ginkel,1 Ivana Toledovovic,1 Cynthia Rozewicz,1 Robert K. Marcus,3 Max Wolf,4 Eva Kimby,1 Anton Hagenbeck,12* EORTC Lymphoma Group, Academic Medical Center, Amsterdam, Netherlands; 2Hovon; 3EORTC Data Center; 4German-Italian follicular Lymphoma and Leukemia Group; 5North American Lymphoma Group.

Background. Last year we reported interim results of a randomised phase III trial in patients with relapsed refractory stage IV M-II positive follicular NHL demonstrating that the addition of rituximab (R) to CHOP chemotherapy for remission induction as well as the addition of rituximab induction prior to CHOP chemotherapy significantly improved the clinical outcome (Blood 2004:104:169a). Based on these interim results, randomisation to the induction part of the trial was stopped and the protocol was amended. Study design. Patients with stages III or IV follicular lymphoma at initial diagnosis and relapsed after or resistant to a maximum of two non-chemotherapeutic (ie, systemetic chemotherapeutic) regimens, were randomized to remission induction with either 6 cycles of CHOP (375 mg/m2 once every 3 weeks) or CHOP + R (375 mg/m2 as a bolus at day 1 of each cycle of CHOP). Those with a complete or partial remission after 6 cycles of therapy underwent a second randomization to no further treatment (obsevational) or maintenance treatment with R (375 mg/m2 once every 3 months) until relapse or for a maximum period of 2 years. At the time of the preplanned second interim analysis (February 2004), 461 patients had been included. Of these, 369 could be evaluated for response (185 CHOP; 181 R-CHOP). Both treatment arms yielded similar initial response rates (CHOP: 55%; R-CHOP: 52.5%), but highly significant differences in CR rates between CHOP (18.1%; R-CHOP: 30.4%; p<0.0004). Of 319 patients randomized for maintenance treatment, 268 were evaluable (132 observation; 136 R maintenance). A highly significant improvement was observed in progression-free survival in R maintenance, when compared with observation arm (median PFS 38 vs 15 months; p=0.0001). At that time there was no impact on OS: the observed difference (in favor of R maintenance) was not significant for any interim analysis. Toxicity of CHOP and R-CHOP induction and maintenance (CR rates as compared to CHOP) was manageable with minimal toxicity. These results of the planned second interim analysis showed that the formal criteria for stopping the trial had been met. It was concluded that this is the first trial to show that: 1) in patients with relapsed refractory follicular lymphoma R-CHOP induction regimens in a high-risk patient population increase in CR rate as compared to CHOP; 2) rituximab maintenance treatment significantly improved PFS in patients responding to induction treatment. The final analysis of the study results will be performed in September 2005, demonstrating that a follow-up of at least 18 months. The final results will be presented at the meeting.

Abstract #354

Low Dose Radiation Induces a Highly Effective p53 Response and Rapid Tumor Regression in Pancreatic Lymphoma. Laurent Kroopp,1 Rick L. Haas,2 Samne de Kemp,3 Annegien Broekx,4 Laura J. van 't Veer,5 Desphene de Jong,6* (from, by Marie Jose Kereste) Pathology, The Netherlands Cancer Institute, Amsterdam, Netherlands; 2Radiotherapy, The Netherlands Cancer Institute, Amsterdam, Netherlands; 3Experimental Therapy, The Netherlands Cancer Institute, Amsterdam, Netherlands.

Results. We administered a fractionated field radiation therapy with 30 to 40 Gy in a usable local treatment for follicular lymphoma (FL) that is routinely used in clinical practice. We previously showed that low dose radiation therapy (2Gy Gx, days 1 and 4) induced a radiosensitive population in up to 10% of patients (Bouma et al, IJC, 2003). However, the biological mechanism of this extremely effective response is not known. To study the molecular response to low dose radiation therapy in FL, gene expression profiling using 32K spotted oligo arrays from lymphoblastoid cDNA samples taken before treatment and 24 hours after the second dose of 2Gy irradiation, in 15 patients. The clinical response was excellent (10 CR, 5 PR). In all patients, a major and consistent induction of p53 and p53 target genes was seen, accompanied by repression of 14 out of 9000 genes (3%). p53 upregulation, p53-mediated proliferation arrest and apoptosis was substantiated using immunohistochemistry with dramatic increase of p53 protein levels in B-cells, T-cells and accessory cells. There was also a significant increase in the numbers of cleaved caspase 8 positive cells (death receptor pathway apoptosis) with a minor increase of cleaved-caspase 3 positive cells and morphological features of apoptosis, suggesting a relatively early stage in the apoptosis pathway.

The primary induced genes were an "immune signature", with a whole set of biologically meaningful genes related to macrophages (e.g., CD68, TH14), ThI immune response (e.g., IL18, ICOS2, 10, 11), clearance of apoptosis cells (e.g., CYP4A), MHC-I expression (HLA-A, B, CDD) and death receptor pathway. The immunohistochemical analysis did not show an increase in T-cell subsets and macrophages density, rather suggesting an activation or differentiation of resident macrophages by radiation and/or apoptotic cells that contributed to the death and clearance of tumour cells. These insights may have important implications for modulation of the cancer-related immune response and for immunotherapeutic approaches in FL.

[1817] Outcome of Patients Developing GVHD after DLI for CML Relapse from HLA-Identical Sibling or VUD HSCT. Session Type: Poster Session 21-II

Yves Chalandon, Christoph Schmid, Kimmo Porkka, Alvaro Urbano-Ispizua, Bernd Hertenstein, Francesco Dazzi, Eduardo Olavarria, Jane Appleby, Per T. Ljungan, Antonius V.M.B. Schattenberg, Stig Lenhoff, Peter Jacobs, Jurgen Finko, Dietgar W. Niederwieser, Cesare Guglielmi On Behalf of the Chronic Leukemia Working Party (CLWP) of the European Group for Blood and Marrow Transplantation (EBMT)

Using data submitted to the EBMT registry, we analyzed outcome on 344 patients (pts) who had received donor lymphocyte infusions (DLI) for relapse after allogeneic hematopoietic stem cell transplantation (HSCT) for chronic myeloid leukemia (CML) in 31 centers. 113/344 pts (33%) developed acute graft-versus-host disease (aGVHD) a median of 50 days post DLI (max grade: 1=42, II=30, III=31, IV=5)(60% grade II-IV). Organs involved (%): skin (88), liver (42), gut (30). Median age was 38 (4-59). 56% of pts were male, 62 transplants were HLA-identical sibling and 51 unrelated. 74 were T-cell depleted, 92 transplanted in CP1, 21 beyond CP1. Relapse was molecular in 19 pts, cytogenetic in 31, hematomatological in 49, accelerated or blastic in 12. Median initial cell dose was $10^7$CD34 cells/kg (0.01-32), median number of DLI was 1 (1-10). aGVHD was treated with prednisone in 92% of pts, CSA in 52%, ATG and monoclonal antibodies in 2% and other in 19%. aGVHD resolved in 53% of the pts within a median of 83 d (7-846). 82/344 pts (24%) had chronic GVHD (cGVHD)(30 limited, 50 extensive, 2 not specified), of those 46 (56%) following aGVHD post DLI. Organs involved (%): skin (75), liver (35), lungs (13), mouth (43), eyes (22) and gut (9). Median age was 35 (6-58). 51% were male, stem cell source was PB in 15% and marrow in 85%, 43 underwent HLA-identical sibling HSCT and 36 unrelated donor HSCT. Forty-three were T-cell depleted, 66 transplanted in CP1, 16 beyond CP1. Relapse was molecular in 21 pts, cytogenetic in 29, hematological in 22, accelerated or blastic in 7. Median initial dose was $10^7$CD34 cells/kg (0.05-40), median number of DLI was 1 (1-7). 61 pts are alive with a median follow-up of 50 mth. Treatment was with steroids in 83% of pts, CSA in 58%, MMF in 20%, thalidomide in 15%, photopheresis in 15%, PUVA in 10% and other in 17%. cGVHD resolved in 39% of the pts within a median of 354 d (44-1588). The estimated 5-y OS post-DLI was significantly lower in pts who developed aGVHD post-DLI, 61 ± 10% vs 74 ± 7% in the one that did not, p=0.007 and also a tendency to have a lower 5-y EFS, 58 ± 10% vs 65 ± 7%, p=0.19. Median duration of response to DLI in aGVHD pts was 4 y. aGVHD post-DLI did not influence the relapse rate (5 ± 5% vs 6 ± 5% in the absence of aGVHD). 5-y DLI related mortality was significantly higher in aGVHD pts, 31 ± 8% vs 4 ± 4%, p=0.000071. On the other hand, pts that developed cGVHD post-DLI had a tendency to have a better 5-y OS and EFS, 74 ± 11% and 71 ± 11% respectively vs 69 ± 5% and 62 ± 7% in those that did not, p=0.32 and 0.09. This was related to a tendency to lower incidence of relapse, 2 ± 3% in pts with cGVHD vs 9 ± 6% without, p=0.2. DLI related mortality was not different, 11 ± 8% vs 10 ± 5%, p=0.77. aGVHD post-DLI for CML relapse is mainly of advanced stage and negatively influence OS and EFS with a higher DLI related mortality cGVHD post-DLI is mainly extensive, but pts with cGVHD tend to have better outcome with better 5-y OS, EFS and less relapse than those without, although this was not statistically significant.

Abstract #1817 appears in Blood, Volume 106, Issue 11, November 16, 2005 Keywords: Relapse|Acute graft-versus-host disease|Chronic graft-versus-host

Marrow versus peripheral blood for geno-identical allogeneic stem cell transplantation in acute myelocytic leukemia: influence of dose and stem cell source shows better outcome with rich marrow

Norbert C. Gorin, Myriam Labopin, Vandersand Focha, William Arcese, Moriel Beksa, Eliane Gluckman, Olle Ringden, Tapani Ruutu, Josy Reilffers, Giuseppe Bandini, Michele Falda, Panagiotis Zikos, Roell Willemen, and Francesco Frassoni, for the Acute Leukemia Working Party (ALWP) of the European Cooperative Group for Blood and Marrow Transplantation (EBMT)

Several studies have compared bone marrow (BM) and peripheral blood (PB) as stem cell sources in patients receiving allografts, but the cell doses infused have not been considered, especially for BM. Using the ALWP/EBMT registry, we retrospectively studied 861 adult patients with acute myelocytic leukemia (AML), who received a non-T-depleted allogeneic BM (n = 515) or mobilized PB (n = 366) standard transplant, in first remission (CR1), from an HLA-identical sibling, over a 5-year period from January 1994. The BM cell dose ranged from 0.17 to 29.6 x 10^6/kg with a median of 2.7 x 10^6/kg. The PB cell dose ranged from 0.02 to 77 x 10^6/kg with a median of 9.3 x 10^6/kg. The median dose for patients receiving BM (2.7 x 10^6/kg) gave the greatest discrimination. In multivariate analyses, high-dose BM compared to PB was associated with lower transplant-related mortality (RR = 0.51; 95% CI, 0.39-0.98; P = .04), better leukemic-free survival (RR = 0.65; 95% CI, 0.46-0.91; P = .013), and better overall survival (RR = 0.64; 95% CI, 0.44-0.92; P = .016). The present study in patients with AML receiving allografts in first remission indicates a better outcome with BM as compared to PB, when the dose of BM infused is rich. (Blood. 2003;102:3043-3051)

Introduction

In the past decade, the use of peripheral blood (PB) as a source of hematopoietic stem cells for allogeneic transplantation has increased considerably. A large number of retrospective studies,4-6 several prospective and randomized,7-10 have compared the outcome of patients receiving allografts with bone marrow (BM) versus PB, using a family identical sibling; in all studies PB has resulted in faster engraftment and shorter hospital stay. In most studies, with the notable exception of the EBMT study,8 the incidence and severity of acute graft-versus-host disease (aGVHD) has been similar with PB and BM; PB on the other hand has been associated with more chronic GVHD (cGVHD). Finally, the outcome with PB, in terms of leukemia-free survival (LFS) and overall survival (OS), has been identical to BM and sometimes superior.14 All things considered, for practicality reasons, PB has therefore become a first choice for many transplantation teams. It has been postulated that the benefit brought by PB was at least in part due to the higher cell dose infused to the recipient when compared to BM.15

In the same period, other studies on BM and PB transplantations have drawn attention to the importance of the dose of stem cells infused; a lower transplant-related mortality (TRM) and also in some studies a lower relapse rate after transplantation have been observed in patients undergoing allografting13,14 or autografting15-19 with higher BM cell doses.

In the present retrospective study based on the ALWP/EBMT registry, we compared the outcome of patients with acute myelocytic leukemia (AML) receiving allografts in first remission (CR1) using BM or PB as a source of stem cells, focusing on the dose of stem cells infused. We found a significantly better outcome in patients receiving higher BM cell doses (rich marrow), when compared to the others, that is, patients receiving low-dose BM or high- or low-dose PB.

Patients and methods

Data collection and patient selection

The European Blood and Marrow Transplant (EBMT) Registry is a voluntary working group of more than 500 transplantation centers. Participants are required once a year to report all consecutive transplantations and follow-up. The Acute Leukemia Working Party (ALWP) of the EBMT is in charge of validating and checking submitted data to ensure data quality.

BLOOD, 15 OCTOBER 2003 • VOLUME 102, NUMBER 8

3043
This study included 881 patients with AML, older than 16 years of age, who received a non-T-depleted allogeneic BM (n = 515) or mobilized PB (n = 366) standard transplant, in CR1, from an HLA-identical sibling, over a 5-year period from January 1994 (date of the first allogeneic PB transplantation) to January 2001. The dose of cells infused with the graft was in nucleated cells per kilogram. The study was approved by the EBMT review board.

**End points of the study**

*Hematopoietic recovery.* Neutrophil and platelet recoveries were analyzed separately and defined by a neutrophil count equal to or more than 0.5 X 10^9/L for 3 consecutive days and a platelet count equal to or more than 50 X 10^9/L for 7 consecutive days with no platelet support, respectively. The median time to recovery was calculated using the product limit method.

*Mortality and relapse.* Transplant-related mortality (TRM) was defined as nonleukemic deaths. Relapse incidence (RI) was defined on the basis of morphologic evidence of leukemia in BM or other extramedullary sites. To evaluate the probability of relapse, patients dying either from direct toxicity of the procedure or from any other cause not related to leukemia were censored. Leukemia-free survival (LFS) was defined as the time interval from transplantation to the first event (either relapse or death in complete remission).

GVHD. Acute GVHD (aGVHD) was diagnosed and graded at each transplantation center according to Seattle criteria. Only patients with grade II or superior were considered as having aGVHD. For chronic GVHD (cGVHD), only patients surviving without relapse for more than 100 days after transplantation with sustained donor engraftment were considered as evaluable; cGVHD was defined according to standard criteria (limited and extensive).

**Statistical analyses**

All analyses were performed with the SPSS statistical analysis program (SPSS, Chicago, IL). Values reported for quantitative variables were median and range. The following patient or graft characteristics were analyzed for their potential prognostic value on each of the outcomes: patient's and donor's characteristics (age, sex, and sex matching), disease factors (white blood cell count at diagnosis, French-American-British classification, interval from diagnosis to CR1, interval from CR1 to transplantation), and transplant-related factors (source of stem cells, nucleated cell dose infused per kilogram, year of transplantation, nature of the conditioning regimen including or not total body irradiation). For these prognostic analyses, continuous variables were categorized according to the median value. To compare the distribution between the subgroups of patients, we used the χ² test for categorical variables and the nonparametric Mann-Whitney U test for continuous variables.

Patients were censored at the time of relapse or the last follow-up. Probability of DFS, RI, TRM, and OS were estimated by the product-limit method. The significance of differences between curves was estimated by the log-rank test (Mantel-Cox). All variables associated with outcome with a P value of less than .1 in univariate analyses and characteristics statistically different (P < .05) between subgroups of patients were included in a multivariate analysis. Because a center effect had been observed in a previous EBMT study in patients receiving a BM transplant for AML in CR1, all further multivariate analyses were adjusted on center.

Results

Patient populations in relation to hematopoietic stem cell doses infused and univariate analyses

The outcome was identical when comparing BM and PB transplantations: At 2 years, the TRM with BM and PB was 22% ± 2% and 22% ± 2% (P = .98), the RI 19% ± 2% and 22% ± 3% (P = .61), the LFS 63% ± 2% and 61% ± 3% (P = .72), and the OS 66% ± 2% and 66 ± 3% (P = .82), respectively.

The BM cell dose ranged from 0.17 to 29 × 10^9/kg recipient weight with a median of 2.7 × 10^9/kg. The PB cell dose ranged from 2.2 to 20 × 10^9/kg with a median of 9.3 × 10^9/kg.

There was no difference for outcome when taking the median dose of PB cells infused as a cutoff within the PB group: The 3-year LFS was 64% ± 6% in patients receiving doses below the median and 59% ± 7% for those receiving doses above the median (P = .76). For patients receiving BM, the median dose (2.7 × 10^9/kg) gave the greatest discrimination for all end points studied.

We therefore studied 3 populations of patients: those receiving higher doses (above median) of marrow (n = 257), those receiving lower (below median) doses of marrow (n = 258), and those receiving PB whatever the dose (n = 366).

Table 1 gives the distribution of the 3 groups for disease and transplantation characteristics; the only differences concerned the year of transplantation, which was more recent for PB, and more TBI and a trend for fewer female donor-to-male recipient combinations in the group receiving higher doses of BM.

The distribution was even for patient age and sex, white blood cell count at diagnosis, FAB classification, and pretransplantation intervals.

Information on cytogenetics was available for 366 patients. In keeping with our previous work, 24-27 patients were in the good-risk category (t(15;17), t(8;21) and inv(16), 25 in the poor-risk category (abnormality 5 or 7, 11q-), and 284 in the intermediate-risk category. The number of missing values was too high to include cytogenetics in the multivariate analysis. However, the distribution by cytogenetics over the 3 groups of patients was even.

Recovery of polymorphonuclear cells (PMNs) to 500/mm^3 with high-dose BM, low-dose BM, and PB occurred at days 18 (range, days 10-39), 19 (range, days 10-53), and 14 (range, days 10-42), respectively. The differences were statistically significant between rich and poor BM (P = .009) and PB and poor BM or rich BM (P < 10^-4 for both). Recovery of platelets to 50 000/mm^3 with high-dose BM, low-dose BM, and PB occurred at days 24 (range, days 12-385), 27 (range, days 12-235), and 17 (range, days 7-343), respectively. The differences were statistically significant between rich and poor BM (P = .02), PB and poor BM (P = .0002) or rich BM (P < 10^-4).

None of the other studied factors (patient and donor age and sex, female donor to male recipient, year of transplantation, and use of TBI) influenced any component of the outcome.

Discussion

In the past 5 years several prospective randomized studies have compared BM and PB as alternative sources of stem cells for allogeneic stem cell transplantation using HLA-identical siblings. Conclusions from these studies have been that PB is associated with faster engraftment, similar or greater incidence of aGVHD, and higher incidence of cGVHD. LFS and OS have been found identical or even better with PB. All these studies have combined transplantations for several hematologic malignancies. A more limited number of retrospective studies have suggested poorer results with PB in more risky situations, such as with mismatched related donors, unrelated donors, or more advanced diseases. Also, it has been recently suggested that results may vary for different diseases, with the observation in transplantations using unrelated donors of similar outcome with BM and PB in AML contrasting with a worse outcome with PB in acute lymphocytic leukemia (ALL). The minimum doses of cells to ensure safe engraftment have been established very early with the development of BM and then PB transplantation. For allogeneic stem cell transplantation, it is generally accepted that a BM graft should contain more than \(2 \times 10^7\) nucleated cells/kg and a PB graft (as initially defined in the setting of autologous PB stem cell transplantation) more than 2 or even better \(5 \times 10^7\) CD34+ cells/kg. These thresholds have been established from observations on the kinetics of engraftment and, with PB, infusion of doses more than \(5 \times 10^7\) CD34+ cells/kg has been shown not to further reduce the duration of aplasia. Only recently, however, has attention focused on the possibility that increasing the doses of stem cells above these thresholds might not only reduce the TRM but also and more unexpectedly reduce the relapse/progression rate of the underlying disease. In the field of AML specifically, in the context of autologous BM transplantation with BM purged by mafosfamide, the dose of stem cells infused has been identified as an important prognostic factor for outcome.

for various hematologic malignancies, a greater dose of nucleated or progenitor CD34+ cells has been shown to reduce fungal infections and TRM and to result in a better OS. As an example in 212 patients who received a transplant of an unmanipulated graft from an HLA-identical sibling donor, 10 year survival and 180-day TRM were, respectively, 64% and 19% for patients receiving a CD34+ cell dose of 3 x 10^6/kg or more and 40% and 37% for the other. EBMT similarly has recently reported on the impact of the dose of BM on the outcome of patients receiving allografts for AML with a geno-identical family donor; higher doses of cells infused expressed in nucleated cells/kg (above median value) not only were associated with a lower TRM but also with a reduced RI, with no effect on GVHD. In high-risk patients, the Seattle group, studying transplantation with unrelated donors, made similar observations,15 that is, an increase in LFS with higher stem cell doses due mainly to a reduction in TRM but also at least in part to an enhanced graft-versus-leukemia (GVL) effect. To explain the reduced RI in relation to the higher dose of cells infused, 2 mechanisms have been proposed, a stem cell competition effect whereby an expanded normal stem cell pool might have a growth advantage over the minimal residual tumor population, and higher numbers of lymphocytes infused with the richer stem cell graft inducing more GVL, both effects possibly combining.

PB grafts contain 5 to 10 times more nucleated cells and about 10 times more T lymphocytes than BM grafts.12 PB following mobilization with granulocyte colony-stimulating factor (G-CSF) has more T polarized cells (Th2) with anti-inflammatory cytokines (hence supposedly the absence of more GVHD, as initially feared),13 and more CD14+ cells. In contrast, mesenchymal cells are present only in BM (approximately 1/10^4 BM cells/kg) and virtually absent in mobilized PB.22 Richer marrows may contain higher doses of mesenchymal stem cells.

Other types of accessory cells also may be differentially distributed in the 2 products and there may be so far unforeseen advantages in using BM, or even combining BM and blood.

Allografting with PB is associated not only with better kinetics of engraftment but also more rapid immune reconstitution.12 Despite an increase in GVHD and a questionable increase in aGVHD with PB, which would favor the use of BM, PB tends presently to be preferred by many teams, but the general assumption is that most of its benefit comes from the higher stem cell dose infused. However, in all studies comparing PB to BM the dose of BM infused never has been considered. In addition, in all studies comparing PB to BM, the median number of BM nucleated cells infused was lower than in the present study. In this respect this study may be of importance because it draws attention to the fact that infusion of rich BM during allogeneic stem cell transplantation from an HLA-identical sibling gives a better outcome than PB, whereas low-dose BM and PB are equivalent. Previous studies comparing PB to BM not only have not taken into account the doses for BM, but also have mixed several diseases and disease status. Because the present study is homogeneous in that it concerns only patients with AML in CR1, the present finding may not necessarily apply to other hematologic malignancies or more advanced stages of AML.

Hematopoietic stem cell transplantation for adults with acute promyelocytic leukemia in the ATRA era: a survey of the European Cooperative Group for Blood and Marrow Transplantation

We performed a survey of the European Cooperative Group for Blood and Marrow Transplantation to analyze the outcome of 625 acute promyelocytic leukemia (APL) patients transplanted with autologous- or allogeneic-hematopoietic stem cell transplantation (autoHCT, alloHCT) after 1993. In first (CR1) or in second complete remission (CR2), Leukemia-free survival (LFS) at 5 years in CR1 was 69% for 149 patients autografted and 68% for 144 patients allografted, whereas in CR2, LFS was 51% in 195 autoHCT and 59% in 137 alloHCT recipients, respectively. In the group of autoHCT for CR1 (n = 149), higher relapse incidence (RI) was associated with shorter time from diagnosis to transplant (<7.6 months); transplant-related mortality (TRM) was increased in older patients (<47 years), whereas for CR2, longer time from diagnosis to transplant (<18 months) was associated with increased LFS and decreased RI. In the alloHCT group for CR1 (n = 144), age (<35 years) was associated with increased LFS and decreased TRM and for CR2 (n = 137), the use of mobilized peripheral blood stem cells was associated with decreased TRM. Female recipient, a female donor to male recipient and transplants performed before 1997 were associated with decreased RI. In conclusion, HCT still appears to have a role in APL, especially for patients in CR2.

Introduction

Several large multicenter studies have shown that regimens combining upfront all-trans retinoic acid (ATRA) and chemotherapy lead to a high curability rate in acute promyelocytic leukemia (APL) that currently exceeds 70% of cases, suggesting that hematopoietic stem cell transplantation (HCT) need not be used to consolidate patients in first complete remission (CR1). In spite of this progress, however, treatment failure still occurs in approximately 10-25% of patients receiving state-of-the-art therapy due to early death or, more frequently, disease relapse.

When clinical relapse occurs, or when it is predicted accurately by molecular monitoring, HCT remains a widely adopted strategy as a part of the salvage therapy. However, there is no general consensus on the choice of transplant type, autologous (autoHCT) or allogeneic (alloHCT) in this setting. In this regard, HCT results in the ATRA era, and particularly outcome data of auto and alloHCT in CR2, have only been reported in small and non-comparative patient series. Results from these studies have suggested that autoHCT in CR2 is still associated with a high probability of long-term survival, particularly for patients undergoing the procedure while in molecular remission (i.e. testing polymerase chain reaction (PCR)-negative for the PML/RARx (promyelocytic leukemia-retinoic acid receptor z) hybrid gene pre-transplant).
In a recent analysis of the European APL group, allogeneic HSCT for 23 APL relapsed patients was associated with higher transplant-related mortality (TRM) compared with autologous HSCT. Since the last EBMT survey by Mandelli et al. in 1994, no studies in large patient series have been reported and more importantly there are no recent data available on stem cell transplantation in CR1, which is considered as a minor, if not unreasonable therapeutic option. Therefore, it is of interest to analyze the current retrospective results and risk factors of HSCT in APL to investigate further the place of autoHSCT and alloHSCT in APL (both in CR1 and in CR2) after the advent of ATRA.

Patients and methods

Patients

Data for 625 adult APL patients undergoing HSCT were reported to the Acute Leukemia Working Party of the European Cooperative Group for Blood and Marrow Transplantation (EBMT). Diagnosis of APL was based on morphological criteria according to the French-American-British classification. Results of HSCT in patients with APL transplanted before 1993 were analyzed partially by Mandelli et al. and reported in 1994. In the present study, we analyzed the results of HSCT in 625 patients in CR (293 in CR1 and 332 in CR2) transplanted between January 1993 and December 2003. In the CR1 group, 149 and 144 patients received an autoHSCT and an alloHSCT, respectively, whereas 195 and 137 patients in CR2 were autografted and allografted, respectively. For the alloHSCT group, only patients with a graft from an HLA-matched sibling were included in the study. The main clinical characteristics of the patients are reported in Table 1.

Owing to the type of study, consisting of a retrospective analysis based on information obtained from the registry, no data were available as to whether or not patients had received ATRA before stem cell transplantation (SCT). Given the considered historic period (1993–2003), however, we assume that most patients in study had been treated with ATRA and chemotherapy, as this was the strategy adopted commonly in most European hematological institutions. Similarly, no information on patient molecular status (reverse transcriptase PCR of PML/RARα) pre- and post-SCT was available.

End points definitions and statistical analysis

Data were analyzed as of 30 June 2005. Median follow-up was 42 months (range 1–132 months).

Four outcomes were studied in this series: (i) TRM was defined as all causes of non-leukemic deaths; (ii) relapse incidence (RI) was defined on the basis of morphological evidence of leukemia in bone marrow, or other extramedullary organs. To evaluate the probability of relapse, patients dying either from direct toxicity of the procedure or from any other cause not related to leukemia were censored; (iii) leukemia-free survival (LFS) was defined as time interval from transplant to first event (either relapse or death in CR); and (iv) overall survival (OS). All outcomes were calculated for CR1 and CR2 patients separately.

Patient or graft characteristics (listed in Tables 2 and 3) were analyzed for their potential prognostic value on each of the outcomes and in each type of transplant (autoHSCT or alloHSCT). For continuous variables, we used either clinically meaningful cut points (interval diagnosis to CR2 less or more than 18 months) or the median as a cut point. Statistical analyses were performed independently for each end point. The incidence of each event was non-parametrically estimated. Probability of OS and LFS were estimated by the product-limit method. The significance of differences between curves was estimated by the log-rank test (Mantel–Cox). Then, all variables were included in Cox proportional hazard model. To have a minimum follow-up period of 18 months, the analysis was performed in June 2005 on patients transplanted until December 2003.

Relapse and non-relapse mortality are mutually competing events. Accordingly, estimations of incidence of these events relied on the non-parametric estimator of cumulative incidence curves, whereas multivariate analyses were based on the proportional hazard model for this subdistribution of competing risks. These analyses were performed using the cmprsk package (developed by Gray, June 2001) on Splus 2000 and SPSS softwares.

Results

Number of HSCT in Europe from 1993 to 2003

Table 1 lists the number of HSCT (auto or allo) for patients in CR1 or CR2. The number of HSCT has decreased progressively for patients in CR1 since 1998; however for those patients transplanted in CR2, it has remained stable until 2002. In 2002 and 2003, there was also a decrease for patients transplanted in CR2.

Autotransplantation

Patients in CR1. The cumulative incidence of TRM and RI at 5 years were 10±3 and 21±4%, respectively. The 5-year estimate of LFS was 69±4% (Figure 1a). Table 2 shows the univariate analysis of variables associated with TRM, RI and LFS. In a multivariate analysis, higher RI was associated with shorter time from diagnosis to transplant (<7.6 months) (HR = 0.32, 95 CI = 0.14–0.75, P = 0.009), and TRM was increased in older patients (>47 years) (HR = 3.7, 95 CI = 1.3–10.5, P = 0.045) (Figure 1b). No risk factor was selected in the model for LFS.

Patients in CR2. For 195 patients transplanted in CR2, the 5-year cumulative incidence of TRM was 16±3% and the RI was 37±4%. LFS at 5 years was 51±4% (Figure 1c). In a univariate analysis, the 5-year estimates of RI and LFS were 31±4 and 56±5% for patients transplanted 18 months after diagnosis compared respectively with 25±7 and 53±6% for those transplanted earlier (Table 2). In a multivariate analysis, only longer time from diagnosis to HSCT (>18 months) was associated with increased LFS (HR = 0.43, 95 CI = 0.27–0.65, P < 0.0001) and decreased RI (HR = 0.42, 95 CI = 0.25–0.71).

Abbreviations: APL = acute promyelocytic leukemia; BM = bone marrow; CR1 = first complete remission; CR2 = second complete remission; CSA = cyclosporin A; HSC = hematopoietic stem cell; HSCT = hematopoietic stem cell transplantation; MTX = methotrexate; PB = peripheral blood; PBSC = peripheral blood stem cells; SC = stem cells; SCT = stem cell transplantation; TBI = total body irradiation.

P = 0.001). No statistically significant risk factor was found to be associated with TRM.

Allogeneic HSCT

Patients in CR1. Acute GVHD II–IV was observed in 30% of the patients (32 patients had grade II, eight grade III and five grade IV) and chronic GVHD was observed in 36% of patients at risk. The 5-year estimates of TRM, RI and LFS for patients were 20.4%, 12.4% and 68.4% (Figure 2a), respectively. Table 3 lists the univariate analysis for 5-year outcomes.

The 5-year estimates of cumulative incidence of TRM and LFS for patients younger than 33 years were 10.4% (Figure 2b) and 78.5%, respectively. There was a trend of lower TRM for patients allotransplanted more than 6 months after diagnosis (Table 3). In a multivariate analysis, recipient age (>33 years) was associated with decreased LFS (HR = 2.25, 95 CI = 1.20–4.20, P = 0.01) and higher TRM (HR = 3.32, 95 CI = 1.38–8.00, P = 0.007). A longer time from diagnosis to HSCT (>6 months) was also an independent factor associated with lower TRM (HR = 0.46, 95 CI = 0.22–0.95, P = 0.036). No risk factor studied was associated with the RI in this setting.

Patients in CR2. Acute GVHD II–IV was observed in 35% of patients (28 patients had grade II, 10 grade III and 11 grade IV) and chronic GVHD was observed in 39% of patients at risk. The 5-year estimate of LFS was 59.4% (Figure 2c). Table 3 lists the univariate analysis of LFS, TRM and RI at 5 years.

Abbreviations: APL = acute promyelocytic leukemia; BM = bone marrow; CR1 = first complete remission; CR2 = second complete remission; HSC = hematopoeitic stem cell transplantation; LFS = leukemia-free survival; RI = relapse incidence; TRM = total body irradiation; TRM = transplant-related mortality; PB = peripheral blood; WBC = white blood cells.

The symbol ± denotes the standard error.

Cumulative incidence of TRM at 5 years was 24 ± 1%. In univariate analysis, cumulative incidence of TRM was 12 ± 4% for allotransplants using peripheral blood stem cells (PBSC) and 31 ± 4% for those using bone marrow cells as a source of hematopoietic stem cells (P = 0.008). There was also significant statistical association of TRM with the period of transplant, that is 15 ± 4% for patients transplanted after 1997 compared with 31 ± 5% for those transplanted before this period (P = 0.03). In a multivariate analysis for TRM, only PBSC transplants were associated with lower TRM (HR = 0.30, 95 CI = 0.12-0.77, P = 0.03).

Cumulative incidence of relapse at 5 years was 17 ± 1%. Results of univariate analysis are listed in Table 3. High white blood cells (WBC) (> median) at diagnosis were a

Abbreviations: APL = acute promyelocytic leukemia; BM = bone marrow; CRI1 = first complete remission; CRI2 = second complete remission; HSC = hematopoietic stem cell; HCT = hematopoietic stem cell transplantation; LFS = leukemia-free survival; RI = relapse incidence; TBI = total body irradiation; TRM = transplant-related mortality; PB = peripheral blood; WBC = white blood cells.

The symbol ± denotes the standard error.
Figure 1: Outcome of patients autografted: (a) LFS in patients autografted in CR1; (b) cumulative incidence of TRM according to age in patients autografted in CR1; and (c) LFS in patients autografted in CR2.

Figure 2: Outcome of patients allografted: (a) LFS in patients allografted in CR1; (b) cumulative incidence of TRM according to age in patients allografted in CR1; and (c) LFS in patients allografted in CR2.

statistically significant factor ($P=0.008$) associated with higher relapse rate (Table 3). In a multivariate analysis, the following factors were associated with decreased incidence of relapse: (i) transplants performed before 1997 (HR = 4.8, 95% CI = 1.8–13, $P=0.002$), (ii) female recipient (HR = 0.30, 95% CI = 0.10–0.84, $P=0.02$) and (iii) female donor to male recipient (HR = 0.14, 95% CI = 0.03–0.55, $P=0.003$). High WBC count was not included in the model due to absence of relapse for those patients with lower WBC count at diagnosis.

Discussion

This survey of the EBMT Group shows that HSCT activity in Europe has decreased progressively since 1998 for...
patients with APL in CR1, whereas the number of patients transplanted in CR2 has remained stable over the study period. In addition, the data from this survey confirms a surprisingly low LFS in allo- and autoHSCT groups, as well as a lower TRM and a higher RI in autoHSCT than in alloHSCT. According to the type of transplant, we were also able to find certain risk factors for outcomes such as age, time from diagnosis to transplant, year of transplants, source of stem cells and donor gender.

The first objective of our study was to perform a survey on the results of HSCT for APL patients in the ATRA era. To our knowledge, no studies including large series of patients with APL receiving an auto- or alloHSCT have been reported after the first EBMT survey published in 1994 by Mandelli et al. when ATRA was not yet used in the majority of the European centers. When we planned the present study, we did not expect to discover such a high number of patients with APL still transplanted after 1993, a number equivalent to those transplanted before 1993 (over a similar period of time), which at that time included mostly patients treated with only chemotherapy.

Although we were unfortunately unable to obtain complete data relative to pre-transplant treatments in the registry, it is conceivable that most patients here analyzed had received modern ATRA-containing regimens pre-HSCT. In fact, the present study included patients transplanted after 1993, when front-line ATRA therapy was adopted for both newly diagnosed and relapsed APL in most European Centers. However, we have observed that the number of patients transplanted in CR1 with an auto- or alloHSCT has decreased progressively since 1998, whereas the number of patients transplanted in CR2 has remained quite stable but with a decrease in 2003, probably reflecting the adoption for these patients of other therapeutic strategies such as arsenic trioxide (ATO). Although the justification for transplanting patients in CR2 is quite obvious, it is unclear why patients with APL were transplanted in CR1. However, those transplants were performed mostly during the earlier years after the introduction of ATRA-based regimens, whereas only few patients in CR1 are currently transplanted, in particular those showing persistent molecular disease after front-line consolidation.

Compared with the previous EBMT survey, the present EBMT study shows a higher LFS, confirming a quite similar final outcome in allo- and autoHSCT groups. This similar final outcome seems related to a significant reduction of TRM in the last years (8% in autoHSCT and 17% in alloHSCT) and to the counterbalance between the higher RI and TRM rates observed in the auto- and alloHSCT groups, respectively. In addition to some improvement over time, these better results may be related to the wide use of ATRA pre- and/or post-transplant.

Our second objective was to analyze risk factors for outcomes, mainly TRM, RI and LFS for patients receiving either auto- or alloHSCT in CR1 and most importantly in CR2. As expected, in first CR, patient's age, that is younger than 33-years old, was the most important factor associated with decreased TRM in both auto- and alloHSCT settings.

Therefore, the option of alloHSCT should be considered seriously for younger patients in CR1 with persistent molecular disease after consolidation, whereas for older patients who test PCR-positive at this time point, other treatment options, such as ATO or gemtuzumab-ozogamicin may be considered.

In CR2, both approaches also produced reasonably good results. In the autoHSCT setting, LFS at 5 years was 51% for the entire study period and more than 60% after 1997. Importantly, patients with longer CR1 duration (diagnosis to transplant >18 months) had a better LFS and a lower RI. This observation makes sense because patients relapsing early are more likely to having received autografts still contaminated by tumor cells. Indeed autografting is recommended presently in APL patients in CR2 only if disappearance of minimal residual disease by PCR has been documented. Nevertheless, some investigators have proposed that the role of autoHSCT to consolidate high-risk patients (i.e. with hyperleucocytosis) should be investigated. Unfortunately, in our retrospective study, which was based on data from a registry, no information was available about the PML/RARA molecular status of the graft and/or of patient bone marrow at transplant. In addition, other relevant information was neither available, including the type of previous front-line nor salvage therapy used, the reason for the indication of transplant in CR1, as well as the type of transplant, among others.

For APL patients with an HLA-identical sibling, alloHSCT continues to be recommended in most centers as the treatment of choice for patients in CR2. We have found that the use of PBSC was associated with decreased TRM as compared to bone marrow. This finding is in agreement with the results of randomized studies comparing bone marrow and PBSC transplants, which showed better results for PBSC in patients transplanted with more advanced disease. Interestingly, decreased RI was associated with a female donor to male recipient suggesting a graft-versus-leukemia effect mediated probably by minor H-Y antigens. Of note, we have observed that a higher WBC count at diagnosis was also an important risk factor for increased RI after autotransplantation. Another interesting finding is that post-transplant RI has increased after 1997, probably reflecting a selection of patients with more aggressive disease relapsing after receiving state-of-the-art front-line regimens.

In conclusion, the present study indicates that HSCT has been decreasing over the years for patients with APL in CR1 in Europe, but it has continued to be part of the treatment strategy for patients in CR2. The data from this survey indicates that, in spite of the favorable results with both auto- and alloHSCT (LFS around 70% at 5 years), HSCT should no longer be used to consolidate CR1 in patients with APL treated with modern ATRA plus chemotherapy regimens. Only selected and young patients with persistent molecular disease can probably benefit from this approach. Likewise, our results show that a high proportion of patients in CR2 achieve long-term OS after auto- and alloHSCT, and both procedures represent valid therapeutic options in this setting. The choice of one or other procedure will depend on the availability of an HLA
identical donor and the time from diagnosis to transplant. Finally, in the near future, HSCT results will need to be compared with long-term results of other therapeutic options for APL relapse such as ATO and gemtuzumab ozogamicin, which have provided promising outcome data in small series with limited follow-up.

Combination Chemotherapy Versus Melphalan Plus Prednisone as Treatment for Multiple Myeloma: An Overview of 6,633 Patients From 27 Randomized Trials

By the Myeloma Trialists' Collaborative Group

Purpose: To compare combination chemotherapy (CCT) versus melphalan plus prednisone (MP) as treatment for multiple myeloma.

Patients and Methods: In a collaborative worldwide overview of randomized trials of CCT versus MP, individual patient data on 4,930 patients from 20 trials were analyzed, with the addition of published data on a further 1,703 patients from seven trials. The main outcome measure was mortality, with response and recurrence rates being subsidiary end points.

Results: Taking all of the trials together, response rates were significantly higher with CCT than with MP (60.0% v 53.2%; P < .00001, two-tailed). There was no evidence of any difference in mortality between CCT and MP, and with a nonsignificant 1.5% reduction in death rate in favor of CCT (P = .6, two-tailed). There is heterogeneity of design between the trials, but subgroup analyses by type of CCT or by dose-intensities of CCT, of melphalan, or of prednisone did not identify any particular forms of therapy that were either clearly beneficial or clearly adverse. Similarly, analysis of the presentation features of the patients did not find any categories in which CCT differed significantly from MP in its effects on mortality; in particular, there was no evidence that poor-risk patients benefited more from CCT.

Conclusion: This overview found no difference, either overall or within any subgroup, in mortality between CCT and MP. In terms of survival, those therapeutic options, as tested in the trials considered, are approximately equivalent.

For many years, the standard induction chemotherapy for patients with multiple myeloma has been melphalan and prednisone (MP). In an attempt to improve the outcome of these patients, many randomized trials have compared MP with combination chemotherapy (CCT) regimens that contain three or more drugs. A meta-analysis of the published data from some of these trials has been performed, but such reviews of the published literature have important limitations. The Myeloma Trialists' Collaborative Group therefore sought to increase the reliability of the evidence on the comparative efficacy of these two treatments by performing an overview using the individual patient data from all of the randomized trials of MP versus CCT.

Patients and Methods

Trials in which patients were randomly allocated to CCT versus MP were searched for extensively by computer-aided search of publications and clinical trial data bases, with search of meeting abstracts, by scrutiny of reference lists of trials and review articles, and by communication with trialists and pharmaceutical companies. This was done as part of a wider overview of all treatments for myeloma. A limited amount of data was sought for each patient randomized in all relevant trials that began before 1990. Trials were excluded if they were found not to be properly randomized—for example, if the allocation method allowed foreknowledge of the treatment that would be assigned if the patient were to be entered onto the trial (eg, date of birth, day of week of entry).

The diagnostic data requested for each randomized patient were as follows: patient identifier, date of diagnosis, date of birth (or age at randomization), sex, Durie-Salmon stage, hemoglobin level, platelet count, WBC count, β2-microglobulin level, M-band type, creatinine concentration, calcium and albumin levels, presence of bone lesions, and performance status. The event data requested were as follows: date randomized, allocated treatment, type of response (complete, partial) and date of response, achievement date of plateau phase, recurrence and its date, current status (alive, dead), and date of death or date of last follow-up evaluation. Data were checked for consistency with any publications, for internal inconsistencies, for balance between treatment groups and for the exclusion of randomized, or the inclusion of nonrandomized, patients. Any apparent problems were referred to the responsible trialists for clarification, so that errors and omissions could be rectified as fast as possible. Summary tables of the results for each trial used in the overview were supplied to the trialists for checking, and a draft of the present report was circulated to each trial group for their comments and to ensure that the results used for their trial were correct.

Standard statistical methods were used. Observed minus expected (O−E) number of events in each treatment group was calculated, and its variance (V) was calculated for each separate trial by means of log-rank survival analysis using the exact dates of any events. These quantities, one per
Trial, are then summarized for all trials to give two grand totals. This ensures that patients within a trial are directly compared only with other patients in the same trial, and not with those in other trials. The grand totals are then used to calculate odds ratios (OR), odds reductions (where an OR of 0.99 would correspond to an odds reduction of 10%) and their 95% confidence intervals (CIs). Tests of heterogeneity or trend are used to examine differences in treatment effect between trials and between different subgroups of patients. However, such tests of heterogeneity are statistically insensitive and so their results must be interpreted cautiously.

The few trials from which individual patient data were not available (Table 1) are not included in the survival curves, since time to event was unknown and it was not possible to perform log-rank survival analyses. Moreover, since information on prognostic factors, or on end points

other than death, was also not generally available from these trials, it has not been possible to use them in any of the stratified analyses or in analyses of subsidiary end points. Instead, where possible, tabular data on the number of patients and deaths in each arm have been obtained from publications and are used solely in the overall analyses of mortality.

The main analyses presented are of mortality from the date of randomization, either unstratified or stratified by various prognostic factors. In addition to mortality, subsidiary analyses of response rates (complete and/or partial) and recurrence were performed for trials with individual patient data. The criteria for response for each trial were those used by the group responsible for the trial.

Where sufficient information was available, dose-intensities were calculated for the CCT and MP regimens in each trial (Table 1), using a method similar to that of Heynrick and Buth.

Calculation of Dose-Intensities

As in the published data meta-analysis by Gregory et al., the Southwest Oncology Group (SWOG) 7704/7705 regimen of vincristine, melphalan, cyclophosphamide, and prednisone (VMP)/vincristine/carmustine (BCNU), doxorubicin, and prednisone (VBAP) was used as the standard for CCT. Therefore, standard dose-intensities for individual drugs were considered to be as follows: doxorubicin 5 mg/m²/wk, BCNU 5 mg/m²/wk, cyclophosphamide 167 mg/m²/wk, lomustine (CCNU) 12.5 mg/m²/wk, melphalan 4 mg/m²/wk, prednisone (or prednisolone) 80 mg/m²/wk, and vincristine 0.5 mg/m²/wk. Dexamethasone was assumed to have an intensity of 6.7 times that of prednisone, and methylprednisolone to have an intensity of 1.25 times that of prednisone (British National Formulary, 32, 1996). For each drug, the dose-intensity was calculated in milligrams per square meter per week by calculating the total dose given over the first 24 weeks and dividing this by 24. These values were compared with the standard dose-intensities described above. Each drug was assumed to be equally efficacious, so each standard dose was given a value of 1 unit per week. Overall standard dose-intensities for both the CCT and MP regimens were calculated by summing the intensities for each drug. The route of administration for drugs such as cyclophosphamide and melphalan was assumed not to affect the intensity of the treatment.

RESULTS

Trials and Patients

Thirty trials that compared CCT versus MP were identified, involving 6,633 patients. Details, including drug dosages, duration, method of administration, and timing, are given in Table 1, in chronologic order of starting date, with each trial being given a unique reference that consists of the start year plus an arbitrary character (eg, 84A, 86D). Individual patient data were supplied from 20 of the trials (4,930 patients). Published data were abstracted for seven of...
Fig 1. Mortality in trials of CCT v MP. Large squares indicate larger trials that provide more information, and hence have narrower 95% CI. If the square is to the left of the solid line, then survival is better in the group allocated CCT, but if the CI crosses this line, then this result is not statistically significant at P < .01 (2-tailed). Open boxes indicate trials for which only published data were used. Totals are represented as diamond centroids on the OR estimate, with 95% CI shown by the width of the diamond and with the odds ratio also given as a percentage along with its standard deviation (SD). Two totals are shown, 1 for the individual patient data (IPD) and 1 including published data, with similar odds reductions in both cases.

the remainder (1,703 patients), which left only three trials with no data available. Table 2 lists the presentation features of the 4,930 patients with individual data supplied. Continuous variables (eg, hemoglobin, platelets) were grouped (to some extent with arbitrary cutoffs) into a small number of categories for the purpose of analysis.

Overall Survival

Figure 1 shows the mortality results of each trial and Fig 2 shows, for those trials that provided individual patient data, the survival curve. Overall, there is no significant difference in survival between patients allocated to CCT or MP (P = .6, two-tailed). The point estimate for the proportional reduction in the annual odds of death is 1.5% in favor of CCT, but the 95% CI is 0.92 to 2.1%, which is statistically significant at P = .01.

1.04) and those for which published data were used (OR, 1.03; 95% CI, 0.83 to 1.25; test for interaction: \( \chi^2 = 0.2, P = .7 \)).

There is clearly considerable heterogeneity between the therapies tested within the trials: the drugs and their doses within the CCT regimens vary greatly, and the doses of melphalan and prednisone within the MP regimens also differ between trials. Furthermore, the patient populations recruited to the various trials will have differed (eg, some trials included younger patients and other trials older ones; and some trials excluded stage 1 patients). Hence, within the overall null result there might be particular types of CCT that are either more or less effective, particular MP regimens that are better than others, or specific subgroups of patients for whom either CCT or MP is preferable.

To assess possible differences between CCT regimens, the trials were subdivided in various ways (Fig 3). Cut-off points between higher and lower dose categories were selected so that about half the trials were in each group. The cut points were: CCT dose-intensity, < 4.0 vs 4.0; melphalan dose,
come, e.g., increasing age, higher Durie-Salmon stage, low hemoglobin level, high creatinine concentration, and high β₂-microglobulin level. Relatively complete information was provided on all of these except the latter. Table 2 lists the survival of the individual data patient population by the various prognostic factors. Subgroup analyses of the trials by these prognostic factors shows no reliable evidence that, for any parameter, there is a group of patients that benefited more, or less, when allocated to CCT (Fig 4). In particular, there is no evidence to indicate that high-risk patients benefit from CCT.

In Fig 2, it appears that CCT is associated with a slight disadvantage during the first year and a slight advantage thereafter. Formal analyses of mortality by time period show a nonsignificant adverse effect of CCT in the first year after randomization (O - E = 28, V = 303; \( P = .1 \), two-tailed) and a nonsignificant benefit for CCT after the first year (O - E = -44, V = 618; \( P = .07 \), two-tailed). This leads to a conventionally significant interaction between the results in these two time periods (\( P = .02 \)), but this data-derived comparison is not extreme enough to demonstrate any real difference between the shapes of the survival curves.

DISCUSSION

Thirty randomized trials that compared CCT with MP for the treatment of multiple myeloma have been identified. Individual patient data were supplied for 20 of these, which represents approximately 75% of the randomized patients identified. It was possible to extract mortality information from publications for seven of the remaining 10 trials, although these data should be regarded as less reliable, given the limitations that have been demonstrated for the use of such data in other reviews.²

Patients allocated to CCT experience higher response rates than those allocated to MP. The incompleteness of the data available for this end point means that this result should be interpreted with caution. Furthermore, there is no difference in response duration between responders in the CCT and MP groups, and yet the better response rate with CCT does not lead to a survival benefit.

Overall, there is no significant difference in mortality between CCT and MP and the large number of patients...
analyzed makes it likely that if there really is any difference, it will be small and not clinically important. It is possible that this overall null result may conceal differences related to particular types of CCT or MP regimens, or to different types of patient, but investigation of these possibilities within this review did not show any particular subgroups of trials or patients in which the findings were definitely different from the overall result.

Because the MP arm consistently contained only two drugs, it is possible to calculate dose-intensities in a reasonably meaningful way. There was no suggestion that more intensive MP arms were any more, or less, beneficial than less intensive ones, although obviously the comparative dose-intensity of the CCT arm within each trial needs to be taken into account.

Assigning comparative dose-intensities to a heterogeneous set of CCT arms is difficult, but an attempt to do this, if only crudely, produced no evidence of any difference. Given the difficulties of investigating dose-intensity in the CCT arms, it is more informative to group similar CCT regimens together to see if they are more effective than MP. Clearly some types of CCT must be better than others, but identifying them with any certainty is difficult. Three categories of CCT (VMCP + VBAP/VCAP, VMP and

Fig 4. Mortality in trials of CCT vs MP, by presentation features. Format as in Fig 1.

![Fig 5. Response duration in trials of CCT vs MP. Format as in Fig 2.](image-url)
VBCMP) appeared slightly better than MP, while three categories (other anthracycline regimen, VMCP and MOCCA) appeared worse. However, it is not possible with the available evidence to decide which, if any, of these are real effects and which are simply due to the play of chance.

Two further trials had designs that are relevant when assessing the role of CCT. A trial of ABCM versus melphalan alone showed a benefit for ABCM, while a trial of VMCP versus cyclophosphamide plus prednisone did not demonstrate a significant difference. Since it is not known whether melphalan alone is as effective as MP or whether cyclophosphamide is equivalent to melphalan, these two trials were not included in the analyses reported here. Even if they had been, the mortality difference would have remained nonsignificant (odds reduction, 4%; 95% CI, -10% to +2%).

This overview also demonstrates that, with an appropriate analysis of different patient groups using individual patient data, there is no evidence that CCT is more beneficial to survival than MP in higher risk patients, but less effective in lower risk patients. This is contrary to the previous meta-analysis of published data.

CCT has evolved, especially with respect to high-dose therapy; and it is possible that some of these newer regimens are more effective than MP; but until randomized trials of these combinations are reported, this review provides the most reliable evidence currently available on the relative value of CCT and MP.

Interferon as therapy for multiple myeloma: an individual patient data overview of 24 randomized trials and 4012 patients

THE MYELOMA TRIALISTS' COLLABORATIVE GROUP Secretariat based at Imperial Cancer Research Fund/Medical Research Council Clinical Trial Service Unit, Radcliffe Infirmary, Oxford, UK

Received 22 December 2000; accepted for publication 16 February 2001

Summary. Many randomized trials have evaluated α-interferon as myeloma therapy, some suggesting a benefit and others not. Most were too small to give reliable answers, so a systematic overview has been performed to provide a more reliable estimate of the effect of interferon. The main end-points were response rates (induction trials), progression-free survival (PFS) and overall survival (OS). Individual patient data were supplied for 24 trials involving 4012 patients, 12 induction trials (2469 patients) and 12 maintenance trials (1543 patients). In induction, response rates were slightly better with interferon (57.5% versus 53.1%, P = 0.01), PFS was better with interferon (33% versus 24% at 3 years, P < 0.00001), an effect seen in both induction (P = 0.0003) and maintenance (P < 0.00001) trials. Median time to progression was increased by about 6 months in both settings. OS was somewhat better with interferon (53% versus 49% at 3 years, P = 0.01) with median survival increased by about 4 months. This benefit was restricted to the smaller trials. The effect of interferon was not significantly related to the dose or duration of interferon or to patients' characteristics. PFS was improved with interferon, but the survival benefit, if any, was small and needs balancing against cost and toxicity.

Keywords: myeloma, interferon, response, progression, survival.

Although patients with multiple myeloma may respond at first to induction chemotherapy, most will eventually suffer progression and death from the disease, irrespective of whether single-agent or combination chemotherapy is used (Myeloma Trialists' Collaborative Group, 1998). In vitro, α-interferon (IFN) has an anti-proliferative effect on myeloma cells (Cooper & Welander, 1987), and there have been many randomized trials of its addition to induction chemotherapy or of its use as maintenance therapy for patients who have already responded to their initial cytotoxic treatment (Bataille & Harousseau, 1997). The majority of these trials have been too small to give reliable answers when taken alone. Most individual trials have not reported a significant improvement in survival, showing that IFN does not have a substantial effect on survival. It might, nevertheless, have a moderate, but still clinically meaningful, benefit (cf. tamoxifen as adjuvant therapy for breast cancer; Early Breast Cancer Trialists' Collaborative Group, 1998). To determine reliably whether or not this is the case, a systematic overview ('meta-analysis') of all available trials is needed. This should preferably involve a central review of the data on each individual patient in each of the trials, not just the review of the published results from those trials (Stewart & Parmar, 1993; Clarke & Godwin, 1998; Fritz & Ludwig, 2000). We report such an overview.

PATIENTS AND METHODS

Standard procedures for overviews based on individual patient data (IPD) were followed (Stewart & Clarke, 1995). Trials in which patients with myeloma were randomized to interferon versus no interferon in either the induction or maintenance phases of therapy were sought in registers and databases [the Cochrane Controlled Trials Register, PDQ (Physician Data Query), MIDLINE and EMBASE]; in abstracts of haematology or oncology meetings; by scrutiny of reports of trials and review articles; and by contact with individual trialists, trial groups and pharmaceutical companies. The cut-off for trial identification was mid 1997.

Baseline data were requested for each randomized patient on date of diagnosis, date of birth (or age), sex, Durie-Salmon stage (Durie & Salmon, 1975), haemoglobin,

*Response criteria were those used by each group.
References for each trial are listed in the Appendix.

platelets, white blood count, $\beta_2$-microglobulin, M-band type, creatinine, calcium, albumin, bone lesions, performance status, date of randomization and allocated treatment (data were not available for other parameters, e.g. cytogenetics, C-reactive protein, plasma cell labelling index).

The data requested on events after randomization were type (complete or partial) and date of response, progression and its date, most recent status (dead or alive) and date of death or date of last follow-up. The data were checked for obvious inconsistencies and were amended as necessary through correspondence with the responsible trialists. The data used in the analyses were confirmed with the responsible trialists. This manuscript was circulated to all relevant trialists and amended in the light of their comments.

**Statistical methods.** All analyses presented are by allocated treatment (intention to treat). The main statistical methods for combining trials are described in detail elsewhere (Early Breast Cancer Trialists' Collaborative Group, 1990). To summarize, the number of events observed (O) in the interferon group of each trial is compared with the number expected (E) if the events in that trial had been equally distributed between the interferon and no interferon groups. The difference between these numbers, O - E, and its variance yields the log-rank test for each trial. The individual patient data allow these statistics to be calculated using the exact dates of events, which is more statistically reliable and clinically informative than basing the calculations on proportions alive at a particular point in time (Stewart & Parmar, 1993). The sum of the statistics for each trial provides the overall statistics, which are then used to calculate reductions in the odds of death. All P-values are two-tailed. Analyses were first performed in October 1997, with updated analyses over the subsequent few months as data queries were clarified.

The main end-points analysed were: (i) overall survival, (ii) complete response (CR) and complete plus partial response (PR) rates, for induction trials, (iii) progression-free survival, defined either as the time from response to recurrence (in induction trials) or as the time from randomization to recurrence or progression (in maintenance trials) ignoring (i.e. censoring at) death without recurrence or progression, and (iv) survival from progression. The criteria for CR, and PR, were those used in each individual trial. Response duration was also analysed, and was defined in the same way as progression-free survival except that deaths without recurrence were included as events.

**RESULTS**

**Trials and patients**

Fig 1. Progression in trials of interferon (IFN) versus none. Large squares indicate trials that provide more information and hence have narrower 95% confidence intervals (CI). If the square is to the left of the solid line then progression-free survival is better in the group allocated IFN, but if the CI crosses this line then this result is not statistically significant ($P < 0.01$). An arrow at the right-hand end of the CI indicates that the CI extends further than the plotting area. The subtotals for induction and maintenance trials separately and the overall total are represented as diamonds centred on the odds ratio (OR) estimate, with 95% CI shown by the width of the diamond and with the odds reduction also given as a percentage along with its standard deviation (SD). Vertical dotted lines show the overall odds ratio estimate, i.e. the centre of the diamond. References for each trial are listed in the Appendix.

identified, involving about 4900 patients. Details of these are given in the Appendix. In some of the induction trials, interferon was continued into the maintenance phase (see Appendix). Individual patient data were supplied from 23 trials (4066 patients): 12 in induction (2469 patients) (Prest et al., 1989; Montuoro et al., 1990; Corrado et al., 1991; Atchison et al., 1993; Österborg et al., 1993; Capniet et al., 1994; Ludwig et al., 1995; The Nordic Myeloma Study Group, 1996; Joshua et al., 1997; Oken et al., 1999; GMM(I), Mexico trial, unpublished observations, presented as an
abstract at the IV International Workshop on Multiple Myeloma, 1993; KJR Avicenne trial, unpublished observations; poster 5-1, presented at the VI International Workshop on Multiple Myeloma, Boston, 1997). 12 in maintenance (1543 patients) (Aviles et al. 1991; Capristi et al. 1994; Salmon et al. 1994; Broman et al. 1995; Ludwig et al. 1995; Feest et al. 1995; Westin et al. 1995; Grosbois et al. 1997; Bladé et al. 1998; Cunningham et al. 1998; Drayson et al. 1998; Pulsori et al. 1998) and one in refractory and relapsed disease (54 patients: as these small numbers do not permit reliable analysis, this trial is not considered further) (Gertz et al. 1995). Table I summarizes the presentation features of the 4012 patients in these induction and maintenance trials. There was generally good balance across treatment arms.

Response
Both complete response and complete plus partial response rates were slightly, but significantly, better with IFN (Table II).

Outcome after response
For patients who responded in induction trials, the response duration was significantly better with IFN than without (30% versus 25% at 3 years, log-rank \( P = 0.0005 \)). Similarly, for all patients in maintenance trials, response duration was better with IFN than without (27% versus 19% at 3 years, log-rank \( P < 0.00001 \)). For induction and maintenance trials together, response duration at 3 years was 28% with IFN and 20% without (log-rank \( P < 0.00001 \)). Among those who had not yet suffered disease progression, the death rates (expressed as deaths/person-years) did not differ significantly between the IFN and control groups: 5% versus 6% in induction trials (\( P = 0.7 \)) and 3% versus 4% in maintenance trials (\( P = 0.5 \)). There was, however, a definite effect of IFN on time to progression (censoring at death without progression) (Figs 1 and 2), both in induction trials (\( P = 0.0003 \)) and in maintenance trials (\( P < 0.00001 \)). Median time to progression was increased with IFN by about 6 months in both groups of trials, with large reductions in the risk of progression both in year 1 and in year 2 (odds reductions: 35% (SD 5) and 38% (SD 7), respectively, both log-rank \( P < 0.00001 \)). There was no evidence of any additional benefit beyond year 2, but there was also no evidence that the early benefit was lost (odds increase 2% (SD 12), log-rank \( P = 1.0 \)), based on analysis from the start of year 3.

Survival from progression
Overall, survival from progression was worse for patients who had been allocated IFN than for control patients (22% versus 26% 3 years later, log-rank \( P = 0.02 \)). Although this was significant only in the maintenance trials (odds ratio 1.21, \( P = 0.07 \)) and not in the induction trials (odds ratio 1.04, \( P = 0.6 \)), this apparent difference between these two groups of trials could well be largely or wholly owing to

Fig 3. Mortality in trials of interferon (IFN) versus none. Format as Fig 1.

---

chance, as there was no significant heterogeneity between the two results ($P = 0.2$).

**Overall survival**

Survival was significantly [odds reduction 10% (SD 4), log-rank $P = 0.01$] improved with IFN (Figs 3 and 4). Although there was not a statistically significant benefit in the induction trials [odds reduction 8% (SD 5), log-rank $P = 0.1$], while there was in the maintenance trials [odds reduction 12% (SD 6), log-rank $P = 0.04$], there was again no significant heterogeneity between these two results ($P = 0.5$). Increases in median survival of about 2 and 7 months were observed in the induction and maintenance trials, respectively, with overall an increase of about 4 months.

**Subgroup analyses**

Subgroup analyses were performed to explore whether the benefit of IFN was greater for some patients than for others, and whether IFN was superior in particular therapeutic situations.

Types of patient
The relative benefit of IFN on time to progression for the 12 presentation parameters listed in Table I is shown in Fig. 5. There was no evidence, from any of these variables, that the benefit of IFN was importantly greater or worse in either good- or poor-risk patients. When the induction and maintenance trials were analysed separately, there was similarly no evidence of important differences between types of patient in their response to IFN within either category of trials. Nor was there evidence of heterogeneity between patient groups with respect to survival, either overall or within induction and maintenance trials separately (data not shown). In the maintenance trials, there was no evidence that the benefit of IFN differed between patients who were in CR, in PR or who had stable disease at the time of randomization (Fig 6).

Type of therapy
The trials can be grouped by certain features of their designs: for example, dose of IFN, duration of IFN, and type of concurrent or prior chemotherapy. This yielded no significant heterogeneity with respect to progression (Fig 7), or with respect to response rate (in the induction trials) or overall survival. There was one feature of the trials that produced a substantial trend, namely that the magnitude of the benefit of IFN on mortality was much greater in small trials than in larger ones (Fig 8), with no clear benefit for IFN in the latter. Similarly, there was a trend for the effects of IFN on progression-free survival to be better in the smaller trials, although there was still a significant benefit in the larger trials (Fig 8).

Trials for which individual patient data were not supplied
It was possible to extract data on response rates from reports of a further five trials (Cooper et al., 1993; Aviles et al., 1995; Rome IFN2 and Spanish Coop Group trials, unpublished observations, presented as abstracts, p299 and p301, at the 24th Congress of the International Society of Haematology, London, 1992; Buenos Aires trial, unpublished observations, presented as an abstract, p321, at the 18th International Congress of Chemotherapy, Stockholm, 1993). For two of which an estimate of the survival benefit could also be made. Inclusion of these data did not materially alter the results, with the benefit of interferon on both response rates and overall survival becoming slightly greater.

DISCUSSION
Overall effect of interferon
This overview of 24 randomized trials, using individual patient data, does demonstrate some clinical benefit for interferon as a treatment for myeloma. Response rates were slightly better when interferon was used during induction treatment (although the definition of response varied between studies, this analysis is valid as patients allocated interferon are only compared with controls in the same

trial). Also, in both induction and maintenance trials, progression of the disease was delayed. Once progression did occur, subsequent survival was slightly worse in those previously given interferon, so the effect on progression was greater than the effect on survival. Overall therefore, there was at most only a small survival benefit.

There is a suggestion that the progression-free survival curve for the interferon arm might be showing a plateau consistently above that in the control arm (Fig 2), but the number of patients at risk beyond 3 years is still relatively small and longer follow-up will be required to determine reliably whether this really is the case. There is currently no apparent plateau in the survival curve (Fig 4).

The results presented here, based on intention-to-treat analyses of all randomized patients, will underestimate the true potential benefit of interferon as there will have been a

degree of non-compliance with allocated treatment. However, this has the advantage that it represents the situation in regular clinical practice in which, inevitably, some patients will stop taking a drug that has side-effects.

A recent meta-analysis based on published data (Pritz & Ludwig, 2000) showed similar results to those reported here, with estimates of a 6.6% better response rate with interferon and median improvements of 4-6 months in relapse-free and 3-7 months in overall survival respectively (cf. 4-6%, 6 months and 4 months, respectively, in the present report). IPD overviews are much more time-consuming and labour-intensive than published data meta-analyses, but have a number of advantages. These include being able to assess trial quality, to include all randomized patients, to use updated data with longer follow-up, to investigate effects over time, to allow more

### Overview of Interferon Therapy for Myeloma

Fig 7. Progression in trials of interferon (IFN) versus none by scheduled dose and duration of interferon. Format as Fig 1. The cut-off points between higher and lower dose categories were selected so that about half the trials were in each group.

Fig 8. Effect of trial size on effect of interferon (IFN). Format as Fig 1. Trial size was defined by the variance obtained in the mortality analysis (with the number of deaths in parentheses): very small = 0–9% (30–39); small = 10–19% (40–50); medium = 20–39% (50–69); large = 40–49% (70–99).

Flexibility of patient subgroup analyses, to permit a consensus paper approved by all relevant trialists and, in this case, to use more standard meta-analysis methods.

A tendency for the smaller trials to indicate a greater survival benefit has also been seen in clinical trials in other diseases (CLASP Collaborative Group, 1994; Fourth International Study of Infarct Survival Collaborative Group (ISIS-4), 1995). The reasons are unclear, but one possible explanation is that there is a publication bias in which unreported results from small trials never got reported, while promising ones do (Egger et al., 1997). We have vigorously sought to identify, and obtain data from, unpublished studies and so this seems unlikely to be a substantial source of bias. Another potential source of bias in smaller trials is less rigorous application of appropriately strict randomization procedures, but as protection against this we have obtained and extensively checked individual patient data from each trial without finding any indication of problems. Inclusion of published data from the five induction trials without IPD did not change the results or their interpretation in any important fashion. Two of the three maintenance trials with no data available were more recent studies that were still open, so this reason for exclusion is unlikely to introduce a bias. If there is any publication bias, or if the smaller studies are for some reason less reliable, then the true survival benefit for interferon would be even less than that observed, and there might actually be little or no benefit. This effect of trial size is the only factor identified that might explain some of the heterogeneity observed between trials (Fig 1), as there are no clear differences in the effect of interferon between patient types and trial designs (see below).

Effect of interferon in different types of patient
Although the overall benefit of interferon is relatively modest, there might be recognizable subgroups of patients who gain larger or smaller benefits from interferon. Twelve prognostic factors have been investigated, but there was no evidence that the benefit of interferon differed substantially between types of patients. In particular, there was no evidence that good-risk patients obtained a greater benefit than poorer-risk ones, or that patients in complete response at the time of maintenance randomization benefited more than those in partial response or with stable disease. With multiple comparisons being performed, it is probable that the effect of IFN will appear larger or smaller in some subgroups simply owing to the play of chance. It cannot therefore be concluded that patients with high β2-microglobulin or light

*Overview of Interferon Therapy for Myeloma, 1013*
chain disease (both relatively small subgroups, with wide confidence intervals that overlap the overall effect estimate) obtain greater benefit from IFN.

**Effect of trial design**

The trials included in the overview differed substantially in their design and there was evidence of heterogeneity between trials with respect to the effect of interferon. It was not, however, possible to reliably identify any aspect of study design that materially affected the size of the benefit of interferon. The use of interferon in induction led to a prolongation of response duration among patients who achieved a response (either partial or complete), as did its use in maintenance among all patients entered. Although the survival benefit for induction trials was not statistically significant (P = 0.1), while that for maintenance trials was of borderline significance (P = 0.04), this does not provide good evidence that the survival benefit is restricted to the maintenance setting, as there was no significant heterogeneity of benefit between the induction trials and the maintenance trials. There was no evidence that the scheduled dose or duration of interferon was important.

Only one maintenance trial used interferon after high-dose therapy (Cunningham et al., 1998). The point estimate result for this one trial (32% odds reduction for progression) was consistent with the overall effect in the maintenance setting (34% odds reduction). This trial was, however, small with wide confidence intervals (95% CI: 74% odds reduction to 10% odds increase), so a greater, or indeed lesser, benefit for interferon in the context of high-dose therapy compared with other forms of chemotherapy cannot be ruled out. More randomized evidence is needed if this issue is to be addressed reliably and the results of a large ongoing intergroup trial in the USA are awaited.

**Other factors**

Interferon is an expensive drug and can have substantial side-effects that adversely affect a patient’s quality of life. One study estimated a cost of S110 000 per quality-adjusted life-year gained (Nord et al., 1997). Information on side-effects was not collected for this overview, but the relatively large Nordic trial of interferon during induction did include a quality-of-life assessment (Wisloff et al., 1996), which showed an adverse impact of interferon during the first year of treatment. Against this must be set the fact that interferon keeps patients progression-free for longer and therefore free of the symptoms of myeloma, which may (at least for a time) improve the patients’ quality of life, although the Nordic quality-of-life study did not find a late benefit. A survey of myeloma patients (Ludwig et al., 1997) showed that approximately half the patients interviewed would be willing to tolerate the side-effects of interferon if it improved progression-free or overall survival by 6 months.

**CONCLUSION**

This overview shows that interferon delays disease progression and that, even after several years, there still
appears to be a persistent reduction in the likelihood of having suffered recurrence. If this does eventually translate into a real difference in mortality, then it is possible that a few more years of follow-up of these same trials and an updated overview of them may yield a much more definite mortality advantage than is indicated by the current survival analyses. Until such evidence becomes available, the current analysis shows only a small survival benefit, if any, and decisions as to whether to use interferon or not will need to balance a modest clinical benefit on progression and mortality against cost and toxicity.

ACKNOWLEDGMENTS

Leukemia advance online publication, 29 May 2008; doi:10.1038/leu.2008.127

Introduction

There are approximately 20,000 new patients diagnosed with myeloma in the United States each year.1 With the availability of better treatments and resultant improved survival, there are currently close to 100,000 patients living with myeloma in the United States. Similar incidence and prevalence rates exist throughout Europe.2 Of these patients, the spine is affected by osteolytic and/or osteoblastic bone disease in 70%.3 Myeloma is the commonest primary cancer affecting the spine. Painful vertebral compression fractures (VCFs) affect approximately 30% of myeloma patients. As myeloma patients live longer, it is especially relevant to provide the best available treatment for pain and reduce disabilities that can result from VCFs.4

The focus of this summary is to assess the role of minimally invasive percutaneous injection of polymethyl methacrylate (PMMA), first developed as ‘vertebroplasty’ in France in the late 1980s. Considerable experience accrued, especially in Europe, with the use of vertebroplasty as treatment for painful VCFs. The fractured bone fragments are stabilized and strengthened by PMMA and pain is substantially improved. A more recent modification of vertebroplasty is percutaneous balloon kyphoplasty whereby inflation of a balloon prior to PMMA injection can restore vertebral height and reduce kyphotic deformity in addition to stabilizing the fractured vertebral body.

The first prospective trial evaluating the role of balloon kyphoplasty in multiple myeloma showed that over 80% of the treated patients experienced significant pain control.5 In addition, there was an overall 30% height restoration with improvement of 65-70% of height restoration when the procedure was performed for fractures less than 6 months old. The procedure was also noted to be effective and safe in other malignancies.6 In another study of 20 multiple myeloma patients (48 levels) treated with balloon kyphoplasty, significant pain improvement as judged by visual analog scale occurred within the first year of follow-up.7 About 80% of patients with initial kyphotic deformity had post-operative kyphosis correction of approximately 6°, with only minimal loss of height after 1 year (~1.8°). The overall data related to both vertebroplasty and balloon kyphoplasty are addressed in a number of publications.5,8-10

In considering the potential benefit of PMMA injection, it is necessary to be aware of the biomechanics of pathologic spine fractures (Figure 1). With the occurrence of a VCF, the center of gravity moves forward. Because of the large bending moment created, the anterior spine, especially in the regions adjacent to the VCF, must resist larger compressive stresses. The posterior muscles and ligaments are additionally stressed, which can be an obvious source of pain. Early intervention is a way to reduce the risk of a ‘domino effect’ with increased forward movement of the center of gravity, additional compressive stresses and possible further VCFs. The consequences of progressively altered vertebral mechanics and the kyphosis-related VCFs in myeloma patients can be substantial as summarized in Table 1.

Obviously, the safety of vertebral augmentation is an important consideration. The potential complications of vertebral augmentation are summarized in Table 2. A literature review meta-analysis of procedure-related complications for balloon kyphoplasty and vertebroplasty indicates that complications such as extravasation of PMMA are less with balloon kyphoplasty.21 It should be noted that asymptomatic extravasation of

PMMA occurs in about 7% balloon kyphoplasty versus 19.7% vertebroplasty but rarely leads to clinical complications.\(^{22}\) As an example, the single center experience at Moffitt Cancer Center gives a realistic expectation as to outcomes in a center specializing in myeloma care (Table 1). The presence of any plasmacytoma tissue between the PMMA and the fractured cortical bone can lead to suboptimal improvement in stabilization and any subsequent pain relief from any form of vertebral augmentation.\(^{23}\) Active awareness of potential complications and careful patient selection are obviously crucial.

The role of vertebral augmentation in the treatment of myeloma of the spine is still evolving. The impact of VCFs upon quality of life and survival is illustrated by results of a large study in women aged ≥65 years. In this study of a total of 9575 women aged 65 years or older, 1915 of the women (20.0%) were diagnosed as having VCF secondary to osteoporosis. The fractures were not only associated with increased morbidity, but also with increased mortality.\(^{23}\) The increased mortality was particularly from pulmonary complications.\(^{23}\) Moreover, patient mortality increased with greater numbers of vertebral fractures, from 19 per 1000 woman-years in women with no fractures to 44 per 1000 woman-years in those with five or more fractures (P<0.001).

These data accentuate the need for management guidelines for VCFs. Formal guidelines on the use of vertebral augmentation for myeloma in the spine are missing. The purpose of this paper is to review the evidence regarding the role of vertebral augmentation in the spine and to provide a consensus statement on the role of vertebral augmentation for the management of myeloma affecting the spine. Those aspects of therapy were reviewed, discussed, and considered by the International Myeloma Working Group and a special advisory board convened at the time of the XI International Myeloma Workshop KOS Greece on 29 June 2007.

The following is the consensus statement from the International Myeloma Working Group:

1. **Indications for vertebral augmentation:** The indications are summarized in Table 4. These indications apply, provided contraindications are not present as summarized in Table 5. If severe pain is present, the advisory board reached a consensus that it is very reasonable to proceed with immediate vertebral augmentation. A major advantage is the rapid pain relief especially compared with alternative analgesic strategies summarized in Table 6. Early augmentation also proactively reduces the risk of the vicious cycle of further VCFs as described above as well as providing the maximum chance of restoring height and correcting angular deformity. Early augmentation also does not preclude additional or subsequent use of any of the alternative strategies such as those summarized in Table 6. In the absence of severe pain, augmentation is a proactive measure to preserve structural integrity. When there is severe bone destruction and in anticipation of potential long patient survival, this secondary indication is very much a viable option to maximize quality of life by preventing potential VCFs.

2. **Identification of patients suitable for vertebral augmentation:** The four major components of the recommended baseline evaluation are summarized in Table 7. Obviously, one must be certain that the pain is emanating from the collapsed or damaged vertebrae(s). In addition to X-ray, which most patients will have undergone to diagnose the problem, more detailed evaluation with magnetic resonance imaging (including STIR (Short T1 Inversion Recovery) images) is essential particularly to determine the presence or absence of spinal cord compression and/or edema. Also, the potential for retropulsion and/or direct leakage of PMMA can be
Table 4  Indications for vertebral augmentation

Primary: severe pain present (pain > 7/10 on VAS)
- Collapse of one or more vertebrae (VCF)
- Bone destruction (osteolytic/osteosclerotic) with high risk of collapse of one or more vertebrae

Secondary: severe pain absent (pain < 7/10 on VAS)
- Significant loss of height and/or structural integrity or stability

Abbreviations: VAS, visual analogue scale; VCF, vertebral compression fractures.
*Provided no contraindications (Table 5).

2. MRI is essential to document the anatomy and assess spinal cord edema/compression.
3. Assessment of myeloma disease status and potential anti-myeloma treatment needs.
4. Assessment of other pain therapy options (Table 6).

Abbreviation: MRI, magnetic resonance imaging.

3. Timing for the vertebral augmentation: Early intervention is currently being investigated in the CAFE (Cancer Fracture Evaluation) trial in which immediate and delayed vertebral augmentation are being contrasted and compared. The group reviewed available data and clinical experience available now and agreed to the following:

- Immediate vertebral augmentation is a treatment option for acute VCF with severe pain or VCF at high risk for progressive deformity. Excellent short- and long-term results have been achieved in this setting.
- For patients with lesser pain and/or vertebral damage, a trial of analgesic therapy with supportive measures including bisphosphonates and systemic therapy is generally recommended. The appropriate duration of this type of therapeutic trial relates to the severity of the pain and potential reversibility with systemic measures. In general, augmentation can be considered as safe and feasible especially if pain worsens and/or persists and/or to prevent further vertebral collapse. Early intervention is especially important if stabilizing the spinal structure and/or restoring the height are critical. Excellent results have been achieved in these settings. Results of the ongoing randomized CAFE trial evaluating pain relief and quality of life with immediate versus delayed balloon kyphoplasty are eagerly awaited.
- If pain persists at the site of VCF, there is no upper time limit beyond which augmentation cannot be considered. However, earlier intervention is preferred to achieve maximal stabilization and/or correction of deformities.

4. Number of levels to be considered for treatment:

- Multiple augmentation procedures may be necessary and appropriate. In general, three to four vertebrae per intervention is considered reasonable and feasible during a single procedure (if required). As many as 16 augmentations have been performed on an individual myeloma patient in separate sessions or stages.
- Vertebral augmentation for adjacent or suspect vertebrae without fracture may be necessary. Such augmentations can be considered when there is a fracture with kyphosis in the thoracolumbar region because the stress due to the deformity in this region is very high. It is particularly common to consider the performance of an additional augmentation procedure in a vertebra when it is located between two fractured vertebrae such as T11 and L1 requiring treatment for T12 to avoid post-procedure T12 collapse.

5. The highest level of augmentation to be performed was briefly discussed. It was decided that experienced operators can perform vertebral augmentation to levels as high as the cervical area and that this can be effective and safe. For practical purposes, T5-L5 is the range that can be performed safely by the percutaneous route.
6. The method of vertebral augmentation: The risk of complications, especially the risk of PMMA leakage, is greater with vertebroplasty. However, it was agreed that both the utility and the likelihood of clinically significant complications are very much dependent upon the experience of the operator. It is therefore recommended that the choice of balloon kyphoplasty versus vertebroplasty be left to the discretion of the operator and be based upon the goals of the procedure.

7. Use of vertebral augmentation versus radiation therapy: Vertebral augmentation is considered the procedure of choice to improve quality of life for painful VCFs. However, external beam radiotherapy (EBR) is a valid option that requires careful consideration. EBR is simple and can be performed in one session without risks of anesthesia, bleeding, infections or compromise of vital structures. Local marrow stem cell damage is most likely minimal different with 30 Gy of EBR versus the impact of heated PMMA injected into one or three vertebral bodies. Thus, if discreet plasma talk massa exist within a vertebra and/or there is a symptomatic extramedullary mass or impending/over spinal cord compression occurs, the use of EBR can be the option of choice. Systemic antimyeloma therapy is an alternative for rapid reduction in myeloma tumor burden. In addition, medical pain therapy can provide helpful relief as necessary.

8. Physical rehabilitation: To maximize the recovery from augmentation, a physical rehabilitation program is recommended. Ideally, this should be in the form of water aerobics and thoracicolumbar stabilization with an extension directed focus, under the supervision of a physical therapist.

9. Further trials are still required to clarify the role of vertebral augmentation in a variety of situations including the following:

- prevention of further fractures in asymptomatic patients;
- treating asymptomatic fractures; and
- treating asymptomatic fractures compromising the spinal structure or pulmonary capacity

Discussion

This International Myeloma Working Group Consensus Statement is the latest in a series of publications from the working group as summarized in Table 8. Additional consensus statements scheduled for 2008 include the role of free light chain analysis; guidelines for use of Epoetin; the role of imaging; and a new genetic classification for myeloma.

Vertebral augmentation techniques discussed as part of this consensus statement can be used for both acute and chronic fractures. Myeloma patients with mechanical pain, that is pain that is most significant in the upright position, standing or walking and significantly decreased in a reclining position, which anatomically correlates with the area of the fracture, are most likely to benefit from vertebral augmentation. Other types or causes of pain (radicular, dyesthetic, discogenic or degenerative) should be carefully assessed as they can coexist with pain related to compression fractures and are unlikely to respond to vertebral augmentation interventions.

Absolute contraindications to augmentation including myelopathy or cauda equina syndrome are listed in Table 5. Relative contraindications include coagulopathy, neutropenia, allergy to substances used for the procedure and high anesthetic risks (Table 5).

Currently, there are no specific guidelines or contraindications regarding factors such as kyphosis, retropulsion and caudal compromise or degree of vertebral body collapse. The issue of spinal instability and its effect on overall decision making need to be determined on an individual basis by the treating spine expert. The unstable spine is at risk of progressive deformity or impairment of the neural elements. Generally, operative care with open surgery rather than percutaneous augmentation techniques is most valuable in the setting of spinal instability. In addition, the number of fractures that can be treated at each intervention or stage; the amount of methylmethacrylate to be injected; the need to treat adjacent or intervening nonfractured segments; the issue of unilateral or bilateral, transpedicular or extra-pedicular; open or percutaneous approaches, under local or general anesthesia all need to be determined by the treating surgeon or radiologist. However, it is recommended that not more than three or four fractures are treated per stage as the risk of pulmonary complications increases with the number of treated fractures. The advisory board delegated the details of this decision making, related to numbers and methodology, to the selected operators of the augmentation procedures.

In general, vertebral augmentation is not recommended for asymptomatic fractures unless there is documented increased collapse and deformity progression or in the context of an adjacent or intervening segment. This could be documented by follow-up radiologic studies performed every 3 months or sooner if the clinical picture dictates. The role of skeletal augmentation for sacral or iliac fractures in patients with myeloma is currently unknown.

As noted above, vertebral augmentation should be considered as the procedure of choice to improve quality of life for painful compression spinal fractures in myeloma patients instead of EBR or placement of intrathecal morphine pumps. In patients with plasmacytoma in bone or extramedullary plasmacytoma extending into the epidural space, open surgical decompression or radiation therapy with or without augmentation may be appropriate. In patients with a stable spine without fracture or progressive deformity, radiotherapy should be considered first. Receiving radiation therapy does not preclude future augmentation. Vertebral augmentation and radiation can be viewed as complementary, with augmentation restoring anatomy and radiation ablationing symptomatic disease. Augmentation has the advantage of rapid relief in a single sitting, which should allow patients requiring radiation to be treated in a more comfortable state. This is particularly important for individuals undergoing
radiosurgery where treatment time approaches an hour and immobility is crucial for accuracy.

In summary, patients with plasmacytoma, extramedullary masses and cord compromise should be considered for use of up-front radiotherapy. Vertebral augmentation is a developing field with current and future trials being necessary to further define what constitutes an 'impending fracture' and establish the role of pre-emptive augmentation procedures. Having all options available for multiple myelomas, patients insures optimal therapeutic intervention to improve both quality of life and overall survival.

The past decade has witnessed a paradigm shift in the initial treatment of multiple myeloma with the introduction of novel agents such as thalidomide, lenalidomide, and bortezomib, leading to improved outcomes. High-dose therapy and autologous stem cell transplantation remains an important therapeutic option for patients with multiple myeloma eligible for the procedure. Before the advent of the novel agents, patients underwent stem cell collection prior to significant alkylating agent exposure, given its potential deleterious effect on stem cell collection. With increasing use of the novel agents in the upfront setting, several reports have emerged raising concerns about their impact on the ability to collect stem cells. An expert panel of the International Myeloma Working Group (IMWG) was convened to examine the implications of these therapies on stem collection in patients with myeloma and to develop recommendations for addressing these issues. Here we summarize the currently available data and present our perspective on the problem and potential options to overcome this problem. Specifically, we recommend early mobilization of stem cells, preferably within the first 4 cycles of initial therapy, in patients treated with novel agents and encourage participation in clinical trials evaluating novel approaches to stem cell mobilization. (Blood. 2009;114:1729-1735)

High-dose therapy and autologous stem cell transplantation for multiple myeloma

High-dose therapy and autologous stem cell transplantation (ASCT) remains an integral component of the myeloma treatment algorithm for patients considered eligible for the procedure. The majority of the randomized clinical trials have demonstrated a superior progression-free survival among patients undergoing ASCT compared with those treated with conventional therapies and ASCT was associated with superior overall survival in 3 of those.1-7 Subsequent randomized trials have further defined the role of ASCT by demonstrating equivalent overall survival for delayed transplantation compared with upfront ASCT, albeit with some compromise in the quality-of-life parameters.8 Introduction of novel agents such as thalidomide, lenalidomide, and bortezomib have resulted in a paradigm change in the therapy of myeloma.8-14 The high response rates with these agents, hitherto seen only in the context of high-dose therapy, have once again raised questions regarding the utility of ASCT in the setting of myeloma. Given the lack of long-term follow-up of patients treated with these new agents, the durability of these responses as well as their potential long-term adverse effects remain unknown and ASCT continues to be an important part of myeloma therapy.

Despite the increased use of the newer drugs for the initial treatment of myeloma, there is a continuous increase in the number of ASCTs reported to the Center for International Blood and Marrow Transplant Research (CIBMTR), highlighting their continued important role. Currently, the novel agents appear best suited to be used as first-line therapy, enhancing the quality of responses prior to proceeding to ASCT and diminishing early mortality from

Submitted April 9, 2008; accepted May 27, 2009. Prepublished online as Blood First Edition paper, June 26, 2009; DOI 10.1182/blood-2009-04-205013. The online version of this article contains a data supplement. © 2009 by The American Society of Hematology.
the disease, or in selected patients as primary therapy, moving ASCT to a second-line position or as adjuncts to transplant conditioning regimens or as maintenance therapy in patients undergoing ASCT. Furthermore, in a randomized trial evaluating single versus double ASCT a survival advantage with tandem ASCT was demonstrated in an unplanned subset analysis for those patients not obtaining at least a very good partial response after the first ASCT. This observation has increased the number of ASCTs being performed for patients not achieving very good partial response after the first ASCT. In addition, ASCT can also be used as part of second-line therapy after relapse, especially among patients who achieved a durable response after the first ASCT.

The traditional approach to patients with newly diagnosed myeloma, considered to be candidates for ASCT, has been to provide initial therapy with 4 to 6 cycles of a non-alkylator-containing regimen followed by collection of stem cells and high-dose therapy. The initial therapy for the disease allows time to obtain necessary insurance approvals as well as control disease-related symptoms, simultaneously controlling toxicity by limiting the number of cycles. In addition, adequate disease control provides an opportunity to reverse disease-related complications where feasible, and generally improve the functional status of the patient, allowing for a safer transplantation. Until the advent of the novel agents, the initial therapy regimens commonly used were vincristine, doxorubicin, and dexamethasone (VAD) or single-agent dexamethasone, both of which shared the advantage of having little impact stem cell mobilization and collection. Previous studies had shown that alkylation agents can potentially affect the stem cell pool and thus interfere with the ability to collect adequate numbers of stem cells.

The number of CD34+ cells collected for ASCT is dependent on a number of factors, most importantly the number of intended transplantations. The cell collection target usually depends on patient age, upfront versus delayed ASCT, patient preference, patient performance status, and presence of comorbidities, among others. Traditionally, the target for CD34 cell collection for a single ASCT has been 4 to 6 x 10^6 CD34+ cells, with studies showing a deleterious impact on engraftment characteristics once the number falls below 2 x 10^6 CD34+ cells. Use of more CD34 cells has not been consistently associated with any significant benefit in the parameters studied. Patient age is an important factor from several perspectives. Clearly there is decreasing use of stem cell transplantation (SCT) with increasing patient age, although selected patients with good performance status may undergo transplantation into their mid-70s. The target for stem cell collection is usually based on single transplantation in the United States, because Medicare reimburses only single SCT for myeloma. Finally, there is a clear impact of age on the ability to collect stem cells, with decreasing yield with advancing age. In the majority of patients undergoing an ASCT for myeloma, stem cells are collected from the peripheral blood following mobilization using growth factor administration with or without preceding chemotherapy. A minority of patients undergo ASCT with stem cells collected through a bone marrow harvest. Use of cyclophosphamide or other chemotherapy regimens for myelosuppression to achieve rebound CD34+ cell spillover into the blood with enhanced effects of myeloid growth factors during the recovery phase of peripheral blood counts allows for a more rapid stem cell collection and higher numbers of collected CD34+ cells compared with myeloid growth factor alone. Institutions differ in their standard approach for collecting stem cells, with pros and cons to either approach. Use of cyclophosphamide, although allowing better stem cell collection and less likelihood of a collection failure (less than the 2 x 10^6 CD34+ cells), prolongs the collection process while awaiting count recovery and increases the risk of febrile neutropenia and other infectious complications.

One of the recent advances in the field of stem cell mobilization strategies has been the introduction of AMD3100 (plerixafor), a receptor chemokine receptor 4 (CXCR4) inhibitor. Previous studies have highlighted the role of CXCR4 in the stem cell mobilization induced by granulocyte colony-stimulating factor (G-CSF) and cyclophosphamide. Lisovski et al showed that mobilization of stem cells by G-CSF coincides in vivo with the cleavage of the N-terminal of the chemokine receptor CXCR4 on the stem cells in the BM, leading to loss of chemotaxis in response to the CXCR4 ligand, the chemokine stromal cell-derived factor-1 (SDF-1/CXCL12). In addition, accumulation of serum proteases led to cleavage and inactivation of SDF-1. Originally developed as an anti-HIV drug, the ability of this drug to enhance peripheral mobilization of CD34+ cells was subsequently recognized. AMD3100, a reversible inhibitor of the binding of stromal cell-derived factor-1α (SDF-1α, also known as CXCL12) to its cognate CXCR4, has been shown to increase the number of circulating CD34+ cells in healthy volunteers when administered alone or with G-CSF prior to treatment. Stem cells express CXCR4 and are known to migrate to the bone marrow through a chemokine ligand of SDF-1α that is produced locally by bone marrow stromal cells. Once in the marrow, it is also believed that stem cell CXCR4 can act to help "anchor" these cells to stromal cell surface SDF-1α. AMD3100-induced leukocytosis and elevations in circulating hematopoietic progenitor cell levels are thought to result from a disruption of the CXCR4/CXCL12 interaction and cell adhesion effects, resulting in the appearance of both mature and pluripotent cells in the systemic circulation. AMD3100 has been shown to exert an additive effect on the number of circulating hematopoietic stem and progenitor cells when administered with G-CSF. AMD3100-3102 was a multicenter randomized, double-blind, placebo-controlled comparative trial designed to examine the ability of 240 μg/kg AMD3100 plus G-CSF versus placebo plus G-CSF to mobilize CD34+ stem cells in patients with multiple myeloma (MM), who had not previously failed stem cell collections and had not received previous stem cell transplant. The primary end point, the percentage of patients who achieved 6 x 10^6 or more CD34+ cells/kg in 2 or fewer apheresis days, was met in 106 (72%) of 128 patients in the AMD plus G-CSF group and 53 (34%) of 154 patients in the placebo plus G-CSF group, (P < .001). Fifty-four percent of study patients reached target after 1 day of apheresis in the AMD + G-CSF group compared with 17.3% in the placebo plus G-CSF group. After 4 days of apheresis, these numbers were 86.8% and 56%, respectively.

**Thalidomide-, Lenalidomide-, or Bortezomib-based Regimens as Initial Therapy for Multiple Myeloma**

Introduction of thalidomide represented the first major therapeutic advance in myeloma in several decades. After the initial trials in relapsed myeloma, several randomized phase 3 trials of thalidomide and dexamethasone in patients with previously untreated myeloma were performed. Thalidomide combinations were associated with superior response rates and improved response.

**TAD indicates thalidomide, doxorubicin, and dexamethasone; VAD, vincristine, doxorubicin, and dexamethasone; CAD, cyclophosphamide 1 gm² per day; x, on day 1; doxorubicin 15 mg² per day, x, on days 1 to 4; dexamethasone 40 mg os, days 1-4, and granulocyte colony-stimulating factor (G-CSF); NA, not available; TAD, thalidomide, dexamethasone; CTX, cyclophosphamide; LD, lenalidomide, dexamethasone; LO, lenalidomide and weekly dexamethasone; BD, bortezomib and dexamethasone.**

*Information on whether a stem cell harvest was attempted was available only for 70% of patients, among whom 37% attempted stem cell harvest. Collection details were not available.

A detailed description of stem cell collection regarding cell counts and definition of failure were not available and are likely to represent a mix of practices given the multicenter nature of the trial.

duration with no definite impact on the overall survival compared with dexamethasone alone or VAD. This was followed by introduction of the thalidomide analog, lenalidomide, that in phase 2 trials resulted in very high response rates as well as deeper responses than seen with previous approaches. Subsequent phase 3 trials of lenalidomide and dexamethasone demonstrated its superiority compared with dexamethasone alone as well as its ability to spare high doses of steroids and simultaneously improve survival. More recent clinical trials have examined the efficacy and tolerability of lenalidomide combined with cyclophosphamide (CTX), bortezomib, and clarithromycin, as well as other combinations. Another major advance in the field had been the introduction of the proteasome inhibitor bortezomib, which along with dexamethasone or in combination with conventional chemotherapy agents is increasingly being used in the setting of newly diagnosed disease with high efficacy. Phase 3 trials of bortezomib in combination with dexamethasone with or without doxorubicin has shown excellent tolerability and improved response rates and progression-free survival compared with traditional VAD in the setting of initial therapy prior to SCT. Both lenalidomide and bortezomib have been combined with cyclophosphamide in the setting of transplantation-eligible patients in phase 2 studies with excellent response rates. Recently reported phase 2 trials have examined the efficacy of combining bortezomib with lenalidomide or thalidomide with or without cyclophosphamide in the setting of newly diagnosed MM. These combinations have led to very high complete and very good partial response rates and will undoubtedly become integral components of the initial treatment choices in the future. This in turn has led to renewed interest in the potential impact of initial therapy on the ability to collect adequate numbers of stem cells for one or more transplantsations.

### Impact of thalidomide, lenalidomide, and bortezomib on peripheral blood stem cell collection

A large volume of data, albeit limited to single institution reports and less detailed data from phase 3 trials, has appeared in the past few years evaluating the effect of these drugs on the stem cell collection process (Table 1). Although there are contradictory data on the impact of thalidomide on stem cell mobilization and collection, the effect if any appears to be relatively small with...
limited impact on the ability to proceed with SCT. In addition, there is no evidence to suggest that initial therapy with thalidomide-containing regimens prior to stem cell collection adversely impacts the engraftment potential of the collected stem cells.

In contrast to thalidomide, one of the common adverse effects of lenalidomide has been hematologic toxicity, especially myelosuppression. This finding raised concern that use of lenalidomide could adversely affect the ability to mobilize and collect adequate numbers of CD34+ cells for ASCT. In 2 large studies from Mayo Clinic and M.D. Anderson, the most significant factor influencing the ability to collect adequate numbers of stem cells appeared to be initial therapy with lenalidomide (Table 1). In addition to lenalidomide therapy, other important factors impacting the stem cell collection appeared to be the patient age and the duration of lenalidomide therapy. The failure rate of mobilization following lenalidomide therapy has varied significantly between the different studies, likely a reflection of the lenalidomide treatment duration, age of the patient population undergoing stem cell collection, mobilization regimens, and collection targets used. However, data so far do not indicate any impact on the quality of stem cells collected, as reflected in the engraftment kinetics as well as success.

The effect of bortezomib on the ability to collect stem cells has also been examined in the context of phase 2 and 3 trials examining the combinations (Table 1). Although no definite impact of initial therapy on stem cell harvest was demonstrated in the smaller phase 2 studies of bortezomib and dexamethasone, in the IFM 2005/01 trial comparing bortezomib/dexamethasone to VAD there was a trend toward lower CD34+ numbers among those receiving bortezomib. In contrast, in the HOVON-65/GMMG-HD4 randomized phase 3 trial comparing bortezomib, adriamycin, dexamethasone (PAD) versus VAD as induction treatment, no impact of the regimen was seen on the ability to collect stem cells. No significant impact of initial therapy has been seen in other trials that have combined the novel agents, bortezomib in combination with either lenalidomide or thalidomide. Addition of alkylating agents to the initial therapy, especially in combination, may increase the risk of collection failures, but no comparative data are available.

In a phase 2 study looking at the combination of lenalidomide with cytoxan and dexamethasone for newly diagnosed myeloma, we observed 8 of 30 failures at mobilization. In contrast, in a phase 2 study of cytoxan, bortezomib, and dexamethasone by Reeder et al, all patients who attempted stem cell collection were able to get enough cells for at least one transplantation.

Although there has been a wide spectrum of reported data on the initial therapy with a novel agent and the ability to collect stem cells, some common themes have emerged. In the 2 larger experiences published to date of lenalidomide therapy prior to harvest, the number of cycles of therapy appears to be important. Although none of the patients with fewer than 6 cycles of lenalidomide failed to collect stem cells in the Mayo Clinic series, more than 3 cycles of lenalidomide were associated with a higher risk in the M.D. Anderson series. However the smaller studies have not demonstrated such a relationship, and in the absence of detailed data from the larger prospective studies, it would be reasonable to assume that longer duration of therapy will increase the risk of failure. Another common finding has been the age of the patients, with more than one study demonstrating increased likelihood of failure in the older patients. In these 2 studies, no relationship was noted between the time off lenalidomide prior to stem cell harvest. Another important finding across the studies has been the low incidence of collection failure among patients mobilized with chemotherapy, typically cyclophosphamide, and G-CSF. Among 28 treatment-naive patients treated with the combination of clarithromycin, lenalidomide, and dexamethasone (BIRD) reported by Mark et al, sufficient stem cells for 2 autologous stem cell transplants were collected from all patients mobilized with CTX plus G-CSF, versus 33% mobilized with G-CSF alone, demonstrating that this approach can potentially overcome the impairment in stem cell mobilization associated with lenalidomide. For patients failing initial attempts at stem cell mobilization with G-CSF alone, chemotherapy + G-CSF approach appears to have a reasonable efficacy. Five of 7 patients failing G-CSF alone were successfully mobilized with CTX + G-CSF in a study and 18 of 21 patients were remobilized successfully with a chemotherapy + G-CSF approach in another study. Maazumder et al also reported 3 patients who failed to collect successfully despite undergoing mobilization with the CXCR4 inhibitor plerixafor, but were subsequently collected using a combination of cyclophosphamide and G-CSF.

Potential mechanisms of the impact of lenalidomide treatment on stem cell collection

The exact mechanism why lenalidomide inhibits stem cell mobilization is not clear. Koh et al investigated the effects of lenalidomide, pomalidomide (CC4047) (IMiDs), and thalidomide on CD34+ hematopoietic progenitors. They showed in human colony formation assays and long-term culture-initiating cell tests that IMiDs and thalidomide are not toxic to hematopoietic stem cells and do not inhibit self-renewal capacity of stem cells. This makes it less likely that a direct toxic effect of lenalidomide on hematopoietic progenitors explains the limitation in stem cell collection. The group further showed that IMiDs promote myelopoesis with a concomitant maturation stop of neutrophil granulocytes by down-regulation of critical transcription factors such as PU.1. This leads to an accumulation of immature granulocytes within the bone marrow compartment and neutropenia in the peripheral blood. Interestingly, the group also observed that the G-CSF secretion is highly up-regulated in cultures of hematopoietic progenitors treated with IMiDs (day 3 of treatment: control 140 pg/mL, lenalidomide 800 pg/mL, CC4047 1500 pg/mL) (S.L., written communication, September 2008). The biologic reason for the strong up-regulation of G-CSF is unknown. It is likely that self-regulatory mechanisms up-regulate G-CSF to overcome the maturation stop of granulocytes. Higher levels of G-CSF might lead to a tachyphylactic response, resulting in resistance to G-CSF mobilization. These findings are also supported by our observation that all other "non-G-CSF-based" mobilization approaches such as CTX and AMD3100 are successful in mobilizing a sufficient CD34+ cell number.

Suggested approach to stem cell collection in patients undergoing initial therapy with novel agents

In June 2008, a panel of experts was convened by the International Myeloma Foundation to address issues regarding stem cell collection for autologous transplantation in patients receiving therapy
with lenalidomide. The following statements reflect the considerations of the panel and the consensus recommendations formulated by the panel. The recommendations take into account the existing data suggesting compromised cell mobilization with the newer agents in some of the patients as well as the data, although limited, examining alternate approaches to stem cell mobilization. These recommendations will be revised when additional data become available, enabling us to make more specific recommendations.

First attempt: Given the potential for the novel agents to impact the ability of the stem cell collection, we recommend early stem cell mobilization when SCT is being contemplated immediately or later in the course of disease. Such an approach, after 3 to 4 cycles of initial therapy, is quite feasible given the rapid response seen with the new combinations. However, there exists considerable confusion at this point in terms of the mechanisms mediating the decreased collection as well as the best approaches to prevent this problem, and every effort should be made to enroll these patients in clinical trials evaluating these questions.

Among patients undergoing initial therapy with thalidomide or bortezomib in combination with dexamethasone or among those treated with lenalidomide and dexamethasone who have received fewer than 4 cycles of therapy and are younger than 65 years, G-CSF alone is considered adequate for the initial attempt at mobilizing stem cells, although many centers will continue to use cyclophosphamide and G-CSF as their standard protocol. Among those who have received more than 4 cycles of lenalidomide therapy, one should consider the initial use of cyclophosphamide and G-CSF for mobilization. This suggestion is based on the findings of increased failure risk in this population as well as the reduced risk of failure associated with the use of cyclophosphamide and G-CSF. Although the use of cyclophosphamide in all patients is likely to decrease the risk of failure at first attempt, the recommendation to use G-CSF alone in the former group is driven by the low risk of failure in that group, the increased risks and delay associated with use of cyclophosphamide, and finally the ability to successfully collect with cyclophosphamide and G-CSF in the few patients who fail the initial attempt with G-CSF alone. In patients older than 65 years old, we recommend consideration of reduced-dose cyclophosphamide with G-CSF or G-CSF alone with addition of AMD-3100 before the second lenalidomide if the first lenalidomide results in less than 2 million CD34+ cells/kg. In patients receiving other myelosuppressive drugs in combination with lenalidomide, cyclophosphamide and G-CSF should be considered for the initial attempt as the rate of failure increases in these situations. There are no data supporting additional time off therapy prior to mobilization enhancing the likelihood of successful mobilization. We do not recommend a minimum period that patients have to be off lenalidomide prior to starting G-CSF for mobilization.

Failed stem cell collection

Among patients receiving initial therapy with lenalidomide-containing regimens failing to collect with G-CSF alone, there are 3 options for the subsequent attempt. The majority of the patients can be collected with cyclophosphamide priming and G-CSF. These patients will be candidates for use of AMD-3100, which in combination with G-CSF has been very successful in mobilizing stem cells. Another approach includes the use of a combination of G-CSF and granulocyte-macrophage colony-stimulating factor (10 μg/kg per day subcutaneously for 2 days, followed by G-CSF 16 μg/kg per day subcutaneously until stem cell collection is complete).

Upfront use of plerixafor (AMD3100) in lenalidomide-treated patients

The panel discussed the question of routine use of plerixafor for mobilization in this patient group. It was felt that at this time, without a detailed cost benefit analysis, such a recommendation cannot be made and additional clinical trials specifically addressing its use in these patients will allow us to answer this question. Prospective trials should be conducted to study the use of plerixafor in patients failing to reach certain thresholds for peripheral blood CD34 counts.

Several imaging technologies are used for the diagnosis and management of patients with multiple myeloma (MM). Conventional radiography, computed tomography (CT), magnetic resonance imaging (MRI) and nuclear medicine imaging are all used in an attempt to better clarify the extent of bone disease and soft tissue disease in MM. This review summarizes all available data in the literature and provides recommendations for the use of each of the technologies. Conventional radiography still remains the 'gold standard' of the staging procedure of newly diagnosed and relapsed myeloma patients. MRI gives information complementary to skeletal survey and is recommended in MM patients with normal conventional radiography and in all patients with an apparently solitary plasmacytoma of bone. Urgent MRI or CT (if MRI is not available) is the diagnostic procedure of choice to assess suspected cord compression. Bone scintigraphy has no role in the routine staging of myeloma, whereas sequential dual-energy X-ray absorptiometry scans are not recommended. Positron emission tomography/CT or MIBI imaging are also not recommended for routine use in the management of myeloma patients, although both techniques may be used in selected cases that warrant clarification of previous imaging findings, but such an approach should ideally be made within the context of a clinical trial.

Lukomia (2009) 23, 1545–1556; doi:10.1038/leu.2009.89; published online 7 May 2009

Keywords: multiple myeloma; conventional radiography; computed tomography; magnetic resonance imaging; nuclear medicine imaging

Introduction

Multiple myeloma (MM) is a plasma-cell malignancy and is characterized by the presence of lytic bone disease causing severe bone pain, pathological fractures, spinal cord compression and hypercalcaemia. Up to 90% of myeloma patients develop osteolytic lesions during the course of their disease. These lesions occur predominantly in the axial skeleton, that is, skull, spine, rib cage and pelvis, as well as the proximal areas of the arms and legs. Furthermore, almost 10% of the patients present with diffuse osteopenia or osteoporosis at diagnosis. Myeloma bone destruction represents a major cause of morbidity and mortality. Progression of skeletal disease is often not affected by chemotherapy even in responding patients. The mechanisms of bone destruction are related to increased osteoclastic bone resorption, which is accompanied by an exhausted osteoblast function and reduced bone formation. Thus, a characteristic feature of myeloma bone disease is that the lesions rarely heal even when the patients are in complete remission. This finding is in keeping with the observation that bone scans are often negative in myeloma patients who have extensive lytic lesions, and offer very little in the follow-up of bone disease in these patients. Appropriate use of imaging techniques is essential in the identification and characterization of the skeletal complications resulting from MM and in determination of the extent of intramedullary bone disease. Imaging also is critical for detection of extramedullary foci, identification and characterization of infections and other complications and evaluation of progression of the disease. However, we lack a consensus and standardized imaging protocol for both newly diagnosed myeloma patients or for following patients in the course of treatment and disease progression.

Lytic lesions are generally diagnosed by radiographic analysis. One weakness of radiographic detection is that it may reveal lytic disease only when over 30% of the trabecular bone has been lost. This results in suboptimal assessment of generalized osteoporosis, which affects MM patients and correlates with an increased risk of early vertebral collapse. The morbidity of vertebral collapse is significant. Chronic pain, functional limitations and respiratory compromise, which increase the risk of pulmonary infections are typical clinical sequelae of vertebral compression fractures. Due to the limitations of standard radiographic analysis, computed tomography (CT) or magnetic resonance imaging (MRI) have been used to increase the sensitivity and specificity of early detection of MM-associated bone destruction. CT and MRI also allow discrimination of malignant and benign compression fractures, visualization of soft tissue involvement and spinal cord and/or nerve root compression or jeopardy.

In recent years, positron emission tomography (PET) has also been used in MM imaging. 18F-fluorodeoxyglucose (FDG) is taken up by metabolically active cells, which can then be imaged using PET. High uptake by tumor cells is visible on PET.
Role of Imaging techniques in multiple myeloma
M. Efroymson et al

imaging, as they have increased metabolic rates. This review summarizes all available data for the role of imaging in MM and aims to provide practical information for the usage of these techniques by clinicians who manage myeloma patients.

Conventional radiology

Since 1903, when Weber first observed that myeloma lesions are evident on radiographs, X-rays have been extensively used to identify myeloma-related bone lesions both at diagnosis and during disease course. Lytic lesions on plain X-rays are typically holes—that is, punched-out lesions with absent reactive sclerosis of the surrounding bone—in the flat bones of the skull and pelvis. In the long bones, there is a range of appearances from endosteal scalloping to discrete small (<1 cm) lytic lesions, to mottled areas of multiple small lesions, to large destructive lesions. These lesions correspond to nodular replacement of marrow by plasma cells with entire bone destruction. Conventional radiography may also reveal diffuse osteoporosis, which is best recognized in the spine.

The presence of lytic lesions is a criterion for myeloma diagnosis, whereas the extent of lytic disease is included in Durie-Salmon staging system. Therefore, it is important to include in a 'complete skeletal survey' all areas of possible myeloma involvement, such as the cervical, thoracic and lumbar spine, skull, chest, pelvis, humeri and femora. Almost 80% of patients with myeloma will have radiological evidence of skeletal involvement on the skeletal survey, most commonly affecting the following sites: vertebrae in 65% of patients, ribs in 45%, skull in 40%, shoulders in 40%, pelvis in 30% and long bones in 25%. However, radiologically detectable lesions distal to the elbows and knees are exceptional. Patients who are asymptomatic but have radiological evidence of bone disease (at least one lytic lesion) are at high risk of progression with a median time to progression of 8 months. The importance of the presence of lytic lesions is further supported by the notion that in the International Myeloma Working Group Classification for plasma cell dyscrasias, patients with bone disease are classified as 'symptomatic' and require treatment even in the absence of clinical symptoms.

However, even with complete radiographic surveys 10–20% of the patients have normal results. This may be due to some important disadvantages of conventional radiology, as suggested in Table 1. In plain X-rays some areas are not well visualized; for this reason both lateral and anteroposterior views of the spine are needed for the better visualization of the vertebral bodies. Furthermore, conventional X-rays have limited sensitivity as they cannot detect early lytic lesions and limited specificity as they fail to distinguish myeloma-related osteoporosis from osteoporosis due to other reasons, such as steroid-induced or postmenopausal osteoporosis. The observer and technology dependence of conventional X-rays have also the risk of underdiagnosis of lytic disease. It has also reported that the reproducibility of the results is very low between different centers and in a recent study an expert radiological review of skeletal surveys was able to detect additional abnormalities in 23% of the studied cases. A major disadvantage of conventional X-rays is that almost 20 separate films/exposures are needed, requiring a lengthy period on the radiographic table. The patient's ability to tolerate the standard bone survey is an important issue because myeloma patients can experience severe pain when they are rotated and positioned for multiple individual radiographic exposures. To override this problem, some centers have introduced a whole-body conventional radiographic skeletal survey, the low-dose whole-body radiographic system (Statixcan) for the detection of focal metastatic deposits in cancer and myeloma patients, which can give a high quality imaging of the bones in less than 5 min. In a study of 30 patients with solid tumors metastatic to the skeleton and MM, the whole-body radiography was found as effective as CT or MRI in revealing focal lesions, a result that has not yet been confirmed by others. Furthermore, plain X-rays cannot be used for the assessment of response to therapy as the lytic bone lesions seldom show evidence of healing whereas new compression vertebral fractures do not always indicate disease progression and may occur due to ongoing bone loss or reduction of tumor mass that supports the bony cortex. For all these reasons, although conventional X-rays are considered as a 'gold standard' for the determination of the extent of myeloma bone disease at diagnosis, further imaging is needed during follow-up mainly in the absence of the detection of lytic lesions or the presence of diffuse osteoporosis only.

Computed tomography

CT scanning allows the detection of small osteolytic lesions in MM, which are not revealed by plain radiography. CT imaging is much faster than standard radiographic procedures and allows excellent 3D reconstruction of images. In a few institutions, CT scanning has replaced conventional radiography as the initial imaging tool used in patients with trauma to the spine or pelvis. Furthermore, CT can accurately depict the extent of associated soft tissue masses and can direct needle biopsy for histological diagnosis. The advantages of CT vs conventional X-rays: (1) the duration of the examination is practically three times less than that necessary to perform standard radiography; therefore, there is significant economy in the work time of the technicians; (2) CT scanning allows the complete diagnostic evaluation in a single examination without having to reposition the patients, a procedure that is necessary in conventional studies; this is certainly an important point to consider when examining a patient in pain; (3) the diagnostic sensitivity of CT imaging is superior to that of standard radiography and reveals more lesions as compared with conventional radiology, mainly in areas that cannot be accurately visualized by plain radiography, for example, scapulae, rib or sternum; (4) CT has proven to be superior in estimating fracture risk and instability; (5) CT scanning can demonstrate other underlying pathological processes, especially those involving the lungs, although the percentage is not significant; (6) it is superior in planning the radiation therapy or the surgical intervention as it depicts the anatomic area very accurately (Table 2). Furthermore, a novel CT technique, the multidetector row computed tomography (MDCT) was found to be very sensitive in detecting small osteolytic lesions (<5 mm) in the spine, as compared with MRI and PET.

Table 2 Advantages of computed tomography (CT)

- Detects small osteolytic lesions
- Faster than standard radiographic survey
- Provides 3D reconstruction of images
- Shows associated soft tissue disease
- Greater sensitivity and specificity versus standard radiography
- Allows estimation of fracture risk
- Excellent for radiotherapy planning and for surgical intervention

Table 3 Role of magnetic resonance imaging (MRI)

- More sensitive than standard radiography
- Excellent imaging of axial skeleton
- Discriminates myeloma vs normal marrow
- Excellent diagnostic discrimination for spinal cord/nerve compression issues, as well as soft tissue disease
- Can detect avascular necrosis of the femoral head
- Can detect arthrolytic joint chain deposits in the heart and other sites
- Can be used to assess disease status in monoclonal gammopathy of undetermined significance (MGS), asymptomatic myeloma and for solitary plasmacytoma of bone
- Can be used to monitor response (although improvements can be delayed)

One of the negative points advanced against CT scanning is the radiation dose delivered to patients. The amount of radiation is 1.3-3 times higher than that delivered during standard radiography.31,34 In summary, conventional or low-dose CT scanning of the spine is considered to be a realistic alternative to standard radiography in MM patients presenting with painful symptoms because it allows for obtaining an exhaustive evaluation of the skeletal lesions in a short period. Furthermore, CT is helpful as a basis for radiation therapy planning, for the preparation for surgical intervention to delineate the anatomic architecture as precisely as possible and for a CT-guided needle biopsy. Finally, CT may identify lesions that are negative on plain radiography, and should be considered in patients who remain symptomatic despite having no evidence of osteolysis on the skeletal survey.

Magnetic resonance imaging

MRI has been widely available for the evaluation of MM during the last two decades and is used by several myeloma centers of excellence for the management of myeloma patients. MRI allows visualization of the medullary cavity and a direct assessment of the degree of MM cell infiltration before bone destruction becomes visible on plain radiographs, in the absence of radiation exposure.29,36 Furthermore, in the event of suspected cord compression, MRI is the technique of choice.37 It provides an accurate assessment of the level and extent of cord or nerve root compression, the size of the tumor mass and the degree to which it has extended into the epidural space. MRI can also be used to predict the risk of vertebral fracture. Patients with advanced myeloma who had more than 10 lesions on spinal MRI had a 6- to 10-fold higher risk of fracture than patients who had normal appearance or fewer than 10 lesions on MRI.38 However, MRI does not predict the risk of fracture by level.59

MRI can assist in the distinction between benign from malignant compression fractures. A benign osteoporotic fracture is suggested when a retrospursed bone fragment is seen, when fat signal is preserved on T1-weighted images throughout the body and there is no high signal on T2-weighted images, when there is only a thin (<1 cm) surrounding soft tissue component and when horizontal band-like areas representing the fracture plane are seen following gadolinium administration. A malignant etiology of collapse is suggested when the posterior cortex is convex toward the spinal canal, epidural mass is seen, when the entire vertebral body or pedicles are replaced by low signal on T1-weighted images, and high or heterogeneous signal is seen within the body following gadolinium injection or on T2-weighted images.10 MRI can be also used for the accurate illustration of the vertebral fractures or the percentage loss of vertebral height before the performance of percutaneous vertebroplasty and kyphoplasty.80,81

MRI imaging is the most sensitive and specific imaging modality for the diagnosis of avascular necrosis of the femoral head that may result from high-dose steroid therapy or radiotherapy, and is demonstrated by the presence of the characteristic double-line sign on T2-weighted MR images.42 Early recognition of avascular necrosis before the development of a subchondral fracture is extremely important for the success of conservative management.

In general, the advantages of MRI over conventional radiography and CT scan include: (1) the excellent imaging of the axial skeleton due to the greater sensitivity of the method, (2) the discrimination of myeloma from normal marrow, (3) the accurate illustration of spinal cord and/or nerve root compression, soft tissue extension, head and neckplasmacytomas, avascular necrosis of the femoral head and (4) better evaluation of cardiac amyloidosis and/or soft tissue amyloid deposits (see Table 3).

MRI sequences in myeloma

Several MRI techniques have been developed to aid in the assessment of the bone marrow in hematological malignancies.43 The MRI sequences that are most informative are the T1-weighted, the T2-weighted with fat suppression, the short time inversion recovery (STIR) and the gadolinium T1-weighted with fat suppression. Typical myeloma lesions have a low signal intensity on T1-weighted images and a high signal intensity on T2-weighted and STIR images44 and generally show enhancement on gadolinium enhanced images. In a recent study, three MRI sequences were evaluated to reveal the method which provides the highest confidence level in depicting the MM lesions.45 The authors compared a precontrast T1w-TE sequence (TR: 700 ms, TE: 10 ms), a T2w-TIRM sequence (TR: 8000 ms, TE: 80 ms) and a contrast-enhanced T1w-TSE sequence with fat saturation (TR: 700 ms, TE: 10 ms). The turbo inversion recovery magnitude (TIRM) sequence is a turbo spin-echo sequence (TSE) with an inversion recovery pulse (IR) in combination with the calculation of the magnitude signal intensity (M). Studying 59 MRI examinations of 23 consecutive patients, the authors found that the T2w-TIRM sequences achieved the highest level of sensitivity and best reliability. However, they suggest that for an exact staging and grading the examination protocol should encompass unenhanced and enhanced T1w-MRI sequences, in addition to T2w-TIRM.45

MRI patterns in myeloma

Five MRI imaging patterns of marrow involvement in myeloma have been recognized: (1) normal appearance of bone marrow despite moderate microscopic plasma cell infiltration, (2) focal involvement, (3) homogeneous diffuse infiltration, (4) combined...
diffuse and focal infiltration, (S) 'salt-and-pepper'-pattern with inhomogeneous bone marrow with interposition of fat islands.\textsuperscript{35,46} In almost 30\% of MM patients a normal-looking bone marrow signal is found in all sequences with high signal on T1-weighted and intermediate signal intensity on T2-weighted spin-echo images as well as low signal in fat-saturated sequences, such as STIR.\textsuperscript{35} More specifically, a normal marrow appearance is present at diagnosis in 30-75\% of untreated Durie-Salmon stage I myeloma and in 20-30\% of untreated Durie-Salmon stage II disease.\textsuperscript{46-48} In histology, this corresponds to a slight interstitial plasma cell infiltration (<0.2\% vol\% in bone marrow biopsy).

The focal pattern consists of localized areas of abnormal marrow and is found in approximately 30\% of myeloma cases. On T1-weighted images, focal lesions are darker that yellow marrow and slightly darker or iso intense to red marrow. On T2-weighted images they are brighter than both red and yellow marrow, and on enhanced T1-weighted images they enhance with various degrees depending on the vascularity of the underlying myeloma. STIR and fat-saturation T2-weighted images provide contrast between focal lesions and uninvolved marrow.\textsuperscript{35,47}

In the diffuse MR pattern of abnormal marrow, the normal bone marrow is completely replaced by the abnormal process. The intervertebral discs appear brighter or iso intense to the diseased marrow. On T1-weighted images, there is a diffuse decrease in the signal intensity of the marrow. On T2-weighted images, a variable increase in the signal intensity of the abnormal marrow is observed. After the administration of intravenous contrast, the abnormal marrow enhances. The intervertebral discs appear darker than the enhanced spine.\textsuperscript{35,47}

A combined focal and diffuse infiltration pattern can be found in about 10\% of myeloma patients. On T1-weighted SE images the bone marrow signal intensity is diffusely decreased with additional foci interspersed. Those foci are often better demarked on fat-saturated or gradient-echo images.

Finally in about 3-5\% of the patients the so-called 'salt-and-pepper'-pattern can be found. On T1-weighted SE images, and also on gradient-echo and T2-weighted SE sequences, the bone marrow presents a very inhomogeneous patchy pattern. However, no hyperintense areas are demarcated in fat-saturated sequences. This imaging corresponds to bone marrow with circumscribed fat islands beside normal bone marrow with a minor infiltration of plasma cells (<20\%).\textsuperscript{35-49}

Low tumor burden is usually associated with a normal MRI pattern, but a high tumor burden is usually suspected when there is diffuse hypointense change on T1-weighted images, diffuse hyperintensity on T2-weighted images and enhancement with gadolinium injection. In general, patients with normal or 'salt-and-pepper' MRI pattern tend to have signs of lower tumor burden than those with diffuse or focal marrow involvement patterns.\textsuperscript{37-49}

Furthermore, a significant correlation between diffuse and focal MRI patterns of marrow involvement with low serum hemoglobin values and high percentage of marrow plasmacytosis has been reported, suggesting that diffuse or focal marrow involvement patterns correlate with high tumor burden.\textsuperscript{47}

The main methodological consideration with MRI imaging is the lack of specificity of the findings. Focal or diffuse changes may exist at diagnosis, may be variations of the normal, or reflect an alternative pathological or physiological process such as iron loading,\textsuperscript{50-51} amyloid deposition \textsuperscript{51} or reactive marrow hyperplasia.

MRI findings in MGUS
Monoclonal gammapathy of undetermined significance (MGUS) is defined by a monoclonal immunoglobulin concentration in serum of 3 g/100 mL or less, the absence of lytic bone lesions, anemia, hypercalcemia and renal insufficiency related to the proliferation of monoclonal plasma cells, and a proportion of plasma cells in the bone marrow of 10\% or less. In large referral centers, half the patients with a monoclonal gammapathy have MGUS, whereas only 15\% to 20\% have MM.\textsuperscript{54} Although, lytic lesions are not found in MGUS by definition, osteoporosis is a common finding among MGUS patients who have a higher incidence of vertebral fractures compared to normal population.\textsuperscript{59} Therefore, sometimes it is difficult to differentiate MGUS from early myeloma. MRI studies have been performed in patients with MGUS. Belloaiche et al found that the MRI of the thoracolumbar spine was normal in all tested patients with MGUS (n = 24) compared with only 6 out of 44 (13.6\%) with newly diagnosed MM.\textsuperscript{60} In another study, bone marrow abnormalities were detected with MRI imaging in 7 out of 37 patients (19\%) with MGUS or monoclonal gammapathy of borderline significance (all MGUS criteria but plasma cell infiltration of between 10 and 30\%). All patients with a normal MRI investigation had not required treatment after a median follow-up of 30 months, whereas time to progression to MM was significantly higher for patients with abnormal MRI.\textsuperscript{51}

MRI and solitary plasmacytoma of the bone
Approximately 2\% of patients with plasma cell dyscrasias have solitary bone plasmacytoma (SBP). The diagnosis of SBP requires a solitary bone lesion, a biopsy of which shows infiltration by plasma cells, negative results on a skeletal survey, absence of clonal plasma cells in a random sample of bone marrow and no
evidence of anemia, hypercalcemia or renal involvement suggesting systemic myeloma. Although definitive radiotherapy usually eradicates the local disease, the majority of patients will develop MM because of the growth of previously occult lesions which have not been detected by conventional radiography. MRI imaging is the preferred imaging modality for the initial assessment and for the follow-up of the osseous and extraneous extent of an SBP. Moulopoulos et al showed that MRI of the thoracic and lumbarosacral spine showed additional foci of marrow replacement in four of 12 patients with SBP; thus some patients who have an SBP diagnosed by standard criteria may be understaged if an MRI is not performed. After treatment with definitive radiotherapy to the painful lesion, three patients developed systemic disease within 18 months from diagnosis. Furthermore, Liebross et al reported that among SBP patients with thoracolumbar spine disease, seven of eight staged with plain radiographs alone developed MM in comparison with only one of seven patients who also had MRI studies of the spine. These results suggest that MRI should be part of the staging procedures in patients with SBP, to better assess both the extent of the local tumor and the revealing of occult lesions elsewhere. Coronal images of the central skeleton may increase the incidence of unsuspected lesions.

**MRI in smoldering multiple myeloma**

Asymptomatic patients with paraprotein level in the serum of >30 g/l and/or bone marrow clonal plasma cells of >10%, and no myeloma-related organ or tissue impairment, are considered to have smoldering multiple myeloma (SMM), according to the International Myeloma Working Group.21 These patients account for about 15–20% of myeloma patients, and have a median time to disease progression of 2–3 years. According to current practice, patients with SMM may remain stable for years without therapy and thus should be followed without treatment until there is evidence of imminent disease progression. Asymptomatic patients with at least one lytic lesion in conventional X-rays have a median time to progression of 10 months; therefore, they should be treated at diagnosis. MRI reveals abnormal marrow appearance in 30–50% of the patients. Moulopoulos et al reported that patients with abnormal MRI studies required therapy after a median of 16 months vs 43 months for those with normal MRI studies (P<0.01). Moreover, Mariette et al showed that during a median follow-up of 25 months, 10 out of 53 SMM patients developed disease progression; of those, 8 out of 17 had abnormal MRI and 2 out of 38 patients had normal MRI. In that study, abnormal MRI independently predicted for time to progression. This result has not been confirmed by other studies. However, MRI may be particularly useful in patients with asymptomatic myeloma who have an intermediate risk for disease progression.

**MRI and assessment of response**

MRI can be used to assess the effects of antmyeloma therapy, although the response rates to conventional chemotherapy are similar among patients with different MRI patterns and the time to complete response (CR) is similar among patients with different number of focal lesions on MRI (>7 vs ≤7). A change in MRI pattern may correlate with response to therapy. Moulopoulos et al reported that CR is characterized by complete resolution of the preceding marrow abnormality, and partial response is demonstrated by conversion of a diffuse to a variegated or focal pattern. Features suggestive of an objective response to treatment include a reduction in signal intensity on T2-weighted spin-echo images and the absence of contrast-induced rim-enhancement that was previously present. Focal lesions may shrink or remain unchanged in size after effective antmyeloma therapy or they may remain hyperintense in both responders and nonresponders to treatment due to treatment-induced necrosis and inflammation. Therefore, post-antmyeloma therapy MRI of the bone marrow may provide important information for patients with equivocal clinical and laboratory results as well as for patients with nonsecretory myeloma. In a study by the Arkansas group, focal lesions were present on MRI in 27 of 30 patients with nonsecretory MM. After treatment, bone marrow-defined CR occurred in 22 (81%) of these 27 patients, and MRI-CR was documented in 41% of patients at 36 months.

Autologous stem cell transplantation (ASCT) is considered the treatment of choice for younger myeloma patients. Lecouvet et al developed an index for the assessment of changes occurring in the spine after transplant. The index numerically combines findings related to the number of lesions, lesion size, contrast enhancement and marrow background. A score of 0, 1 or 2 is given for each parameter depending on whether there is improvement, stability or worsening. Patients with an index below 4 had a better treatment response than those with an index of 4 or more. In this point, it is crucial to mention that MRI evaluation post-ASCT has to be performed at least 1 month after G-CSF administration. There can be diffuse or focal marrow changes after treatment with G-CSF that cannot be easily distinguished by active disease.

**MRI findings and prognosis in symptomatic myeloma**

The prognostic value of MRI findings in symptomatic myeloma has been evaluated in different studies. Patients with a single lytic lesion on plain radiography, who are found to have further lesions on MRI have a shorter time to progression and shorter time to starting therapy compared to those with a normal MRI study. Patients with advanced disease who have normal MR findings and receive conventional dose chemotherapy have a longer survival compared to those with diffuse or focal abnormalities on MRI imaging. The pattern of MR bone marrow involvement in myeloma also has prognostic significance, with both focal and diffuse patterns being associated with a higher tumor burden. In 142 symptomatic myeloma patients, Moulopoulos et al showed that the median survival was 24 months for patients with the diffuse pattern, 51 months for those with the focal pattern, 52 months for those with the variegated pattern and 56 months for patients with the normal pattern (P=0.001). The presence or absence of a diffuse MRI pattern separated patients with ISS stages I and II into two subgroups with significantly different survival times of 28 months and 61 months, respectively (P=0.01). Furthermore, a diffuse MRI pattern predicted inferior outcome regardless of whether or not patients had received high-dose therapy with ASCT.

The largest study in the literature, which reported on the prognostic value of MRI in myeloma patients was published by the Arkansas group. In 611 myeloma patients who were treated uniformly with a tandem autologous transplantation-based protocol, MRI, but not conventional radiography, defined focal lesions independently affected survival. In particular, cytogenetic abnormalities and more than seven focal lesions on MRI distinguished three risk groups: 5-year survival was 76% in the absence of both more than seven focal lesions on MRI and cytogenetic abnormality (n = 276), 61% in the presence of one
of these adverse features (n = 262) and 37% in the presence of both unfavorable parameters (n = 67). High number of MRI focal lesions (> 7) correlated with low albumin and elevated levels of C-reactive protein, lactate dehydrogenase and creatinine, but did not correlate with age, β2-microglobulin and cytogenetic abnormalities. Resolution of the focal lesions on MRI post-antimyeloma therapy that occurred in 60% of the patients identified a subgroup with superior survival. Furthermore, at disease progression after CR, according to clinical criteria, MRI focal lesions were present in 70% of the patients, including 26% with new focal lesions outside of the areas of initial involvement, 28% focal lesions that were larger than the original lesions and 15% with both an increase in original size and new MRI focal lesions.57

**Nuclear medicine imaging**

Traditional technetium bone scintigraphy has high sensitivity for the detection of solid tumors metastatic to the skeleton but its sensitivity in MM and solitary plasmacytoma is very low. Technetium bone scintigraphy scanning may detect lytic lesions in 35–60% of MM patients, but its specificity and sensitivity at the time of the initial diagnosis, in follow-up studies and in the evaluation of bone pain is lower compared to conventional radiography.78-80 In myeloma patients, the skull, the extremities, the iliac and pubic bones are better assessed with plain radiography, whereas for new vertebral lesions and for lesions in the ribs and sternum, bone scintigraphy seems to be superior and for sacrum both methods are equal.81 The inferiority of bone scans vs conventional radiography is primarily due to the osteolast dysfunction in myeloma.1,4,9-11 as skeletal uptake of 99mTc-diphosphonate is related mainly to osteoelastic process. Therefore, newer techniques have been developed in an effort to improve the sensitivity of detection of myeloma bone disease.

**99mTc-sestamibi**

99mTc-labeled hexakis-2-methoxyisobutylisonitrile (99mTc-sestamibi) is a lipophilic cationic γ-emitting radiopharmaceutical originally introduced as a myocardial perfusion imaging tracer. Because of its biochemical characteristics, which favor accumulation in tissues with high cell density and mitochondrial activation, 99mTc-sestamibi (MIBI) is actively concentrated in a variety of malignant tumors such as sarcomas, breast, brain, lung and thyroid cancers.82 MIBI imaging closely reflects myeloma disease activity in bone marrow with very high sensitivity and specificity.83-84 Additionally, bone marrow MIBI uptake is linearly related to bone marrow biopsy results and MIBI was reported to be localized inside the plasma cells infiltrating the bone marrow.5-67

In MGUS patients, MIBI is always negative81,86,87 and it cannot be used to predict MGUS transformation; thus it is not useful in MGUS work-up.88 MIBI imaging can detect soft and skeletal lesions in MM patients and is more sensitive than conventional radiography.89 Its overall sensitivity is approximately 92% and its specificity is 96%.89 However, MIBI imaging has inferior value compared to FDG-PET/CT,91 and found to underestimate the extent of myelomatous bone marrow infiltration in the spine, especially in patients with low disease stage, compared to MRI.97 The pattern of MIBI uptake is significantly different in MM patients. Focal uptake reflects active myeloma sites, whereas diffuse uptake without the presence of focal uptake does not indicate active myeloma.95 MIBI score was significantly related to ISS, bone marrow biopsy infiltration rate and serum β2-microglobulin.88,94 Furthermore, MIBI washout may predict for response to conventional or high-dose chemotherapy.95,96 MIBI scan added no relevant prognostic information to the ISS in patients with stages I and III MM, but the MIBI scan was of prognostic value in stage II MM patients.98 MIBI scan cannot detect the necrotic lesions of osteonecrosis of the jaw in myeloma patients.97

**Positron emission tomography**

PET is a tomographic nuclear imaging procedure that uses positrons as radiolabels and positron-electron annihilation reaction γ-rays to locate the radiolabels. A low dose of a radiopharmaceutical labeled with a positron emitter, such as 18-fluorine-fluoro-deoxyglucose (FDG), is injected into the patient, who is scanned by a tomographic system. The main limitation of PET scanning is limited spatial resolution; thus subcentimeter lytic lesions seen on plain radiographs may not be detectable on PET scanning.99 The advent of fusion scanning combining both PET and CT addresses the issue of limited spatial resolution. In PET/CT fusion scanning, the patient receives an injection of FDG about 1h before image acquisition. After the patient is positioned on the scanner bed, an initial topogram is acquired to define the examination range for the PET/CT image acquisition (usually from the ears to the hips). A spiral CT is then performed after which the scanner bed is moved back to the starting position and the PET scan commenced. Reconstruction of the image, incorporating PET and CT data are completed soon after PET/CT image acquisition. The actual scanning time is shorter for PET/CT (approximately 30 min) than a PET scan alone (approximately 1h) because CT data are used to perform attenuation correction.99

Several studies have shown PET/CT is reliable for most bone lesions that are at least 1 cm in diameter using a standard SUV cutoff of 2.5 to indicate the presence of disease.100 For lesions smaller than 5 mm in diameter, it has been suggested that any amount of FDG uptake should be considered positive regardless of SUV. Lesions between 5 and 10 mm are considered indeterminate if the SUV is less than 2.5. The patient’s weight and body mass are additional factors that affect the SUV.101 The sensitivity of FDG PET in detecting myelomatous involvement is approximately 85% and its specificity is 92%.98 The first assessment FDG PET in myeloma, a study of 66 patients followed serially, showed that FDG PET allows identification of high-risk myeloma and can be used to monitor nonsecretory myeloma as well as patients in CR without measurable M-component.102 This led to the inclusion of myeloma into larger studies of PET/CT in the United States.103,104 The National Oncologic PET Registry (NOPR), a large prospective program, enrolled 22975 cancer patients in the first year and revealed that 36.5% of the time treating physicians changed the intended management of the basis of PET/CT results. The registry has thus far included over 1300 myeloma patients. PET/CT has been included as an option in the diagnosis and monitoring of myeloma patients within NCCN guidelines.105 Further targeted studies in myeloma are required to further clarify aspects of the specific utility in myeloma patients. In addition to demonstrating persistent or recurrent osseous disease, PET/CT studies are more sensitive than other imaging techniques for localizing extramedullary sites of disease, where they reveal additional lesions in almost 30% of the patients who had been diagnosed with solitary plasmacytoma by MRI.106,107 In two recent studies in patients with SIB, PET/CT allowed detection of other unsuspected sites of bone involvement, upstaging the extent of
the disease and significantly affect the therapeutic decisions. In a prospective comparison among 18F-FDG PET/CT, MRI and conventional radiography (whole-body X-rays) in 46 newly diagnosed myeloma patients, PET/CT was superior to plain radiographs in 46% of patients, including 19% with negative X-rays. However, in 30% of patients, PET/CT scans of the spine and pelvis failed to show abnormal findings in areas in which MRI revealed an abnormal pattern of bone marrow involvement, more frequently of diffuse type. In contrast, in 35% of patients, PET/CT enabled the detection of myelomatous lesions in areas which were out of the field of view of MRI. By combining MRI of the spine/pelvis and PET/CT the ability to detect sites of active MM, both medullary and extramedullary, was as high as 92%. Following ASCT, 15 out of 23 patients had negative PET/CT scans (including 13 with a very good partial response or at least a near CR), but only 8 had normal MRI. There are several small studies supporting that either 18F-FDG PET/CT is comparable to the in the detection of focal lesions in spine and pelvis, but it was superior for an accurate whole-body evaluation or MRI is superior to FDG-PET in detecting bone marrow involvement in the spine of patients with advanced MM. In summary, although all reported studies have confirmed the superiority of PET/CT over conventional radiography, they have also revealed that PET/CT was the sole imaging study done, it would miss many additional small lytic skeletal lesions and could miss diffuse spine involvement compared to MRI. Another disadvantage of PET/CT is the false-positive results it has especially in areas of inflammation or infection, deposits of brown fat (especially in the mediastinum and neck), postsurgical changes, vertebralplasty changes and occasionally other benign or malignant processes, such as renal, pancreatic, uterine and prostate cancer.

FDG PET/CT was found more sensitive than MRI for making the diagnosis of mandibular osteonecrosis although it is not an accurate method for the detection of femoral head osteonecrosis. To override these problems, novel radiolabeled agents have also been used in PET/CT. The use of the radiolabeled amino-acid carbon 11 (11C) methionine with PET/CT showed 11C-methionine-positive lesions in normal cancellous bone in the majority of 19 MM patients, and in all patients with extramedullary disease.

In general, MIBI and PET/CT are useful additional diagnostic tools for detecting otherwise occult sites of myeloma. A recent large study of MIBI on the relative impact of PET on patients with 15 different types of known cancers for three distinct indications (initial staging, restaging and detection of suspected recurrence) revealed that when intended management was classified as treatment or nontreatment, physicians changed their intended management for almost 49% of myeloma cases. This result depicts the change of management of MM patients with the broad use of PET in myeloma. However, further studies are needed before the recommendation of using PET as a standard tool in both diagnosis and follow-up of MM patients. Finally, the use of MIBI PET should particularly be considered in the evaluation of a patient with an early-stage MM to exclude the presence of more extensive disease.

Dual-energy X-ray absorptionometry

Osteoporosis in the general population is currently diagnosed using dual-energy X-ray absorptionometry (DEXA). In MM patients, reduced lumbar spine bone mineral density correlates with increased risk for early vertebral fractures. This makes DEXA a valuable test to consider, as it may also influence the decision to begin bisphosphonate treatment, which can produce a 5–10% improvement over a 6-month period. Another advantage of DEXA is that the technique, which involves assessment of bone mineral density (BMD) in the lumbar spine, hip and distal radius, is a quick, noninvasive investigation that uses a small dose (<1 ISV) of radiation. Disadvantages of the method include its influence by spondylisis, spinal osteophytes and the presence of vertebral collapse, and its difficulty to recognize myeloma osteoporosis from malignant osteoporosis. Furthermore, sequential DEXA-scans shows heterogeneous local BMD changes, and cannot predict disease progression.

Conclusions

Various imaging technologies have been used for the diagnosis and management of myeloma patients. As part of the staging procedure of newly diagnosed myeloma, the skeletal survey is mandatory and should include a posteroanterior view of the chest, anteroposterior and lateral views of the cervical spine (including an open mouth view), thoracic spine, lumbar spine, humeri and femora, anteroposterior and lateral views of the skull and anteroposterior view of the pelvis. In addition, symptomatic areas should also be specifically visualized. Whole-body, low-dose MDCT has substituted conventional radiography in some centers for both diagnosis and follow-up of MM patients and the clinicians have to take this method into consideration if it is available. Whole-body MRI can give complementary information to skeletal survey and is recommended in patients with normal conventional radiography. MRI of the whole spine should be performed in addition to the skeletal survey as part of staging in all patients with an apparently solitary plasmacytoma of bone irrespective of site of index lesion. Urgent MRI is the diagnostic procedure of choice to assess suspected cord compression in myeloma patients even in the absence of vertebral collapse. Urgent CT may be used to establish the presence of suspected cord compression in cases where MR Imaging is unavailable, impossible due to patient intolerance or contraindicated, for example, intraorbital metallic foreign bodies or cardiac pacemakers. CT of the spine or other areas of the skeleton may be considered to clarify the presence or absence of bone destruction in cases of clinical concern. Furthermore, CT is indicated to clarify the nature and extent of soft tissue disease and, where appropriate, to guide tissue biopsy. MRI should be used to clarify the significance of ambiguous CT findings, as these two imaging techniques can give complementary information, whereas both can be used before vertebralplasty or kyphoplasty. Bone scintigraphy has no role in the routine staging of myeloma, although sequential DEXA scans are not recommended. Based on the currently available evidence, neither PET nor MIBI imaging can be recommended for routine use in the management of myeloma patients, although both techniques may be useful in selected cases that warrant clarification of previous imaging findings, but such an approach should ideally be made within the context of a clinical trial.

In the event of disease progression, the skeletal survey should be repeated as part of the restaging process. Any newly symptomatic areas of the skeleton should be specifically targeted. MRI should be performed in all patients with negative skeletal survey. MRI or CT can be used for monitoring the response of soft tissue masses to therapy. The usefulness of PET/CT and MIBI on the follow-up of myeloma has not been
confirmed and further trials are needed. Treating physicians
must keep foremost in mind that myeloma bone disease is often
the cause of the most disabling problems that patients face and,
therefore, careful baseline and serial radiographic assessments
are essential to maintaining and improving their patients' quality
of life.

Conflict of interest

The authors declare no conflict of interest.

REVIEW

Immunohematopoietic stem cell transplantation: introduction and 35 years of development in South Africa—the historical and scientific perspective

P Jacob1,2 and L Wood2

1 University of Cape Town, Cape Town, South Africa and 2 Faculty of Health Sciences, Stellenbosch University—Tygerberg Academic Hospital, Stellenbosch, South Africa

Bone marrow was the traditional graft source when we introduced these procedures to South Africa. Technical details were established using rabbits as the experimental model with translation into a formally structured clinical programme at the University of Cape Town, based in the Groote Schuur Hospital, in 1972. Lack of any infrastructure was overcome by the acquisition of the first continuous-flow cell separator in sub-Saharan to provide for granulocyte transfusions. This was shortly followed by creating a dedicated platelet donor panel and establishing a specialized laboratory for clonogenic assays, flow cytometry, and programmed freezing and by including cryopreservation. Development was constant and seamless but four distinct periods are recognizable. First, guided and constantly encouraged by Professor E Donnall Thomas, was the use of an unfractonated mononuclear population derived from multiple sternal and iliac crest aspirations where complications, as in other centres, included rejection and, particularly troublesome, acute as well as chronic GVHD. The second was centred on CsA in association with Professor Jean Borel at Sandoz in Basle, leading to a decrease in the incidence and severity of the latter immunologic phenomena but not to their abrogation. Third was the opportunity of working with Professor Herman Waldmann and Dr Geoff Hale, first in Cambridge and latterly in Oxford, on immunosuppression achieved by ex vivo T-cell depletion within the broad ambit of the Campath users group. It was here that there was pioneered the alternative new approach of adding the anti-CD 52 MoAb only to the graft in what has become known as the in-the-bag technique. The fourth, securely based on early laboratory and clinical experiences, was a switch to the use of PBSCs mobilized into the circulation with stimulatory peptides. In 1995, this original transplant team relocated to a new academic centre in the private sector and has continued to actively refine the programme over the subsequent decade: the facility at Groote Schuur hospital continues independently. Early recognition that accountability for these expensive and high profile procedures was an important obligation led to consecutive transplants being reported to the International and Autologous registries and now continuing to the Centre for Bone Marrow Transplant Research in concert with the European Bone Marrow Transplant Registry. This disciplined approach has ensured that all data undergo constant audit and, on such a basis, underpin the unbroken accreditation extending over more than three and a half decades. With difficulties in finding sibling donors, a further achievement was the creation of The South African Bone Marrow Registry and now a proposal to also start a national transplant registry that will complement the survey currently being conducted, on a worldwide basis, by the European Group for Blood and Marrow Transplantation. It is concluded that a properly constituted and functioning multidisciplinary team can cost-effectively carry out immunohematopoietic stem cell grafting even in an under-resourced country with an outcome approximating that reported from recognized First World reference centres. The caveat is that, outside such comprehensive units, results may be less impressive, thereby arguing for resource allocation being directed to academically designated, rather than incentive-driven, preferred providers.

Keywords: immunohematopoietic SCT; introduction—development; South Africa

Professor E Donnall Thomas developed the concept and established the technical feasibility of BMT in a canine model. He and his team then courageously pioneered the translation of these orderly research studies into the clinic and first proposed what have become the currently accepted indications.1,2 From the start of these activities in Cooperstown to the Public Health Hospital in Seattle and finally to the Fred Hutchinson Cancer, he has through sheer talent inspired leadership and a unique compassion for patients and every member of his staff alike and attracted generations of Fellows, many of whom have gone on to sustain the ever clearer definition for the usage and unravelling of early and now late side effects. The hallmark of these graduates is his clear imprint of identifying a clinical problem and then increasingly applying cellular and

molecular biologic techniques to understanding pathogenesis as a basis for refined or focused intervention. Small wonder that such achievements were recognized by the award of the Nobel Prize.

It would be inappropriate to describe the historical parallels that took place in South Africa without the preceding acknowledgement or an explanation of how the programme started in sub-Saharan. During the years as a haematology Fellow in Seattle with Professor Clement A Finch, there was regular contact and exposure to the excitement surrounding BMT. It would be both difficult—and invidious—to select from that group of dedicated investigators more than a representative mention of four who remain currently active, including Dr Rainer Storb, Dr Fred Appelbaum, Dr Joachim Deeg and Dr Joan Sanders with whom, among others, we are privileged to maintain an association that now extends back to more than 30 years.

One other event that cannot be overlooked is the momentous achievement of Professor Christian Neethling Barnard in carrying out the first human heart transplant in the world. It was into that receptive environment, prevailing at the University of Cape Town and Groote Schuur Hospital, that one Peter Jacobs had the great honour of being appointed as the Foundation Professor of Haematology. The inevitable question from Sir Richard Luyt and the appointments committee was what direction the new department had selected for particular focus! With no in-depth training in immunology and precious little in transplantation biology, it was with temerity that this emerging area of interest-BM grafting was chosen. And so the die was cast. The brief historical record that follows freely acknowledges unrestricted encouragement from innumerable colleagues of all persuasions, particularly during the early development with periods of frustration balanced by elation, and the many members of the multidisciplinary team who collectively made it a reality. It equally reminds us all never to lose sight of that extraordinary courage shown by patients and their families alike.

From individual centre and case studies to the meticulously orchestrated collection and analysis of data by the Centre for International Bone Marrow Transplant Research, indications in adults and children are now clearly defined (Table 1), whereas outcome remains the subject of continuous review and updating. Against this background, a number of relevant observations emerge that logically start with patient selection and a consideration of variables including age and comorbidity. It is here that the collective experience of the multidisciplinary team is crucial, with best results reflecting an under-appreciated centre effect.

All important is the conditioning of the recipient to accept the incoming graft, but, in selected instances and depending on diagnosis, it may be the need for further chemotherapy directed at eradicating residual disease. Historically, myeloablative preparation with high-dose chemotherapy or irradiation and more innovatively by the use of radioconjugates continues to undergo study. An area of particular interest has been the use of anti-CD 32 MoAb, which can be given either to a patient or a used ex vivo in what has become known as the in-the-bag technique.

Modified from: Forman S.J. The entry of patients only into clinical trials protocols is strongly favoured. Such structures provide for accountability and outcome analyses upon which rest accreditation. Also inclusive is the all-important quality-of-life evaluation and documentation of time-related side effects.

associated with this step has resulted in the description of reduced intensity regimens that make it possible to extend the upper age limit, but this may be offset by higher disease relapse rates. However, a reversal of the latter complication is possible in some cases by capitalizing on antitumour effects mediated by alloreactive T-cells in the form of delayed donor lymphocyte infusion. At this point remains the unresolved and challenging issue of optimum post transplant immunosuppression ranging from traditional corticosteroids with CsA and MTX through a wide range of new and potentially more effective—perhaps even safer—options.

This sophisticated form of treatment is best carried out in a dedicated reverse isolation unit or protected environment, but debate rages on precisely what defines such a physical facility or plant. Arguably, of far greater importance is investment in a properly constituted cross-disciplinary management team with, at least in Africa, input from practitioners of alternative or complementary medicine. Also, there is a need for a reliable and safe supply of blood and related products, a laboratory capable and registered as competent to carry out apheresis procedures, experienced in programmed freezing and licensed for cryopreservation in terms of locally promulgated acts for dealing with human tissues. Donor availability, particularly with increasing use of matched unrelated donors, and alternative sources including cord blood are those unique considerations securing access to tissue typing with immunogenetics accreditation. Transplants not carried out in such an organized, audited and accredited centre, designated as competent for both harvesting and grafting, are viewed as inappropriate and to be discouraged.

Then, in the short term defined as the first 100 days, is transplant-related mortality, which has a number of

In the interim, all individuals are seen as frequently as needed, but as a generalization, when asymptomatic, every 3 months. Once a year, more detailed assessment is prudent.

Standard of care using international norms. Arguments that such criteria do not apply to developing countries, where less good outcomes might be tolerated, are clearly specious as well as inappropriate! Such an attitude should not be entertained—and much less supported—particularly as there is evidence that precisely the opposite is true.16,17

It is against these observations that, first, the introduction and then the continuous development of immunohematopoietic SCT in South Africa over a 35-year period can now be detailed. There emerges the conclusion that at the present time they continue to provide life-saving and cost-effective, as well as resource-appropriate, therapeutic options in selected, properly managed centres that enjoy international designation.

Demographic considerations and current transplant activity

South Africa has a surface area of 1,219,080 km² (Table 3, Figure 1) with a population of 47,849,800 and a population density of 135/km². Complete records are available from the time BMT was started by the originally designated team (Table 4). Now, with the recent proposal that a national database be started, matching activities throughout the

country can be collected hopefully through the existing Bone Marrow Registry.18 Such voluntary participation should, in future, make these activities a matter of general record. At the same time, South Africa has been included in a survey by a questionnaire circulated by the European Bone Marrow Transplant Registry gathering essentially the same figures. Clearly, these two activities need to be complementary.19 Logically, this exercise is but an initiating step that can easily be extended to formal outcome analysis. Implicit in such a rather more constructive endeavour will be the need to comply with ethics and research rules, including attention to issues that include donor confidentiality. This should be easy given the simple expedient of completing only already available, and circulated, relatively standardized data capture sheets!

Establishment of the Cape Town infrastructure

When this programme was inaugurated in 1970, blood was provided in glass bottles and platelets available only as single unit concentrates. To ensure that adequate transfusion support would be available, an IBM 2990 was secured by donation and this prompt action initiated a long and ongoing collaboration with Professor Jean Porter Hester.20 Although initially used for granulocyte transfusion, the apheresis technology rapidly became the anchor, together with the creation of a dedicated volunteer panel for donors, as one of the crucial moves towards realizing clinical transplantation. Physical facilities were limited and the start-up procedures were carried out with literally unlimited encouragement in the newly built block for cardiac transplantation through the courtesy of Professor Christian Neethling Barnard. As a result of his programme, histocompatibility testing also became available having only recently been introduced into our country. It was therefore possible to get class I by serology and some idea of class II by mixed lymphocyte reaction. These shortcomings were appreciated relatively soon and, in close collaboration with Professor Ernette du Toit, high-resolution typing became available with eventual immunogenetic testing approved in her laboratory.14 The activity of the South African Bone Marrow Registry is reflected in the latest statistics report (Table 5). The technical procedures of marrow processing, including characterization of the recovered mononuclear product, necessitated the development of a rabbit model in association with Professor Bruno Speck and Professor Aaloi Gratwohl in Basle to refine the methods, and the almost immediate establishment of flow cytometry and clonogenic assays using these transplants between strains showed that acute and chronic GVHD21 closely paralleled what was
being seen in the clinical programme. These manifestations were used to document the effects of G6A just made available by Professor Jean Borel at Sandoz in Switzerland. The same approach proved crucial in evaluating the administration of the Campath series of MoAbs to the recipient but subsequently showing that even more effective immunosuppression was possible by exposing the graft to the protein ex vivo in what has subsequently been described as the in-the-bag technique. This method has emerged as surprisingly rugged in abrogating classical acute GVHD and so substantially diminishing, almost to the point of extinction, the subsequently occurring chronic variant.

The clinical programme

The constant development, in a structured and actively evolving series, of experimental and clinical studies fell into four convenient but artificially distinct periods that characterize these activities in sub-Saharan Africa and particularly as chronicled at the University of Cape Town and Groote Schuur Hospital.

Unfractionated BM era mirrored experience occurring elsewhere in the world. Engraftment was often successful but plagued by graft failure and substantial morbidity as well as significant mortality consequent upon the syndrome of acute GVHD. Here, an often-profound injury to the skin, biliary endothelium and enterocytes, compounded by severe infection, responded only partially to immunosuppression with corticosteroids and MTX with extension to a severe sclerosing chronic form that created intractable disability in adults and children alike. In addition to the severe disability caused to recipients with devastating disorganization of family life, there emerged a more profound and often underplayed psychological injury to medical and nursing staff alike. This caused high staff turnover and understandable criticism from detractors of transplantation in general and more particularly to the use in hematology with the focus on the perceived worse side effects in children.

Cyclosporin A era started when this undecapeptide was isolated by Jean Borel in Sandoz and with our involvement in some of the earliest investigations of this biological breakthrough that was again thoroughly explored in the rabbit. Here, as also when the experimental studies were translated into the clinic, the incidence and severity, particularly of acute GVHD, was decreased but the broad range of complications changed surprisingly little. Nevertheless, this was a seminal step in being able to reverse the weakening confidence of the local medical community in the role of immunohematopoietic SCT and to set the stage for the continued active exploration of new and more effective agents.

Monoclonal antibody or campath era was in many ways the single biggest advance with which we were directly involved. Thus, the opportunity was afforded us of working with Professor Herman Waldmann and Dr Geoff Hale, initially in Cambridge and subsequently in Oxford, through participation in the scientific deliberations of the Campath users group. There was the innovative approach of employing selectively synthesized series of these Igs for

Figure 2. Overall survival in children. Kaplan-Meier analysis shows that at 6.8 years there is a stable plateau consistent with cure. It is notable that results are similar for idiopathic aplasia, Fanconi anemia and AML with nonsignificant differences for lymphoblastic leukemia and the remaining cases. There is also no difference in outcome for graft source but a slight benefit for the female gender, which did not attain statistical significance.

Figure 3. Overall survival in adults. One of the more interesting aspects of this programme is the similarity in survival by Kaplan-Meier analysis between consecutive patients with BM exposed to Campath 1-G-in-the-bag, peripheral blood treated with the same Ig or humanized variant and autografts. This particular approach is notable for the lower level of GVHD, and high remission rates in AML, but with an increasing incidence of CMV positivity that is the subject of ongoing investigation.

the alternative approach of effecting immunosuppression by means of relatively selective T-cell depletion. Experience in the animal transplant model, initially with the lytic IgM protein, showed GVHD to be beneficially affected and this could be duplicated in human allograft recipients with improvement in outcome. These events were enhanced first by the use of the opsonic IgG and then, more recently, by the humanized chimeric protein, confirmed in other countries.

At about the midpoint of these collaborative studies, innovative experimental evidence in our laboratory demonstrated that the addition of Ig to the graft, before infusion alone and without any subsequent immunosuppression using antibody or drugs, impacted favourably on acute GVHD. This syndrome virtually disappeared, although a late-presenting mild acute variant was recognized limited to the skin, being grade 1 and typically responding to topical steroids but seldom needing systemic administration. This was the birth of the in vitro, ex vivo or, as it has subsequently become known, Campath in-the-bag technique.10

Overlapping with these developments was the recognition that a stem cell population having many characteristics similar to those derived from the BM could be obtained by the much simpler expedient of recovery from the peripheral circulation usingpheresis technology, with enhancement resulting from the donor receiving stimulatory peptides in the form of G-CSF.28 A new observation emerged in that CMV infections, which had not been particularly prominent while using marrow, now required increased constant monitoring and prompt administration of gancyclovir to avoid progression from viraemia to the much more hazardous situation of clinical disease typically in the lung or the gastrointestinal tract.

The current era, spanning the last 12 years, has been particularly illuminating in the context of an under-resourced area where state support for teaching hospitals continues to relentlessly erode so that commercial ventures have become more receptive to accepting tertiary-level
responsibilities. Thus, it has been possible to relocate, within a single Facility, most of the original team to a privately based Academic Department of Hematology and Bone Marrow Transplant Unit that incorporates the Searl Research Laboratory for Cellular and Molecular Biology. The experiment has been successful, proving that it is realistic to maintain the consecutive patient reporting system first to the International and then to the Autologous registries that are currently combined into the Centre for Bone Marrow Transplant Research. This period demonstrates the feasibility of meeting the audit criteria for continued accreditation as both a transplant and harvest centre now extending for an unbroken period in excess of three decades, as well as accommodating the need for matched unrelated volunteer donors. The latter sparked the need to start a donor registry that has become a national entity providing tissue-typing services for other centres in the country, regularly interacting with corresponding facilities and participating in searches from elsewhere in the world with activity recently updated. The standard is such that endorsement is maintained from the American National Donor Programme as well as the European Bone Marrow Transplant Registry. In parallel outcome has been analysed and reported in both children and adults (Figure 2) and adults (Figure 3), whereas the particular relevance of these procedures in patients with lymphoma continues to attract our ongoing and special attention.

An important consideration in the Third World is to balance the need for these high cost procedures against resources available in state hospitals having a limited budget and a competing private sector where restraints are of a slightly different nature dictated by the particular insurance plan available through managed care. In order that some idea of national activity can be gauged, it was recently proposed that a BM transplant registry be established within the ambit of the existing national body, the South African Bone Marrow Registry. The argument in favour of such a base is that it would allow comprehensive or inclusive recording of autologous and all forms of allogeneic transplantation and include alternative sources, such as cord blood and matched unrelated volunteer donors, and so in a non-partisan way. It would also permit the government, through the Department of Health, access to reliable statistics as to activity of the teams, whether they be in university hospitals or private sectors. Additionally, it would anticipate future needs for appropriate regulation that may be promulgated in terms of the Human Tissues Act. Here, particular issues relate to harvesting, any form of processing or manipulation of grafts and subsequent cryopreservation while monitoring the movement of these human products not only within the country but also as a cross-border between countries through the medium of collaborating international registries.

Conclusion

The basis for this national experience can be factually recorded in three phases of past achievement and present status with a projection for the future. Historically, the experimental hematology and subsequent systemic transplantation into the clinical programme documents the capability of an under-resourced country to provide advanced and life-saving interventions as dictated only by the genuine needs within the community, across the age spectrum and catered for by the state or private sector, even where costs are a major consideration (Tables 5 and 6). It is equally clearly demonstrated that in those few facilities that have elected to meet the criteria for ongoing audit and accreditation from international peers, designation is possible as a donor and harvest centre leading to participation in a worldwide community linked through registries that share search and provision of matched unrelated volunteers when these are not available locally. Finally, it is time to survey the activity within our borders and to this end the reporting of consecutive procedures by each practice has proposed forming a registry to operate within the ambit of the nationally constituted South African Bone Marrow Registry. The latter initiative is given sharp focus by a similar approach already launched by the European Bone Marrow Transplant Registry, and both should be mutually complementary. Such a proactive move would have the capacity for expansion to document outcome, although this would require appropriate ethics and research monitoring. A further attraction is the creation of a reliable database providing comparisons between different regions of the world and, in the local context, a basis to guide and educate practices in terms of regulation for transfusion practices and handling human tissues. The natural end point becomes academic recognition for properly accredited programmes to safeguard future scientific and training requirements while simultaneously reducing any need for commercial or incentive-driven providers.

CHAPTER 2

DEVELOPMENT OF NEW MODALITIES

FROM 1980
The experimental model

The rabbit was chosen although much of the ongoing work, worldwide, at that time was murine. The management of animals was in a vivarium and under constant surveillance by the relevant University research committee with attention to every detail of proper experimentation techniques and in accordance with all prevailing recommendations. This carefully considered decision was based on an opportunity to collaborate with colleagues in Basle – Bruno Speck and Alois Gratwohl. They had developed two distinct inbred strains and characterised these immunologically as being suitable to examine not only engraftment but also rejection and acute as well as chronic graft-versus-host disease. To constantly evaluate the results outcome was regularly presented at international meetings. These animals were also of a suitable size and could be handled safely during the cardinal first steps of marrow recovery in addition to providing adequate material for the processing, using existing morphologic criteria, with available mononuclear separation techniques. Techniques were introduced for repeated blood sampling in small animals and bone marrow reconstitution using a block grafting technique explored. After feasibility had been established preliminary studies evaluated immunosuppressive therapy with Corynebacterium parvum as modulating graft-versus-host disease in allografted pairs.

The specialised transplantation laboratory

Experience in manipulation of different cell populations required new collection and separation methods, accumulating experience in microbiology and safe operation of laminar - down flow environments for ex vivo cultures. Initially there was characterisation of progenitors and stroma focussing on patterns of growth determined by both physiological cytokines and alterations resulting from additional stimulatory peptides. Such reference or baseline ratios defining colonies and clusters each with distinctive cytomorphology. A modification was needed to record, with appropriate staining and innovative fixation, a means to retain the pattern. These became part of permanent reference library for the composition and behaviour of quite different populations found in the marrow of both the animals and human samples.
Additionally cytogenetics, flow cytometry and cytochemical techniques were introduced, instruments calibrated, normal ranges defined and these innovations extended to characterising fluid phase tumours\textsuperscript{72-74}.

\textbf{Creation of essential infrastructure in the clinic}

As these preparative stages were being completed the role of this procedure attracted increasing medical\textsuperscript{75} and nursing attention\textsuperscript{76}. Among these were the technicalities for the adequate sampling of bone marrow\textsuperscript{77,78} and the parallel interaction with other local scientists exploring such anticipated problems as chemotherapy-induced cardiomyopathy\textsuperscript{79,80}.

Substantial new challenges were predicated by lack of modern transfusion medicine exemplified by the fact that whole blood was supplied in bottles and platelets as single units\textsuperscript{88,89} leading to introduction of new methodology\textsuperscript{91}. These obsolete two practices were incriminated in increasing the risk of antigenic exposure and posed insurmountable barriers for any projected bone marrow transplantation program.

It was therefore necessary to establish an apheresis or cell support unit\textsuperscript{78} that brought with it new problems. Also the dependence on patients for repeated venous access and, yet again experience with the rabbit model pioneered the forerunner of the Hickman line\textsuperscript{82}. The next logical step was to obtain a discontinuous and then the first continuous blood flow cell separator on the continent which was commissioned and after all the operating characteristics carefully documented progress to setting up an appropriate component support program\textsuperscript{83-85}. This was followed by establishing a dedicated in-hospital platelet volunteer program\textsuperscript{86,87} and use of this methodology for treating sickle crisis\textsuperscript{88}. After a probationary period consistent incident-free outcome led to the two investigators being licensed for all these procedures on authorisation from the Department of Health.
On the basis of such experience operating procedures were developed for the recovery of granulocytes\textsuperscript{89} followed by the all important and cardinal studies in collection and with subsequent cryopreservation of human stem and progenitor cells as the anchor for bone marrow transplantation\textsuperscript{90}. Neither was the potential side-effects of the technique overlooked\textsuperscript{91} and in a very forward-looking and visionary way donor safety\textsuperscript{92} introduced and continues to this day\textsuperscript{93,94} although the focus is shifting to longer term observation in the light of recent reports\textsuperscript{95,96}.

\textit{The scene is finally set}

Securely founded on these years of systematically developing, in a structured and stepwise fashion, the standardised laboratory methodology moved through translational research taking each innovation into the clinic. All the technology supported by allocation of the necessary resources in terms of inpatient and outpatient beds, medical nursing and other paramedical staff led to the first successful bone marrow transplantation in this country\textsuperscript{93}. 
THE EFFECT OF CYCLOSPORIN A ON THE SURVIVAL OF RABBITS FOLLOWING ALLOGENEIC BONE MARROW TRANSPLANTATION. P. Jacobs, D. Barends, J. Parker, G. Manuel, The Department of Haematology, The University of Cape Town and Groote Schuur Hospital, Observatory, Cape - South Africa; University of the Western Cape; Provincial Blood Grouping Laboratory.

Graft-versus-host disease (GVHD) is the most important cause of death in patients and animals following allogeneic bone marrow transplantation. Neither attempts to prevent the syndrome with methotrexate or treatment of the established disease with corticosteroids or antithymocyte globulin have significantly altered morbidity or mortality. The immunosuppressive agent cyclosporin A (CSA) is reported to be effective in therapy of GVHD in rodents. The present study was undertaken to extend this observation. Using a previously described animal model New Zealand White strain of rabbits were irradiated with 1,200 rads mid-plane to render them aplastic; this was followed by infusion of a bone marrow suspension obtained from R strain rabbit donors. The recipients were randomly allocated to receive either no treatment or 28 consecutive daily intramuscular injections of CSA (10 mg/kg). There was no evidence of renal, hepatic or haematopoietic protractility associated with the CSA administration. Survival figures at 28 days in the control animals were 1/3 (12.5%) and in those receiving CSA this was 11/18 (61%): at 100 days there were no survivors in the untreated animals and 6/18 (36%) of those receiving CSA were alive and well. Histology of tissue obtained at autopsy from the controls showed changes compatible with GVHD in all the animals examined. In the CSA treated animals dying before day 28 there was a lower incidence of these findings and death was due to infection. However, after 28 days GVHD was again manifest affecting predominately the gut. In none of our animals was there evidence of malignancy developing in the long-term survivors. It is concluded that, as in rodents, the administration of CSA to rabbits undergoing allogeneic bone marrow transplantation significantly prolonged survival.

This study was supported by grants from the Medical Research Council, The National Cancer Association and the Harry Crossley Foundation of the University of Cape Town. We thank SANRP for a donation of cyclosporin A.

The use of Cyclosporin A to increase the duration of survival of rabbits following allogeneic bone marrow transplantation.
AN EVALUATION OF CYCLOSPORIN A IN REDUCING THE INCIDENCE OF GRAFT VERSUS HOST DISEASE IN RABBITS UNDERGOING ALLOGENIC BONE MARROW TRANSPLANTATION.

by P. Jacobs, D. Bareford, J.R. Parker, B. Milns & G. Manuel, University of Cape Town Leukaemia Centre & Department of Haematology, Groote Schuur Hospital, Observatory, Cape Town, South Africa

A PRELIMINARY REPORT

INTRODUCTION

Bone marrow transplantation using HLA-identical and MLC non-reactive siblings is the accepted form of treatment for patients with severe acute aplastic anaemia and immunodeficiency disease, and it has given encouraging early results in leukaemic patients when transplanted in their first complete remission.

In a recent study of 30 patients with severe acute aplastic anaemia who had been minimally exposed to antigens contained in blood the projected survival at six years is 75% (1). In such selected individuals the incidence of graft rejection, previously in the range of 25% - 60%, is greatly reduced. Nevertheless, graft-versus-host disease still affects over half the patients and causes long-term problems in 20% of the survivors.

In leukaemic patients undergoing bone marrow transplantation in remission,
survival figures are over 60 %, and rejection is a lesser problem (2,3). These results should be compared to long-term survival with conventional cytotoxic chemotherapy, which is less than 10 %. Not surprisingly, there is current enthusiasm for bone marrow transplantation in these patients wherever an HLA-identical and MLC non-reactive sibling is available but graft-versus-host disease occurs with a similar frequency to that found in patients with severe acute aplastic anaemia who have been transplanted.

In general terms, this process is the major cause of morbidity and mortality in transplanted patients and the incidence appears to increase if poorly matched siblings are used as donors. The pathophysiology is the infusion and survival of immunocompetent cells contained in the bone marrow graft into immunologically incompetent recipients. The exact cellular mechanisms mediating the clinical syndrome are not fully understood. It is thought that the antigens on the cells of the recipient, probably determined by the major histocompatibility locus, are recognised as foreign by the engrafted immunocompetent cells and these are attacked with resulting cell death consequent upon the formation of T-killer cells.

EXPERIMENTAL STUDIES

An animal model has been developed to study the effect of a number of agents on the incidence of graft-versus-host disease. Initially, studies were directed at the effect of parenteral Corynebacterium Parvum and subsequently to assess the effect of the administration of Cyclosporin A on the severity of the process and also on animal survival. Cyclosporin A is an anti-lymphocyte peptide derived from two species of fungi (Cyclindrocarpon lucidum booth and Thickodermia polysporum) having the capacity to suppress cell-mediated immunity in experimental skin graft rejection, graft-versus-host disease, and experimental allergic encephalomyelitis in rodent models. It has also been successfully used to prolong allograft survival in rabbit and dog kidney, and pig and rat heart transplantation studies. More recently Cyclosporin A has been evaluated in human renal and bone marrow transplantation, and early results are encouraging.

Studies reported from the Royal Marsden Hospital in England on the use of Cyclosporin A for treatment of graft-versus-host disease in humans, showed that the skin manifestations abated in two days but no improvement in liver function was noted, and four of the five patients died of liver failure (4). In a subsequent trial using Cyclosporin A for prophylaxis, 21 patients were given the agent starting immediately before transplantation in a dose of 12.5 mg/kg for up to six months (5). There appears to be an appreciable reduction in the incidence of graft-versus-host disease, and five of those patients have now been off the drug for up to three months and continue to do well.

Side-effects include renal, hepatic, and gastrointestinal toxicity. Rising blood urea and creatinine have been observed in most patients, but this is reversible and can be controlled by adjustment in Cyclosporin A dosage: Approximately 50 % of the bone marrow transplant patients show a rising bilirubin and this may reach levels of 10 mg %. Additionally, hepatic enzyme elevation may occur. These abnormalities in liver function tests appear to be reversible. A number of patients show anorexia with conse-
quent weight loss but these symptoms occur predominantly with oral drug administration.

EXPERIMENTAL STUDIES CARRIED OUT AT THE UNIVERSITY OF CAPE TOWN LEUKAEMIA CENTRE.

A rabbit model was used in which R-strain females donated bone marrow to New Zealand White male recipients. The latter were individually housed and received prophylactic antibiotics for four weeks following transplantation. Twenty-four hours before the procedure, the recipients were rendered aplastic with 1.200 rads total body irradiation delivered from a cobalt point source. A mononuclear suspension of donor bone marrow cells was infused intravenously into the irradiated recipients and the dose standardised between 2.0 and 4.0 x 10^8 nucleated cells per kg. The recipients were randomly allocated to three groups. Group 1 were radiation control animals which received no marrow cells. Group 2 were transplantation or graft-versus-host disease controls; these received no modifying drugs before or after transplantation. Group 3 were the Cyclosporin A study group and received 10 mg/kg parenterally between the first and the 28th post-transplantation day.

RESULTS

All radiation control animals died on or before day 7. A small number of rabbits in both the transplantation control and the Cyclosporin A group died before day 7 due to infection or haemorrhage before engraftment had occurred and peripheral granulocytes and platelets had reached normal levels. These animals were excluded from the study since the design was to investigate the effect of Cyclosporin A on the incidence of graft-versus-host disease, and the latter would be more likely to occur once the donor marrow had become established in the recipient.

Of the animals suitable for analysis 10% in the allograft control series (group 2) were alive at day 40, and none at day 100. In the Cyclosporin A group the corresponding figures were 44% and 33%, respectively.

Routine haematologic assessment confirmed that engraftment had occurred at the same time in both groups: usually between days 5 and 8. There was no difference in peripheral haemoglobin, platelet, or white cell count for the period of observation (100 days).

Postmortem examination of the transplant (graft-versus-host disease) control group showed an appreciable number (66%) dying with histological manifestations of this syndrome. By way of contrast, only 25% of those in the Cyclosporin A treated group died with comparable organ histology. The remaining animals died of incidental causes such as perforated gastric ulcers, septicaemia, and either interstitial or broncho-pneumonia.

In none of the animals was evidence of lymphoma demonstrated.

It is notable that in this pilot study the Cyclosporin A was discontinued at day 28 and further studies are needed to determine whether longer periods of administration will be associated with further improvement in survival data and additional reduction in the histologic evidence of graft-versus-host disease.

In a separate study on normal rabbits given Cyclosporin A in a matching dose for 28 days no rise in hepatic
enzymes or renal function was demonstrated.

CONCLUSION

This study in experimental animals is encouraging in demonstrating a clear reduction in histologically proven graft-versus-host disease in the allo-transplanted rabbit model where animals receive prophylactic Cyclosporin A.

PROJECTED STUDIES

Studies are in progress to examine Cyclosporin A toxicity as a function of plasma level determined either on high pressure liquid chromatography or by radioimmuno-assay and also to define the effect of prolonged administration of Cyclosporin A on both the incidence of graft-versus-host disease and on survival in prophylactically treated animals. Studies are also being done to correlate these findings with additional, in vitro, measurements of lymphocyte and macrophage function and to examine the effects of Cyclosporin A administration on in vitro marrow culture and on the rate of immunologic reconstitution.

These studies are the basis for the ongoing clinical transplantation programme where patients with severe acute aplastic anaemia and those with leukaemia achieving their first complete remission are transplanted from suitably matched siblings and receive this agent as the only post-transplantation immunosuppressive therapy.

A simple method for repeated blood sampling in small animals

PETER JACOBS and LIEVE ADRIAENSSENS Seattle, Wash.

A method is described for introducing a shunt into the carotid artery of small animals. A subcutaneous reservoir remains easily accessible between the cannulas allowing frequent collections of relatively large volumes of unhemolyzed blood. Such sampling is convenient and can be accomplished with minimal discomfort to the animal, which is gently restrained but not anesthetized.

Many experimental situations in small animals necessitate repeated blood sampling. On occasions the specimens collected need to be of relatively large volume or it may be essential that they are free from hemolysis. On other occasions more complex manipulations such as exchange transfusions are required. In many situations some degree of success can be achieved by repeated cardiac puncture or the use of multiple venipunctures, but both of these techniques have well-recognized limitations. The following method is described because of its simplicity and the case with which repeated, nonhemolyzed samples may be collected over prolonged periods of time.

Material and methods

In adult rabbits or cats a modified heparin lock* (Fig. 1) is introduced subcutaneously so that the reservoir lies between the cannulas and the free end of the cannula is located in the left carotid artery. The right carotid artery may be used, but the anatomy of the

great vessels is such that the introduction of the cannula is a little more difficult and mechanical obstruction and thrombosis occur with greater frequency.

The animals are lightly anesthetized with halothane so the shunt can be inserted, and a one-centimeter skin incision is made in the midline between the carotid. The animal is then turned onto its back and a 2 to 3 centimeter skin incision is made in the neck from the level of the thyroid cartilage downward. The free end of the hopia-look is firmly grasped in a pair of curved forceps and directed subcutaneously into the back of the neck and then anteriorly to emerge at the top of the wound overlying the trachea (Fig. 2).

After the reservoir is adjusted subcutaneously, the forceps are withdrawn and the cannula is gently tensioned. The fat overlying the trachea is divided, and the left sternomastoid muscles are dislocated medially. This maneuver will expose the carotid artery and
Repeted blood sampling in small animals

Fig. 3.

the accompanying vagus nerve. The artery is ligated at the upper level of the thyroid cartilage, and the cannula is introduced 3 cm. into this vessel through a small nick made immediately below this ligature (Fig. 3). Once the cannula is in position, without any kinking, it is secured with a second ligature approximately 1 cm. below the first. The 2 wounds are closed with either clips or sutures.

While a completely sterile surgical technique might be employed, we have found this unnecessary and administer a 3 day course of penicillin and streptomycin to prevent post-operative infection. Blood is sampled by passing of a 20 gauge needle through the skin and directly into the heparin lock via its rubber cap; in this way any volume may be withdrawn as frequently as necessary. In order to keep the shunt patent, 1 ml. of saline containing between 50 and 100 units of heparin is injected after each sample collection and, when the shunt is not being regularly used, once every 24 hours. The volume of heparin should be adjusted to the frequency with which sampling takes place.

Discussion

Standard techniques for blood collection in small mammals include multiple cardiac puncture and the use of the marginal vein or central artery of the ear in the rabbit or from subcutaneous veins in animals such as small dogs and cats. In the former situation a small number of animals die regardless of the ability of the operator. The deaths are probably related to occasional trauma to the
coronary artery or disruption of valves or conducting tissue. On occasion significant hematothorax follows accidental division of such vessels as the internal mammary artery. While these situations are not serious in donor animals, they may become significant when death or unwanted blood loss follows manipulation during a course of a particular experiment. Similarly, collection of blood from the ear vessels cannot be repeated with any great frequency and often results in samples of inadequate volume or in the presence of significant degrees of hemolysis.

Approximately 50 shunts have been used in studies carried out in rabbits and cats, and these have functioned satisfactorily for periods as long as 8 weeks. The shunts described have, in our hands, had no operative mortality, and we have not recognized infection in the path of the shunt or within the heparin-lock itself.

Problems do arise in those circumstances where the rubber cork is inadvertently pulled out during sample collection. If such an accident is unrecognized, exsanguinating hemorrhage may occur. In situations where very frequent sampling takes place, some degree of leak inevitably occurs backward through the punctured rubber cork and may also give rise to hematoma formation with subsequent local infection; this may be avoided by changing the rubber cork every second or third day.

On rare occasions occlusion of the shunt has occurred. This has always followed inadequate care and, if recognized early enough, can be unblocked by injection of 2 ml of heparinized saline forcibly into the reservoir. Twice, this has resulted in convulsions and death of the animal due to cerebral emboli. This complication has not been seen when the cannulas are located in the left carotid artery. Care must be taken with these retrograde injections since rapid injection of cold saline, particularly down the right artery, can produce sudden cardiac arrest possibly due to cardiac arrhythmia.

The occasional use of both carotid arteries in a single animal has not produced any neurological disturbance, possibly because of a well-developed vertebro-basilar circulation. In other animals cannulas have been introduced simultaneously into the carotid artery and the jugular veins, and, although venous sampling has usually been adequate, more frequent occlusion occurs in the jugular vessels.

It is a pleasure to thank Dr. Clement A. Finch for helpful suggestions in preparation of this manuscript and for the use of facilities in his laboratory.
Bone Marrow Reconstitution Using a Block Grafting Technique

JOAN R. PARKER, SUSAN P. TAYLOR, G. MANUEL, P. JACOBS

SUMMARY

Experiments in rabbits with radiation-induced bone marrow aplasia have demonstrated that intramedullary block grafting is a feasible procedure. This technique requires surgical interference and offers no advantage over intravenous reconstitution. We therefore suggest that it has no value in therapeutic bone marrow transplantation.

The transplantation of bone marrow from HL-A identical and MLC non-reactive donors into patients with aplastic anaemia results in permanent recovery of marrow function in approximately 50% of cases. The currently accepted technique for such reconstitution is the intravenous infusion of a mononuclear suspension, and the use of this method in animals and man has been well documented. However, a number of cells are unavoidably damaged during preparation of the suspension, and there may thus be some selective loss of stem cells. Furthermore, a large number of the infused cells are sequestered in the lung following administration of the graft and, while this is likely to be transient, their exact fate remains unknown. These observations have suggested a need to explore alternative methods for reconstitution. It seems logical that if the marrow could be replaced directly into the bone marrow cavity in particle form, both of the above limitations would be avoided. In addition, it is theoretically possible that if the architecture is intact and cell relationships are therefore undisturbed, recovery may be significantly enhanced.

This study was undertaken to explore the feasibility of such an intramedullary grafting technique, using lethally irradiated rabbits as a model.

METHODS

Rabbits were selected both for easy manipulation and for the ready availability of bone marrow from the femora. The animals had an average body weight of 2 kg. A dose of 1 200 rads was delivered to the horizontal midplane from a cobalt source, and this invariably resulted in death of the control animal from bone marrow damage between 4 and 12 days after irradiation, without causing significant gastro-intestinal or other radiation-induced disturbance. It was important to deliver the radiation with the anaesthetised rabbit lying on its stomach, since in the lateral positions the femora were at different heights in the radiation field, and this resulted in an uneven distribution of damage to the marrow.

To determine the adequacy of a marrow graft from the femur in preventing death after lethal irradiation, one femur, or both, was shielded with lead during irradiation, and the recovery of peripheral blood values and bone marrow was measured.

The technique for removing the femoral marrow prior to intravenous infusion was then developed in the rabbit. A small hole was drilled at the level of the greater trochanter to admit a 20-gauge needle, and a slightly larger hole was drilled at the lower end of the bone into which a Teflon tube of 1.0 mm internal diameter fitted tightly. The contents of the femur were then washed out with tissue culture medium (TC 199, containing 20% autologous serum and 25 units of preservative-free heparin), by gentle pressure on a syringe containing the medium and attached to the 20-gauge needle. The marrow was converted into a mononuclear suspension by the method previously described. After exposing the rabbits to 1 200 rads, whole body irradiation, the autologous suspension was reintroduced into the marginal vein of the ear (group I). An aliquot of the marrow was retained for measurement of colony formation in soft agar, for determination of cell viability, and for differential counting.

The critical question of intramedullary reimplantation was then systematically explored. In initial experiments the femur was de-roofed and the marrow was curetted out (group II). After irradiation, the autologous marrow was repacked into the femoral cavity en bloc, and the excised bone fragment was replaced and secured with either internal mechanical fixation or acrylic cement.

In the third group of animals (group III), a larger hole (0.5 cm in diameter) was drilled at the lower end of the femur to avoid the de-roofing procedure. The marrow was removed by applying pressure with the syringe and a 20-gauge needle at the upper end of the femur, so that a solid marrow core was extruded intact. The animal then received lethal whole-body irradiation, and the block of marrow was reintroduced retrogradely into the now vacant femoral cavity via the lower hole. This procedure prevented the femoral fractures which occurred in group II.

In a further group of animals (group IV) the marrow was removed as described above, but was converted into coarse particles by passage through a screen of 0.6 mm
mesh size before retrograde intramedullary replacement, for which the same procedure as in group III was used.

RESULTS

The effect of the varying doses of radiation on survival is shown in Fig. 1. The L.D. was 1 200 rads, and this point was clearly defined. It is particularly significant that this dose level caused total and irreversible bone marrow aplasia without other complications from the irradiation. Specifically, haemorrhage of the gastro-intestinal tract or pulmonary changes were not demonstrable.

All 12 animals in the control group died from overwhelming infection within a period of 4-12 days. Postmortem examination showed that the organs were heavily infected with micro-organisms, which were prominent within the vascular system. None of the recognised short-term effects of irradiation were demonstrable at postmortem examination.

**Fig. 1. The relationship of radiation dosage to survival. The L.D. is 1 200 rads delivered to the horizontal midplane of the rabbit.**

---

In the control animals haemoglobin levels of between 10 g/100 ml and 12 g/100 ml were recorded. The average platelet count was 12 000/μl but, significantly, bleeding was not a problem, and leucocyte counts varied between 500/μl and 1 000/μl, without any granulocytes.

In the animals where one or both femora had been shielded (Fig. 2), peripheral blood values all returned to normal. The rise was quicker where both femora had been shielded, although during the 30 days of observation the values never returned to completely normal levels.

Of the 8 animals that received the standard irradiation, followed immediately by intravenous infusion of autologous marrow (group I), 6 survived the procedure with permanent recovery of marrow function (Table I). The 2 rabbits in this group that died, did so from infection before engraftment had occurred.

Aliquots of the monocellular suspension which were studied in the laboratory revealed a viability of intact cells in excess of 95%, and bone marrow differential cell counts were in close agreement with those previously reported. Colony formation in soft agar was used to predict the likelihood of engraftment, but, apart from a broad correlation with nucleated cell counts, was found to have limited value when used in this context.

None of the 4 animals in group II, in which the femur had been de-roofed, survived for more than 12 days. These animals died from overwhelming infection, and postmortem examination showed extensive necrosis of the replaced marrow.

Of the 8 animals in group III, in which the marrow was replaced en bloc into the femur by the retrograde route using a syringe, 2 survived. In these animals normal bone marrow function was demonstrated, but large areas of marrow necrosis were evident in biopsy specimens. Among the animals that died, the striking feature was infection, with a great deal of phagocytic activity in which macrophages were ingesting the necrotic bone marrow.

In group IV, 3 of the 6 rabbits recovered, with adequate bone marrow function. Fig. 3 shows the recovery of the leucocyte count in groups I and IV. Significantly, the rate of increase was no faster after intramedullary than after
intravenous reconstitution, and the animals in both these groups showed a more rapid haematological recovery than those in the group in which one or both of the femora had been shielded.

**DISCUSSION**

This radiation model of bone marrow aplasia has been found practical because LD<sub>50</sub> is precisely defined, and because the bone marrow aplasia is irreversible and is not complicated by other side-effects of irradiation. This model is ideal for studying immediate autologous reconstitution, since chemotherapeutically induced marrow aplasia has the disadvantage that some of the chemotherapeutic agent may circulate for a varying period of time, and so modify the response of engrafted marrow.

The cause of death in the animals which were irradiated but not reconstituted was infection, with a survival period of 4-12 days. This correlates with an absolute loss of granulocytes and monocytes and reflects severe bone marrow damage. The finding that when one or both femora were shielded all the animals survived, established that the amount of marrow contained in one femur (11.0 × 10<sup>6</sup> nucleated cells) is adequate for reconstitution. A slightly more rapid rise occurred with a larger graft, obtained by using both femora (Fig. 2). However, other studies<sup>2</sup> have established that a graft of 1.7 — 4.0 × 10<sup>6</sup> nucleated cells per kilogram body weight is adequate, and that larger grafts appear to confer no significant further benefit. If the weight of our animals is taken into account, these observations accord well with published data.

The technique in which the femur was de-roofed was abandoned, since neither internal fixation nor acrylic cementing was suitable for stabilising the weight-bearing bone. The mortality from infection in some animals in this group was thought to be influenced by femoral fractures with local haematoma formation.

In the group where the entire marrow core was replaced intact immediately after irradiation, the low survival rate is clearly explained by the extensive necrosis of the graft which occurred, and which was demonstrated at post- mortem. The necrosis probably resulted from an inability to vascularise the graft sufficiently rapidly to sustain cell survival. In the 2 animals which survived, superficial colonisation with haematopoietic tissue occurred, but the unpredictability of this occurring contra-indicates the use of large blocks.

Of significance are the results in the animals in which intramedullary grafting was carried out using small particles. In this group, the survival rate approached that of the animals that were autologously transplanted by the intravenous route. Histological examination of the bone marrow in these animals proved that it was entirely normal. Death in this group was related to infection at a period before engraftment had taken place. As in the previous group, necrosis was observed, and although it was patchy in distribution, it is thought to have limited the delivery of nutrients essential for rapid engraftment. This finding raises a question about particle implantation as opposed to mononuclear reconstitution where, we assume, nutrition would not be in balance.

Of particular interest is the finding that the grafting of 2.4 × 10<sup>6</sup> nucleated cells from one femur led to more rapid recovery of peripheral blood values than when either one femur, or both, was shielded. With the shielding of the femur, normal architecture is retained, and a rapid return of bone marrow function could be expected. This paradoxical delay in recovery may be explained by the systemic effect of irradiation, the so-called abscopal effect.

These studies have led us to conclude that in the experimental animal intramedullary block grafting is feasible, but offers no advantage over the intravenous route. When these findings are extrapolated to man, the benefits of the intravenous route are further emphasised, since the problems of a surgical procedure in the thrombocytopenic and agranulocytic patient will pose a formidable challenge.

Improved Survival Mediated by *Corynebacterium parvum* Following Allogeneic Bone Marrow Transplantation in Rabbits

**Joan R. Parker, Graham Manuel & Peter Jacobs**

_The University of Cape Town Leukaemia Centre & The Department of Haematology, Groote Schuur Hospital, Observatory 7925, Cape, South Africa_

Received 30 March, accepted 8 September 1981

The effect of *Corynebacterium parvum* on survival was studied in aplastic rabbits transplanted with allogeneic bone marrow cells. Twenty four hours after receiving 1200 rad of total body irradiation, NZW males were reconstituted from unrelated R females using bone marrow combined with spleen cells or with marrow alone. The effects of treating donor, or both donor and recipient, with *C. parvum* were contrasted.

Rabbits in Group I were infused with a mixture of bone marrow and spleen cells. In control animals (Group Ia) none of the 14 animals survived to 40 days. Similarly, there were no survivors among 17 animals in group Ib where only the donors were pretreated with *C. parvum*. When both donor and recipient received this agent (Group Ic) three of the 13 animals (23%) survived beyond 40 days.

Animals in Group II were infused with marrow cells alone. Of the controls (Group IIa), 3 out of 24 animals (12.5%) survived to 40 days; pretreatment of the donor with *C. parvum* (Group IIb) resulted in survival of 8 of the 18 animals (44%); when both donor and recipient received this agent (Group IIc), 16 of 26 animals (62%) survived beyond 40 days.

Both the incidence and the severity of histologically demonstrable graft-versus-host disease was markedly reduced in the surviving animals. These observations demonstrate a significant effect of parenteral *C. parvum* on the prolongation of survival in the irradiated rabbit following transplantation with allogeneic bone marrow cells, which is related to reduction in GVHD.

**Key words:** allotransplantation — rabbits — *Corynebacterium parvum* — prolonged survival — decreased GVHD

Two immunologic phenomena have been predominantly responsible for preventing the considerable potential of clinical bone marrow transplantation from being realized: first, graft rejection; and, second, the high morbidity and mortality occurring in graft-versus-host disease, which may take either an acute or chronic form in successfully transplanted recipients.
In man, both prophylaxis and treatment of established graft-versus-host disease are unsatisfactory. Clinical and histopathologic manifestations of this unique immunologic phenomenon are well recognized, and the many therapeutic regimens being evaluated reflect the controversy surrounding pathogenesis. Thus, the appearance of this syndrome in approximately 70% of patients matched with their donors at the major histocompatibility complex suggests that other loci may be involved in the immune recognition. Furthermore, uncertainty persists about the way in which tissue destruction is mediated (1), although it appears that aberrations in the T-cell population result in the development of autotoxic or toxic cells (2). The role of the monocyte-macrophage system in this reaction is also not clear, but there is at least experimental evidence suggesting that cytotoxic macrophages may have a role to play (3).

Not surprisingly, this uncertainty has resulted in studies designed to prevent or to treat graft-versus-host disease with methotrexate (4), cyclophosphamide (5), or other agents, including antilymphocyte serum (6). However, most of these have met with limited success. In experimental animals attempts to modify graft-versus-host disease have been successful. In a mouse spleen model the phenomenon has been abrogated in the F1 hybrid by pretreating the host with Corynebacterium parvum (C. parvum) (7). These studies were undertaken to define the effects of this agent in another species and to examine the prolongation of survival in aplastic rabbits reconstituted with allogeneic bone marrow and spleen cells or bone marrow alone.

MATERIALS AND METHODS

Rabbits. New Zealand White (NZW) and R strain animals, having an average weight of 2.0 kg were used throughout. The animals were individually housed and received water containing prophylactic sulphaquinoxaline sodium (Embazin, May and Baker, Dagenham, England), and a standard rabbit diet (Epol, Johannesburg) medicated with Amprolium (Merck & Co., Inc., USA). Temperature, weight, and full blood count with differentials were done twice a week.

Strain difference. In all experiments donors were R females and the recipients NZW males. Lack of suitable antisera prevented histocompatibility typing. Standard mixed lymphocyte cultures (8) to demonstrate strain differences were not uniformly successful. Using a modified technique (9), consistent antigenic disparity was demonstrated between the two strains, and was most striking when mitomycin-treated lymphocytes derived from mesenteric lymph node were used as antigen and appendicular lymphocytes as responding target cells. Results at day 3 give stimulation indices between 1:3.6 and 1:13.9.

In each experimental study identical donor and recipient combinations were used, and the results obtained with the modified mixed lymphocyte reaction were confirmed by means of skin graft acceptance or rejection. In 12 studies uniform rejection of allografts was present between 6 and 12 days (mean day 10); autografts were uniformly accepted without sloughing.

Irradiation. The rabbits were rendered aplastic by delivery of 1200 rad total body irradiation from a cobalt source 100 centimeters above the midplane of the prone animals at a rate of 50 rad/minute. We have previously demonstrated (10) that irradiation delivered in this way produces uniform aplasia without unacceptable radiation complications. Specifically, no gastro-intestinal tract lesions were demonstrated. We did not find any difference between this technique and that in which radiotherapy was fractionated, as has been suggested by other investigators (11,12).

Radiation controls. 28 animals received irradiation and were monitored without transplantation.

Reconstitution with bone marrow and spleen cells—Group I. These animals received a combination of bone marrow and spleen cells by intravenous infusion 24 h after irradiation. Group Ia (n = 14) were transplanted without additional
manipulation. Group Ib (n = 17) received cells from donors pretreated with 2.8–3.5 mg C. parvum intravenously on days –4 and –1 prior to sacrifice and cell collection. Group Ic (n = 13) received the cell mixture from donors pretreated as above, and the recipient received, in addition, the same dose of C. parvum intravenously on the third and sixth day post-transplantation.

Reconstitution with marrow cells alone—Group II. These animals received only bone marrow cells by intravenous infusion 24 h after irradiation. Group IIa (n = 21) were transplanted without additional manipulation. Group IIb (n = 18) received cells from donors pretreated with 2.8–3.5 mg of C. parvum intravenously on days –4 and –1 prior to sacrifice and cell collection. Group IIc (n = 26) received the cell mixture from donors pretreated as above and the recipient received, in addition, the same dose of C. parvum intravenously on the third and sixth day post-transplantation.

Corynebacterium parvum. Wellcome Coparvax, a formalin-fixed suspension of organisms, was administered intravenously in a dose of 2.8–3.5 mg/2 kg rabbit.

Procedure for cell collection from the donor. Marrow was obtained from the long bones of the donor animals who were sacrificed with a short acting barbiturate (Sagatal). The cells were rendered monocellular by passing them through a series of stainless steel screens as described (10). Rabbits received an intravenous infusion of 2.0–4.0 × 10^8 cells/kg. Where marrow and spleen combinations were used for transplantation, the same range of marrow cells were given, but an additional 0.71–1.3 splenic cells/kg were added before infusion; the spleen cells had also been passed through the screens.

Some variation in the number of donor cells infused was unavoidable. As the basis for a previous study (10) we have established that infusion of 1.8 × 10^8 cells/kg or above is on a plateau for survival and therefore not a variable in the study. In addition, curves for the return of peripheral granulocyte and platelet count were constant within that range of nucleated cells infused. Furthermore, at any given time interval histology and marrow hematopoietic tissue were similar, provided more than 2.0 × 10^6 cells/kg were grafted.

Trypan blue exclusion confirmed a 98% viability of the cells administered and differential count of the marrow showed a full range of hematopoietic tissues to be present in the graft.

Histology. At sacrifice, or when the animal died, detailed autopsy studies were carried out on tissue fixed in buffered 10% formal saline. Sections were prepared from representative areas and examined after staining with hematoxylin and eosin.

Statistics. Taking into account the relatively small numbers of observations and differences in numbers between groups, comparison of means was undertaken as for independent samples (13). The difference between the means of the two samples was calculated and probability assigned on the basis of the Student’s t test (14). Differences between the means were compared after 40 days survival since, from this point, survival curves were constant on a plateau.

RESULTS

Control animals. 28 animals, irradiated but not transplanted, died with a mean survival of 6.8 days (SEM ± 0.08) (range 2–11 days). The fall in peripheral granulocyte and platelet count reached a nadir between four and six days after the irradiation. Autopsy studies confirmed marrow aplasia, and cause of death was established as infection in the majority of animals. Minimal associated hemorrhage was present in the gastrointestinal tract of occasional rabbits. The characteristic histologic finding was bone marrow aplasia, widespread presence of colonies of bacteria in all the organs, and loss of lymphoid tissue through the gut, thymus and the spleen.

Radiation complications were excluded by autotransplantation in a series of rabbits, all of whom survived and regenerated normal peripheral counts and bone marrow as reported (10). Serial studies failed to show complications such as late infection, myelofibrosis or delayed bone marrow failure.

Transplanted animals

a) Survival curves. Animals which died within 7 days of allogeneic transplan-
tation are excluded from further consideration.

i. No C. parvum administration:
   At 40 days there were no survivors among 14 animals infused with a mixture of bone marrow and spleen cells (Group Ia), and 3 of 24 animals (12.5%) who received marrow alone (Group IIa) reached this end point.

ii. Donors pretreated with C. parvum:
   There were no survivors among 17 animals transplanted with a mixture of marrow and spleen cells (Group Ib); 8 out of 18 animals (44%) survived 40 days following reconstitution with marrow cells alone (Group IIb).

iii. C. parvum administration to both donors and recipients:
   Three of the 13 animals (23%) who received a mixture of bone marrow and spleen cells (Group Ic) survived 40 days, whereas 16 of 26 animals (62%) who received marrow alone (Group IIc) also survived 40 days.

The influence of C. parvum on animals being reconstituted with bone marrow and spleen cells is summarized in Fig I; there is no statistically significant difference in survival between these three sub-groups. A similar comparison is made in Fig 2 for the animals receiving marrow alone. There is no significant difference between control animals and those receiving cells from C. parvum-treated donors \( (0.1 < P < 0.5) \). In contrast, significance is achieved between the survival of control animals and those where C. parvum is administered to both donor and recipient \( (0.2 < P < 0.05) \). The difference between Group IIb and IIc is not significant \( (0.1 < P < 0.5) \).

Figure 1. Comparison of survival in groups of rabbits allotransplanted with a mixture of bone marrow and spleen cells. There is no significant difference between the three groups.

b) Hematology. The pattern for regeneration of peripheral granulocyte and platelet count was analyzed. No difference was evident between Group I and Group II and, furthermore, the subgroups in the two transplanted series were also comparable. There was no difference in hematological recovery between allografted or autografted animals receiving between 2.0 and \( 4.0 \times 10^8 \) nucleated cells/kg. Furthermore, these patterns closely approximated the regeneration of peripheral blood granulocyte and platelet count in animals where one or both femora were shielded during the radiotherapy.

c) Clinical syndrome. The allografted animals differed dramatically from autograft controls or where femoral shielding had been used. Gross loss of weight was the striking feature; at day 40 mean weights were 0.9 and 2.8 kg respectively. There was, in addition, patchy but typically extensive hair loss. Diarrhea was a variable feature, with cultures generally being negative. This profound wasting syndrome with the copious watery diarrhea was limited to those that received allogeneic marrow, and was not present in irradiated animals or in those undergoing autografting.
The cause of death was typically infection in the respiratory tract with nasal discharge of pus. Pneumonia was often present, with extensive destructive abscess formation being a feature. Macroscopic findings were generally unremarkable apart from the subcutaneous atrophy, reduction in spleen size, and rather friable bowel most obvious in the ileum.

d) Histopathologic studies. In all the animals a rising peripheral blood count was associated with histologically normal hematopoietic repopulation of the marrow.

Histology of the skin, gastrointestinal tract, and the liver were characteristic of graft-versus-host disease: in the skin, aggressor lymphocytes were present in the epidermis and spongiosis was present, particularly at the junction with the derma; in the gastrointestinal tract, loss of glands and patchy to total mucosal denudation were most striking in the small bowel; in the liver, infiltration of lymphocytes, loss of the limiting plates, and destruction of bile ducts by lymphocytes were present; in the spleen, lymph nodes and thymus, generalized lymphoid atrophy was evident. These features were similar to those reported in man (15) and other experimental animals.

DISCUSSION

The total body irradiation technique used in this animal model produces uniform aplasia of the entire bone marrow without complications such as the lethal gastrointestinal tract symptoms described by others (11,12,16). It is not known why 1200 rad as a single fraction should, in our studies, be associated with apparently less morbidity than fractionated doses used by others. Furthermore, the control rabbits in our study which were allografted with bone marrow alone and had no exposure to C. parvum, had 40-day survival of only 12.5%, in contrast to higher figures reported by others (17,18). This variation in results may be explained by two fundamental differences between the present study and others that we have cited. First, the radiation schedules differed: other investigators used fractions of 600 rad and, 24 h later, a further 500 rad, whereas, we used a single exposure of 1200 rad. It remains theoretically possible that the fractionated doses may have less completely ablated hematopoietic stem cells, thereby permitting a higher percentage of spontaneous hematopoietic reconstitution with survival. Secondly, in their studies a single strain of New Zealand White rabbit was used, although these were not apparently inbred. In contrast, we transplanted across a strain difference, and greater antigenic disparity may have contributed directly to lower survival in our untreated group consequent upon graft-versus-host disease.

The traditionally accepted cellular infiltrate found in graft-versus-host dis-
ease was not initially present in the organs of our successfully engrafted animals. As time elapsed, however, lymphocyte repopulation occurred and at 40 days the clinically evident wasting syndrome could be correlated with histopathologic changes of graft-versus-host disease. The spleens were initially atrophic but gradually regained their lymphoid follicles. Essentially similar findings have been described (17). Spleen size, although smaller than unirradiated animals, was comparable to that found following autologous bone marrow reconstitution. We have been unsuccessful in demonstrating the hemolytic anemia that has been a prominent feature in some of the other studies (18).

The rationale for infusing spleen cells together with bone marrow in some of the animals was to try to produce a more acute form of graft-versus-host disease; similar approaches have been described by others (19). Such a sub-set of animals would permit further characterization of any effects resulting from the administration of C. parvum. Notably, these animals did not differ in the rate of engraftment, the course of the post-transplantation wasting syndrome, or the histology of the organs when compared to animals reconstituted with bone marrow cells alone. Nevertheless, supplementary spleen cells do appear to influence the death rate from graft-versus-host disease. Thus, in these animals, C. parvum treatment of the donors is without effect and only minimal benefit accrues when both donor and recipient receive this agent (Group Ic), so that 23% of the animals survived for 40 days. In contrast, clear improvement in the survival rate occurs when C. parvum is given to animals allotransplanted with marrow cells alone. Here, survival is prolonged when only the donors receive this agent; this effect is much greater when, in addition, recipients receive the immunologic adjuvant on the third and the sixth day following marrow infusion.

It is noteworthy that in the latter series (group IIC), 9 of the 26 animals who reached 40 days have survived beyond 100 days. The explanation for further deaths in this group due to graft-versus-host disease may be related to the way in which the C. parvum is scheduled. Thus, continued administration of C. parvum beyond the first week following transplantation may be an effective means of prolonging survival.

The decision to examine the effect of C. parvum administration on graft-versus-host disease is an extension of the observation by Biocchi et al (7) that this agent effectively abrogated the syndrome in the parental F1 hybrid mouse combination. That model is not strictly comparable to the situation which occurs when allogeneic marrow is transplanted from one HLA identical and MLC non-reactive sibling to another; the studies in our rabbits partly resolve the issue. Thus, they differ in that we were not able to match donor and recipient on the basis of histocompatibility testing, for want of appropriate antisera. Parallel with that clinical situation, however, there is, except in the case of identical twin transplants, genetic disparity between donor and recipient as the basis for graft-versus-host disease, although not at the major histocompatibility complex.

A further reason for selecting C. parvum for study are observations that T-lymphocytes are involved in the process of graft-versus-host disease and that this immunologic agent affects this
population (20) via interaction with the macrophage (21,22). Furthermore, *C. parvum* is known to be a potent stimulator of the reticuloendothelial system and to have adjuvant and antitumor activity (23–26). The central role of the macrophage, and the way it is influenced by *C. parvum*, is supported by observations (27) that the antitumor effect of this agent can be annulled by using antimacrophage sera. Furthermore, Bash (28) demonstrated that a T-lymphocyte sub-population is required in the inductive phase of macrophage activation by *C. parvum* and that subsequent suppression of this specific cell function is mediated by these macrophages.

*C. parvum* has been shown in our experimental model to have a clear effect in prolonging survival of irradiated rabbits reconstituted with allogeneic bone marrow cells, even when only the donor is treated prior to transplantation. Although only two doses are used, it is notable that this agent has a much more profound benefit when donor treatment is combined with its administration to the recipient after transplantation. In contrast, *C. parvum* has a lesser effect in prolonging survival of rabbits when spleen cells are transfused together with the marrow. At the present time it is not clear how *C. parvum* brings about improved survival in this model system. Theoretical possibilities include a direct influence on the macrophage or, more probably, modification of T-lymphocyte function in pathogenesis of graft-versus-host disease.

ACKNOWLEDGMENTS

This study was supported by grants from the University of Cape Town Leukaemia Centre, The Medical Research Council, The University Staff Research Fund and the National Cancer Association of South Africa. We thank Professor R Sealy and his staff for help with the radiotherapy, Wellcome Laboratories for donations of the *Corynebacterium parvum*, Mr K Hart, Miss B Milns, Mrs S Bird and Dr D Bareford for technical assistance. We are grateful to Dr Ernette du Toit for the facilities of her laboratory, Miss Sheila Katcher for bibliographic assistance, Mrs Jackie Davies for typing and Miss Jeanne Walker for illustrations.

Differential white blood cell counts were taken from 42 previously untreated patients with mammary carcinoma who received radiotherapy. 10 patients with Stage III mammary carcinoma who received chemotherapy, 19 patients previously treated by a simple mastectomy, and 4 untreated patients. The percentage of B- and T-cells in the peripheral blood also was measured. Severe lymphopenia was seen in patients treated with radiotherapy and chemotherapy. The percentage of B- and T-cells remained constant before and after radiotherapy, and there was no selective depression of T-cells. The monocyte count, 3 months after radiotherapy, was significantly higher than the pre-treatment mean count. The percentage of B- and T-cells in the peripheral blood remained unchanged before and after treatment with chemotherapy. The mean lymphocyte counts following surgery were slightly higher than the control values whereas the monocyte counts were slightly lower than the control values. Surgery did not appear to influence the percentages of B- and T-cells in the peripheral blood.

EAC and E rosettes (B- and T-cells), Monocyte lymphocyte ratio, Radiotherapy, Cyclophosphamide, Surgery, Fractionation, Mammary carcinoma.

INTRODUCTION

Stjernwärd et al.1 reported a selective depletion of T-cells in the peripheral blood following radiation therapy for mammary carcinoma, as well as a long lasting lymphopenia. Turk and Poulter2 reported a selective depletion of B-cells in the lymph nodes of mice following large single doses of cyclophosphamide. This finding suggested a way to depress B-cells selectively in humans with mammary carcinoma. If B-cells could be selectively depressed, immunoglobulin formation and “enhancing” antibodies could possibly be suppressed.3 We were also interested in the killing ability of B-cells following cyclophosphamide. Dowdle et al.5 reported impaired B-cell killing ability in leukemic patients, and we were interested to see if this was true in patients with mammary carcinoma. Rotman et al.6 reported that monocytosis occurred in patients on radiotherapy. They used a sophisticated electronic counter that could count 10,000 cells at a time. Although our differential counts were still done by hand, our data tends to corroborate the findings of Rotman. In addition, an inverse relationship between the monocyte and the lymphocyte count could be illustrated following chemotherapy, radiotherapy or surgery.

Finally, we could not substantiate previous reports4 that the lymphocyte count decreased with increasing tumor burden. Our patients with advanced mammary carcinoma were not lymphopenic, with the exception of 5 patients with so-called inflammatory carcinoma (cancer en cuirass).

METHODS AND MATERIALS

Radiotherapy: Mammary carcinoma

We took differential white cell counts before radiotherapy from 42 untreated patients with various stages of mammary carcinoma; we took them again immediately after completion of radiotherapy and at 3 monthly intervals thereafter.

White cell counts were done by electronic counter

†Supported by the University of Cape Town Leukemia Centre, Medical Research Council.
†Department of Radiotherapy, Tygerberg Hospital, Cape-town, South Africa.
§The Ludwig Institute for Cancer Research, Bern, Switzerland.
in the routine hematology laboratory and the
differential counts were done manually by counting
100 cells.

The total lymphocyte and monocyte counts were
calculated by multiplying the percentage of these
cells by the total number of white cells per cubic ml
of blood; this total was divided by 100.

EAC and E rosette forming cells (B- and T-cells)
20 ml of heparinized blood was taken by venipunc-
ture. Preservative free heparin was used. Lym-
phocyte separation was done by the method of
Böyum, Thorsby and Brattie. EAC and E rosette
forming cells were determined by the methods des-
cribed by Jondal et al. and Bianco et al.

Radiotherapy: cervical carcinoma
In order to determine the effects of radiotherapy on
the lymphocyte and monocyte counts during the first
4 weeks of treatment, we did differential white blood
cell counts on 29 patients with carcinoma of the
cervix prior to treatment and weekly thereafter for 4
weeks. Since 3 fractionation schemes were used, we
analysed the data in terms of fractionation as well.
The 3 schemes used were: twice weekly fractions of
600 rad each to a total dose of 3600 rad; twice weekly
fractions of 400 rad each to a total dose of 4000 rad;
and 2 fractions of 200 rad daily to a total dose of
5500 rad. The field arrangement for the 600 rad frac-
tions was by 2 parallel opposing fields, 15 cm²; for the
other 2 fractionation schemes, the so-called 4 field
"box" technique was used. ⁶⁰Co at a source to skin
distance of 80 cms was used in each case.

Chemotherapy
Ten previously untreated patients with stage III
mammary carcinoma had differential white blood cell
counts taken prior to, and for 3 consecutive weeks
after treatment with a single intravenous dose of
cyclophosphamide (50 mg per kg). Peripheral B- and
T-cells were determined before and 3 weeks after
treatment. B-cells were determined by their ability to
form rosettes (EAC rosette forming cells) as well as
an immunofluorescent method.

The B-cell killing ability of the lymphocytes were
determined before and after treatment by the method
described by MacLennan and was expressed as the
effect on target cell ratio to achieve 50% cell kill
after 19 hr incubation.

Surgery
19 Patients who had simple mastectomies pre-
viously had differential white cell counts taken at
intervals from 1 week to 6 months after surgery. EAC
and E rosette forming cells were determined as well.
The mean lymphocyte and monocyte count of 42
untreated patients with mammary carcinoma was
used as controls.

Radiation technique for mammary carcinoma
The 42 patients previously untreated, had mam-
mary carcinomas of varying stages and were there-
fore treated by 1 of 3 methods:
⁶⁰Co: A single irregular anterior field was used to
cover the internal mammary and supravacular
lymph nodes. Daily fractions of 200 rad for 5 days
each week to a total given dose of 5500 rad at 80 cm
source to skin distance (SSD) was used. This tech-
nique was used for post mastectomy patients with
negative apical lymph nodes.

Orthovoltage: 250 K V, 3.5 mm Cu half value layer
HVL at 50 cm SSD. For patients with metastatic
disease, 2 palliative tangential fields to the affected
breast were used. We attempted to deliver a skin dose
or central dose of 4500 rad. The field sizes were
usually 20 × 10 cm. The fractionation scheme used
was 200 rad daily for 5 days. For patients with apical
lymph node involvement, or other signs of Stage III
disease, a 5-field technique was used. This included a
sternal field, usually 20 × 7.5 cm, 2 tangential fields
with or without supplementary fields and 2 parallel
opposing fields to the supravacular area. We
attempted to deliver a central dose of 4500 rad; if this
was not possible, the given dose would be taken to
skin tolerance, usually 4500 rad.

The lymphocyte count as a function of the tumor
burden (stage) in patients with mammary carcinoma
The lymphocyte counts of 38 healthy females were
compared to 22 Stage I, 20 Stage II, 36 Stage III and
30 Stage IV patients with mammary carcinoma, and 5
patients with inflammatory carcinoma (Table 1).

The mean lymphocyte count for 42 previously untreated breast patients was 2223 ± 703; monocyte count 332 ± 163. The numbers in the right hand columns are the number of counts done at each interval.

Radiotherapy: Cervical carcinoma

The lymphocyte count following radiotherapy for cervical carcinoma follows the same pattern as that seen in the breast cancer patients. In this small longitudinally followed series, the monocyte count was also depressed in the first 4 weeks of treatment with our conventional counting method although the lymphocyte count was again significantly depressed at all points and fell from pretreatment mean values of 2318 ± 565 to 584 ± 307 2 weeks after the start of radiotherapy (p < 0.001; Fig. 2).

The influence of 3 different fractionation schemes is interesting and suggests that small daily fractions are more damaging to the lymphocyte population than large fractions given twice weekly. This remains true if the lymphocyte counts for the various fractionation schemes are compared at equivalent TDF (time dose fractionation) values. For TDF values of 33, e.g. the lymphocyte count for 5 fractions of 200 rad each has a mean value of 547 ± 289 compared to 1065 ± 481 and 1904 ± 350 for the 2 large fractionation schemes respectively (0.01p < 0.001; Table 4).

Fig. 2. The influence of radiotherapy on the lymphocyte and monocyte count in patients with carcinoma of the uterine cervix as a function of time—the first 4 weeks. Twenty-nine previously untreated patients were followed longitudinally.

Chemotherapy: Total white cell count

After 50 mg/kg cyclophosphamide intravenously, the total white cell count dropped significantly ($p < 0.005$) from pre-treatment values of $7759 \pm 1864$ to $3271 \pm 1690$ at the end of the first week and $4200 \pm 2474$ at the end of the second week. The count was $8380 \pm 390$ at the end of the third week, higher than the starting value (overshoot phenomenon).

The lymphocyte count

The total peripheral lymphocyte count dropped significantly ($p < 0.005$; Fig. 3), from a pre-treatment mean value of $2090 \pm 114$ to $875 \pm 622$ at the end of the first week. At the end of the third week the mean lymphocyte count was $1072 \pm 684$. This value was still significantly depressed compared to the starting value ($p < 0.025$; t-test).

The monocyte count

From pre-treatment values of $527 \pm 187$ the mean value for the monocyte count dropped significantly ($p < 0.005$; Fig. 3) to $279 \pm 304$ at the end of the first week and overshot significantly to values of $833 \pm 400$ ($p < 0.01$) at the end of the third week.

B- and T-cells (EAC and E rosette forming cells)

The B-cells formed 34% of the peripheral lymphocytes before cyclophosphamide and 31% 3 weeks after. This percentage difference was not significant. Turk and Poulter reported selective depletion of the B-cell areas in lymph nodes of mice following large single doses of cyclophosphamide.

In the human patient with mammary carcinoma, however, there is no selective depletion of the B-cells in the peripheral blood. We did not study lymph node morphology. The percentage of B-cells registered in the peripheral blood prior to treatment, by the immunofluorescent method was 34, 14%; at the end of 3 weeks this method identified 50.16% of the peripheral blood lymphocytes as B-cells. This difference was statistically significant ($0.01 < p < 0.05$; t-test). T-cells formed 64% of the peripheral lymphocyte count prior to treatment with cyclophosphamide; 3 weeks after, they accounted for 55%. This percentage drop was not statistically significant.

B-cell killing ability

The effect to target cell ratio for 50% cytotoxicity at 19 hr incubation for control (normal healthy
females) lymphocytes ranged from 1.2 to 4.2 with a mean value of 3.78. Before cyclophosphamide the range in 10 patients with Stage III mammary carcinoma was 1.3 to 6.4 with a mean value of 3.7. Three weeks after 50 mg/kg of cyclophosphamide the mean value was 3.70. These values do not differ significantly from those of healthy controls.

Impaired lymphocyte killing ability in this laboratory was seen in 7 patients with chronic lymphocytic leukemia (E: T50 value of 36.3), as reported by Dowdle et al.2

Surgery

Differential white cell counts were taken from 19 patients who previously had mastectomies. The mean lymphocyte and monocyte counts from 42 previously untreated patients with mammary carcinoma were taken as baseline values.

Following surgery the lymphocyte count did not appear to be affected (Fig. 4), except for the low point at 2 weeks post-operatively. Thereafter it remained at normal or slightly higher than normal values for 6 months or longer (Table 2).

The monocyte count dropped to values slightly lower than normal after surgery (Fig. 4, Table 2). B- and T-cells expressed as a percentage of the peripheral lymphocytes had a mean value of 32±13 and 62±12 respectively, compared to a value of 33.4±10.8 and 64±10.3 respectively in 42 previously untreated patients with mammary carcinoma.

The lymphocyte count and tumor burden (stage)

We could not find any correlation of the tumor burden with the lymphocyte count in 108 patients with various stages of mammary carcinoma. The exception was the mean lymphocyte count in 5 patients with inflammatory carcinoma. The mean count in these 5 patients was significantly depressed (Table 1).

DISCUSSION

Meyer10 states that radiotherapy induces a lymphopenia which may last for years; our data collected on patients who had radiotherapy for mammary carcinoma many years previously agrees with this finding (Table 2).

The induced lymphopenia is maximal at the end of a course of radiotherapy for mammary carcinoma and drops to 381/2223 or 18% of the pre-treatment values; 96 weeks later the lymphocyte count is still only 1682/2223 or 77% of the original mean values.

In radiotherapy for cervical carcinoma, the degree of lymphopenia after the completion of a course of radiotherapy depends on the fractionation scheme used (Table 4). At equal T.D.F. values, the lymphocyte count dropped to 23% of starting values for small fractions, 64% and 65% for the large fractionation schemes respectively. A possible explanation for this phenomenon is repopulation of the lymphocytes between fractions.

Chemotherapy (cyclophosphamide) likewise induces a lymphopenia which is maximal (42% of baseline values) 1 week after a single large dose (50 mg/kg). Three weeks later, there is still a significant lymphopenia (53%).

Surgery, on the other hand, does not seem to have any long term effects on the lymphocyte count (Fig. 4, Table 2); if anything the lymphocyte count is higher than baseline values.

Papetetous et al.15 reported that a larger percentage (57%) of Stage I patients had lymphocyte counts over 2000 when compared to Stage III patients (48%).

Our data does not confirm this finding. Of 108 patients tested, 53% of Stage I, 59% of Stage II, 51% of Stage III and 67% of Stage IV patients had lymphocyte counts over 2000. Papetetous has chosen 2000 as criterion because that was the approximate mean lymphocyte count for healthy control patients. Our own control (healthy) patients had a mean lymphocyte count of 2050. The mean lymphocyte counts in our patients with mammary carcinoma does not decrease with increasing tumor burden (stage of disease, Table 1). The exception is for 5 patients with inflammatory carcinoma (cancer en cuirass), where there is significant lymphopenia (p<0.005, t statistic).

Rotman et al.14 reported that therapeutic irradiation induces monocytosis in the patients so treated, and that they could tell whether a patient was receiving radiotherapy merely by observing a series of differential blood counts. They used a sophisticated new counting method. Our data for patients with mammary carcinoma who had radiotherapy, supports

Fig. 4. The influence of surgery on the lymphocyte and monocyte count as a function of time—the first 6 months. Nineteen patients were followed horizontally.‡

Incidental patients investigated some time, at random, after an event.
this finding even though we used the old hand-counting method (Fig. 1, Table 2). However, we also observed a mononcytosis 3 weeks after a single large dose of cyclophosphamide (Fig. 3) so that this finding (monocytosis in the presence of a simultaneous lymphopenia) may not be peculiar to radiotherapy; it would be interesting to see the monocyte count followed by the more sophisticated counting method described by Rotman et al.41 in patients on chemotherapy.

Following surgery, the monocyte count tends to remain lower than baseline values (Fig. 4, Table 2). In general, looking at the previously mentioned Figs. (1, 3, 4) there seems to be an inverse relationship between the monocyte and lymphocyte counts; is there a homeostatic stimulus operative following radiotherapy that is fully successful for the monocyte and only partly for the lymphocyte? Does radiotherapy cause a reduction in the number of lymphocyte stem cells capable of responding, so that the remaining ones, maximally stimulated, cannot repopulate the lymphocytes to pre-treatment levels, even years afterwards? Does radiotherapy release factors into the bloodstream with a long half life that "sets" the lymphocyte "norm" at new low levels, and at the same time allows the monocyte count to stabilize at higher levels?

Despite these impressions, the monocyte count fell despite the lymphopenia induced following radiotherapy for cervical carcinoma (Fig. 2). This could result from the relative inaccuracy of the hand-counting method for monocytes, or perhaps it could represent a different reaction of the monocytes to cervical carcinoma, compared to mammary carcinoma. Here again, a repetition of this type of data with a better counting method for monocytes may be of value.

Turk and Poulter5 reported a selective depletion of the lymphocytes from the B-cell territories in the lymph nodes and spleen of the mouse after single doses of cyclophosphamide. Sobolovic et al. showed that in rabbits, cyclophosphamide reduced the lymphocyte number in all organs considerably, with maximal reduction in the appendix. The lymphocytes that disappeared were Ig positive cells with slow electrophoretic mobility (B-cells).

Dumont6 likewise reported B-cell depletion after cyclophosphamide treatment in the mouse.

These findings were of considerable interest, since coating with blocking antibodies in vivo on tumor cells may be one explanation of the non-stimulability of autochthonous peripheral lymphocytes by the patient's tumor cells, by suppressing B-cell activity, the production of "enhancing" antibodies may be stopped.

Following a single large dose of cyclophosphamide (50 mg/kg) given as a bolus, 10 patients with advanced (Stage III) mammary carcinoma were assessed.

The cyclophosphamide induced a leukopenia, lymphopenia, as discussed. We did not study lymph node morphology, but determined the patients' peripheral B-cells by the EAC rosette forming method, as well as the immunofluorescent method. We could not demonstrate any selective depletion of the peripheral B-cell population by either method; if anything, the percentage of the peripheral B-cells was increased when measured by the immunofluorescent technique.

Functionally, the ability of the B-cells to kill sensitized target cells did not change before and after cyclophosphamide therapy. We used the effector to target cell ratio for 50% cytotoxicity after 19 hr incubation as an index of B-cell killing ability.

Stjernswärd et al.8 reported a selective depletion of the T-cells following radiotherapy for mammary carcinoma.

Our data did not confirm this finding: a possible explanation may be that we extracted all phagocytic cells by means of a magnet and carbonyl iron; these cells have C3 receptors and could have been counted.
as B-cells. Stjernswärd et al. did not use this technique for extracting phagocytic cells.

What is the clinical relevance of the prolonged lymphopenia following radiotherapy? The controversy whether radiotherapy for operable mammary carcinoma leads to increased mortality is not settled yet; the fact remains that we have an altered set of circumstances after radiotherapy; the "milieu interieur" is disturbed, and the consequence of this disturbance remains to be fully assessed.

DEFECTIVE B CELL KILLING BY LEUKAEMIC LYMPHOCYTES

E. R. DOWDLE, E. L. WILSON AND P. JACOBS,
Departments of Clinical Science and Immunology and of Haematology, University of Cape Town

The expanded population of peripheral blood lymphocytes (PBL) in most patients with chronic lymphocytic leukaemia have, to a greater or lesser degree, the characteristics of bone marrow-derived lymphocytes (B cells). Since antibody-dependent cytotoxicity by uninduced mononuclear cells has been shown to be a function of a cell-mediated mechanism, this property has been attributed to B cells. We have studied the ability of blood lymphocytes from 7 patients with chronic lymphocytic leukaemia to participate in this so-called 'B cell killing'. Normal or leukemic lymphocytes (effector cells) were purified and freed of phagocytic cells with carbonized iron powder, magnetic separation and centrifugation on a ficoll-hypaque density gradient. Chicken erythrocytes (target cells) were labelled with 51Cr and sensitised by incubation, at optimal concentration, with rabbit anti-chicken erythrocyte Ig antibody. Effector cells were incubated with target cells at four different effector:target cell (E:T) ratios of approximately 16:1, 8:1, 4:1 and 2:1 and cytotoxicity was assessed by 51Cr release after 1 hour and 19 hours' incubation in RPMI-1640 tissue culture medium. The E:T ratio required for 50% cytotoxicity (E:T 50) was determined from the linear relationship between the log of the E:T ratio and the log of percent cytotoxicity, and was used as an index of cytotoxic effectiveness. E:T ratios for normal lymphocytes ranged from 12:1 to 88 (mean 30) after 1 hour and from 2.3 to 4.4 (mean 3.1) after 19 hours' incubation. Corresponding values for leukemic lymphocytes ranged from 88 to 4,600 (mean 930) after 1 hour and from 15.1 to 67.3 (mean 36.3) after 19 hours. The results indicate that chronic leukemic lymphocytes are defective in their ability to mediate antibody-dependent cytotoxicity.

T AND B LYMPHOCYTES IN BABOONS AND VERVET MONKEYS

P. BRAIN, Natal Institute of Immunology, Durban

Recent work has shown that in certain auto-immune diseases of man the T-B lymphocyte ratio is disturbed and the suppressibility of T lymphocytes with a standard antilymphocyte serum is altered. With the aim of ultimately investigating lymphocyte function in autoimmune primate disease, which auto-immune thyroiditis has been artificially induced, we studied the lymphocytes of normal baboons and vervet monkeys. T lymphocytes were detected by rosette formation, and B lymphocytes, by the formation of erythrocyte rosettes, as in man. Purification of these lymphocytic populations was achieved by placing the lymphocytes of normal baboons and vervet monkeys on a ficoll-hypaque density gradient. The purified lymphocytes were then incubated with autologous rabbit antibody and complement. The results indicate that baboon lymphocytes are unaltered, whereas vervet lymphocytes, especially B lymphocytes, are activated. The activation of B lymphocytes in vervet monkeys may be due to a priming effect of the induced autoimmune disease.

INTERRELATIONSHIP BETWEEN HL-A AND MIXED LYMPHOCYTE CULTURE (MLC) REACTIONS

ERNETTE DU TOIT, J. REES AND M. C. BOTHA,
Provincial Blood Grouping Laboratory, Cape Town

We have studied the MLC reactivity in HL-A-identical unrelated individuals and in families with various degrees of consanguinity in a further attempt to demonstrate the genetic
Immunosuppressive therapy in bone marrow aplasia: The stroma functions normally to support hematopoiesis

Abstract
In aplastic anemia (AA) patients responsive to antilymphocyte globulin (ALG) therapy, abnormalities in both stroma and progenitor cell (PC) pool have been described. The relevance of each pathophysiologic defect was characterized in 16 individuals, and data were compared to results from seven normal volunteers. Bone marrow mononuclear cells were split into two fractions. Stromal layers (SL) were prepared from the first, and a CD34+ enriched population was obtained by immunomagnetic selection from the second. In cross-culture experiments, 1×10⁶ of the latter from patients or controls were seeded on preformed SL, and adhesive PC were scored for the formation of blast colonies (CFU-BI) on day 5 of culture. Nonadherent progenitors were recovered and quantitated in a standard clonogenic assay (CFU-GM). There were significantly fewer CD34+ cells in the AA group (median 0.65%, SD 0.39%, vs. 1.62%, SD 1.4% p = 0.002). No morphological or cytologic differences between normal and aplastic SL were detected. Both equally supported the growth of CFU-BI from normal progenitors (mean 117, SD 20.4, and 103.1, SD 30.4), while this was reduced for the aplastic PC (mean 41.06, SD 42.9; p = 0.0002, exact two-tailed test). Similarly, the AA nonadherent PC had a decreased CFU-GM growth (mean 142.6, SD 104.8, vs. mean 361.7, SD 91.3), with a lower total clonogenic output (p = 0.0009). We conclude that aplastic stroma appropriately supports the growth of normal progenitors, whereas the depressed clonogenicity of the corresponding population derived from AA is unrelated to their attachment to SL but intrinsic to the CD34+ cells, whether adherent or not.

Key words: Aplastic anemia—Bone marrow stroma—Antilymphocyte globulin

Introduction
In adult mammals, hematopoiesis occurs in the bone marrow, where both myeloid and lymphoid lineages differentiate from common pluripotent stem cells and then mature into their respective functional elements. The steady-state production of blood cells reflects a dynamic interaction between positive and negative regulators secreted by the stroma [1–5], acting through specific receptors [6,7]. Additionally, a paracrine modulation of this system [8–10] has been described, constitutive or induced in response to indirect signals [1], such as release of M-CSF or G-CSF following the exposure of monocytes to interferon-γ, interleukin-1 (II-1), or endotoxin [2]. Further regulatory effects are exerted by cells of the lymphoreticular system, which are abundantly represented as an integral component of the microenvironment [11–13]. It is therefore not surprising that alterations in the immune response can affect hematopoiesis.

The pathophysiologic lesion in aplasia is unknown, but data from genetically anemic mice models (SS) and W/W mutations) [14] or from in vitro studies have localized the abnormality to the stem cell pool [15,16] or the myeloid microenvironment [17–19].

Clinically, aplasia may reverse after immunosuppressive therapy [20] or when autologous reconstitution follows allotransplantation. The mature cells are functionally abnormal [21,22], however, and a subgroup of patients evolve to paroxysmal nocturnal hemoglobinuria (PNH), myelodysplasia, or acute leukemia [23,24]. In vitro studies have shown that clonogenic potential is reduced, suggesting damage to the progenitor population [15] or their unbalanced interaction with the supportive stroma [25–27]. Similarly, in long-term bone marrow culture systems [28,29], formation of the adherent layer is reported to be suboptimal [30], while further studies have suggested that the primary defect resides in the stem cell [15,16].

In a modification of this system that exploits the adhesive properties of these progenitors, it is possible to examine an early population of undifferentiated blasts (CFU-BI) [31], which resemble murine spleen colony-forming cells (CFU-S) in their resistance to cycle-specific cytotoxins [32]. These precursors are capable of self-renewal, as demonstrated by the production of secondary blast colonies [31,33]. Applying this model, we have previously reported that the stroma derived from untreated AA patients or those responding to immunosuppression supports normal precursor growth effectively, but the hematopoietic progenitors are defective [34]. We have now extended these studies and confirm that the growth of stroma adherent and nonadherent CD34+ cells is reduced, adding support to the concept that the primary defect resides within the hematopoietic stem cells.

Patient population
Thirty-four individuals with severe aplasia [35] were referred for therapy; one had rapid improvement following a thera-
peutic abortion, and the remainder received ALG and high-dose methylprednisolone (HDMP) [36], followed by oxymetholone maintenance for a period of 6–9 months.

Twenty-three fulfilled our criteria for response, defined as freedom from transfusions, granulocyte count of >1×10⁹ and platelets of >40×10⁹; at a median of 1250 days, 65% were alive. From this group, a cohort of 16 patients and seven controls gave written informed consent to donate bone marrow for a study approved by the Ethics and Research Committee of the University of Cape Town and Groote Schuur Hospital.

Among these 16 individuals, aplasia was secondary to infectious hepatitis in one, following chloroquine intake for rheumatoid arthritis in two, associated with pregnancy in another, and idiopathic in the remainder. Nine were females; the median age was 33 years (range 17–61). At a median follow-up period of 4 years (range 1–7), the median performance status was 0 (World Health Organization). During that time, six patients relapsed and three required further immunosuppression—two of these are currently in partial response and receiving cyclosporin combined with androgenic corticosteroid maintenance. Two patients in complete response developed clinical features of PNH and a positive Ham's test. At the time of study and a median of 4 years (range 1–8) from therapy, the median hemoglobin was 134.5 g/L (SD 27.2), MCV 98 fl (SD 7.17), granulocytes 2.21×10⁹/L (SD 1.89), lymphocytes 1.53×10⁹/L (SD 0.71), monocytes 0.23×10⁹/L (SD 0.18), and platelets 127×10⁹/L (SD 80.44). Morphology of the bone marrow revealed variable degrees of dysplasia and dyserythropoiesis in 15 individuals. Cytogenetic analysis of the myeloid cells demonstrated chromosomal breaks and gaps in five of the 15 in 13–40% of metaphases. No specific translocations or other cytogenetic abnormalities were noted.

Methods

Bone marrow cells

The study group was represented by 16 patients who had responded to prior immunosuppressive therapy. Their bone marrow was aspirated under pethidine hydrochloride analgesia, 1 mg/kg, given 30 minutes before local anesthesia. In hematoologically normal controls, samples were obtained at sternotomy during cardiac surgery under general anesthesia.

Normal or aplastic mononuclear cells recovered from polysucrose diatrizoate density gradients (1.077 g/mL; Histopaque; Sigma, St. Louis, MO) were washed three times in a minimal essential medium (α-MEM) (Gibco, Life Technologies, UK) and resuspended in 10 mL of the same medium. Aliquots were taken for morphological assessment, indirect immunofluorescence, and quantitative determinations with an electronic particle counter (Multisizer, Coulter Electronics) and divided into two fractions, one for the establishment of adherent stroma and the other for the selection of the progenitor population.

Bone marrow stromal layers

Throughout the study, sequential cultures of stroma from three hematologically normal males ages 34, 41, and 42, who were undergoing surgery for coronary artery bypass grafting, were employed and compared to the aplastic SL in the morphological and functional studies. Neither the patients nor the controls had a history of recent inflammatory or infectious disorders.

Light-density bone marrow cells (LDBMC) were suspended in α-MEM containing 12% each of horse serum (HS) (Gibco, UK) and fetal calf serum (FCS) (Gibco), supplemented with hydrocortisone 2×10⁻⁶ mol and gentamycin 5 μg/mL. Cells were cultured in 33-mm petri dishes (T.C. dishes; Bibby-2500B, UK) at a concentration of 0.5×10⁶ per dish at 37°C in a humidified atmosphere containing 5% carbon dioxide, until the stromal cultures became confluent. The medium was changed once a week throughout the culture life. Stromal layers were inspected every 7 days, time to culture confluence was noted, and determinations of the area covered by fat cells were recorded.

Cytotoxic staining of the stroma

Upon confluence, representative cultures were air-dried and stained in situ with May-Grünwald-Giemsa [37] or incubated with 1 mL 0.1% bovine trypsin (Difco, Detroit, MI) for 10 minutes at 37°C, inactivated with cold FCS, and washed twice in α-MEM. Cytosplasts of the complete stromal suspensions were prepared (Cytospin 2; Shandon, UK) and stained with May-Grünwald-Giemsa, Sudan Black, Oil Red O, or alkaline or acid phosphatase. Differential counts of marrow stromal populations were performed on 300 cells, and results from patients and controls were compared.

Progenitor cell selection

The second fraction of LDBMC from normal individuals or aplastic patients was suspended in α-MEM containing 1% FCS, placed into 15×220-mm plastic dishes (Bibby; Gibco) and incubated for 2 hours at 37°C to remove adherent cells. The nonadherent population was lymphocyte-depleted with 100 μL CAMPATH 1M (6.25 mg/mL; 0.01 mL antibody/5×10⁶ cells) [38] in the presence of 30% fresh AB serum as a source of complement for 50 minutes at 37°C.

The resulting lymphocyte- and monocyte-poor progenitor cell concentrates were washed three times in medium, resuspended in 0.2 mL of cold (4°C) phosphate-buffered saline (PBS) containing 0.02 mL/10⁵ cells of antihuman CD34 antigen murine monoclonal antibody (Anti HPCA-1, My 10; Becton Dickinson, Sunnyvale, CA) [39], and incubated on ice for 30 minutes. Labeled cells were selected with paramagnetic beads covalently bound to affinity-purified goat IgG against all mouse IgG subclasses (M-450, product no. 125.01; Dynal, Oslo, Norway) [40]. Magnetic spheres were removed by suspending cells in 0.1 mL PBS containing 0.01 mL of a polyclonal murine immunoglobulin (Detachabead; Dynal, Oslo, Norway) [41], cell viability determined by trypan blue exclusion, cells counted in a Neubauer chamber, and numbers adjusted to a concentration of 1–5×10⁶/mL. Aliquots of cells obtained from the initial density gradient and from the final separation were incubated overnight at 37°C in medium containing 15% FCS, washed twice, dripped on multistrip slides (Highveld Biologicals, Transvaal, South Africa), air-dried over 4–6 hours, and frozen to −80°C for immunophenotyping or employed for cytological determination after staining with Romanowsky dyes [37] and non-specific esterase.
Blast colony assay
Blast colonies were grown following a previously described method [31] with some modifications. Magnetically selected 1×10⁴ CD34+ cells obtained from controls or patients were layered in duplicate in cross-culture experiments on preformed normal or aplastic SL for 2 hours to ensure optimal adherence; the unattached cells were then removed by standard washing with α-MEM. Progenitors affixed to SL were covered with 1 mL of 0.3% agar (final concentration) in α-MEM containing 30% FCS and cultured for 5 days at 37°C in 5% CO₂. Aggregates containing more than 20 cells were counted with an inverted microscope on days 5 and 7 of culture. Layers that had not been seeded with CD34+ cells served as negative controls. CD34+ cells from six normal individuals were also co-cultured on normal stroma and CFU-BI were scored to provide comparative values for colony numbers obtained from control progenitors layered on aplastic stroma.
Nonadherent CD34+ progenitors that had been washed off the stroma were pooled and cultured in the CPU-C assay [42]. As contents of decanted nonadherent progenitors were contaminated with stromal macrophages, aggregates of these cells were not scored; colonies of granulocytes and granulocyte-macrophage CFU containing more than 40 cells were counted, and the results of colony numbers from duplicates were divided by 2 and expressed per 10⁴ cells.

Immunofluorescence studies
Frozen multwell slides of LDBMC and selected cells from normal individuals or patients with aplasia were thawed and dried overnight, fixed in 100% acetone for 5 minutes, washed with PBS, and labeled for 45 minutes with FITC-conjugated CD3 (0.005 mL UCHT-1; Dako, Denmark) or CD19 (0.005 mL Dako HD-37) antibodies or CD14 (0.01 mL CD14, Mo2; Coulter) and CD34 (0.01 mL Anti-HPCA, My 10; Becton Dickinson) for indirect studies. With each case, positive [43] and negative (monoclonal antibody against β-galactosidase; Professor E.B. Dowdle, Department of Clinical Science and Immunology, University of Cape Town) controls were always included. Where relevant (in wells containing CD14 and CD34), a fluorescein-conjugated second rabbit antibody (Dakopatts) was added for 30 minutes. All excess reagents were washed off with PBS and the nuclei counterstained with 1 μg/mL ethidium bromide for 1 minute, washed, mounted, and read under ultraviolet illumination at 50 nm with a mercury gas lamp on a Nikon microscope.

Statistical analysis
Student’s t-test was used to assess the standard error of the difference between two means in the analysis of the blast colony assay data.

Results

Progenitor cell selection
Immunofluorescence studies on unselected LDBMC from patients with aplasia resulted in a median of 0.65% CD34+ (SD 0.39%) cells, significantly fewer progenitors than normal controls at 1.62% (SD 1.40%) (p = 0.002). Although the unselected population was not studied, results derived from the Initial number of CD34+ cells and selection recoveries suggests that the median efficiency of the method was 67.6% (SD 11.07) and 62.9% (SD 9.22) of the mononuclear cell population, respectively. Upon morphologic or immunophenotypic examination of the selected fraction, there were no obvious differences in the cell content.
Morphologically, undifferentiated blasts represented a median of 81 and 87% in each group. The majority of contaminating cells were of early granulocyte series, while monocytic cells were always <2% in each selected group. Immunofluorescence studies for the CD34+ antigen showed that 80% (SD 4.97) and 82.5% (SD 5.79) were reactive.

Stromal layers
Both normal and aplastic stroma became confluent at a median of 4 weeks (3–4 vs. 3–5). In one patient, stroma did not reach confluence by 5.5 weeks, when it started to detach. When inspected with an inverted microscope employing phase contrast, there were no major morphological abnormalities in the stroma from patients with narrow aplasia; their appearance was similar to that of normals. In adherent layers from four patients with aplastic anemia, fat cells appeared to be decreased and were not detected in some of the dishes in two patients and one control.

Cytochemical staining of the stroma
There was no difference in stromal appearance with the various dyes used in situ. Differential counts of stained cytopsin preparations from five normal controls (including two not in this study) showed that Sudan black positivity was present in a mean of 13% (SD 7.2) of cells, Oil Red O in 9% (SD 6.1), acid phosphatase 61% (SD 17.2), and alkaline phosphatase 72% (SD 19.5). The corresponding figures for the 16 aplastic patients were 16% (SD 7.7), 3% (SD 2.5), 55.5% (SD 11.4), and 64.3% (SD 20). None of these values differed significantly.

Blast colony assay
In seven normal controls, the mean CFU-BI number from cells selected for the CD34+ antigen and cultured for 5 days on aplastic stroma was 103.1 colonies/10⁵ cells (median 104, SD 30.4) (Fig. 1). Two types of colonies were obvious; the majority belonged to compact aggregates, which were well circumscribed, round, or more often elongated, following the body of fibroblast cells in the stroma, while the second group appeared to detach from the stroma and rise into the agar. The mean number of CFU-BI from selected progenitors from six normal individuals cultured on control stroma was 117 colonies/10⁵ cells (median 109, SD 20.4) (p > 0.05) on day 5; this number did not change significantly on day 7, when some clones became looser and started detaching from the adherent layer.
When aplastic CD34+ precursors were panned on normal stromal cultures, a mean of 41.06 colonies/10⁵ cells (median 29.5, SD 42.9) were scored, which was significantly lower than the colony numbers obtained from normal CFU-BI (mean 103.1, SD 30.4) on aplastic SL (p = 0.0002, exact two-tailed median test). The majority of the colonies were small and loose, with many scattered cells when observed on day 7. Although the colony number score did not change significantly, some aggregates continued to increase in size until day 10, when all cultures were terminated.
Fig. 1. Clonogenic potential of cells from patients with aplastic anemia. CD34" progenitors from patients with aplasia (n=15) were incubated on normal stromal layers and compared to normal precursors (n=7) grown on aplastic stroma (n=16) or control stromal layers (n=6). Results are expressed as stroma adherent CFU-BI colonies and stroma nonadherent fractions cultured on the CFU-GM assay.

None of the SI that were not seeded with selected progenitors showed any CFU-BI formation.

Stroma nonadherent clonogenic growth

When cultures from stroma nonadherent CD34" cells, decanted after 2-hour incubation and grown for 14 days in the presence of phytohemagglutinin-leukocyte conditioned medium (PHA-LCM), were scored for clonogenic growth and compared to production of CFU-BI, results revealed that both normal and aplastic CD34" had proportionately similar numbers of stroma adherent and nonadherent precursors. Specifically, when aplastic progenitors were incubated on normal stroma, the mean CFU-BI:CFU-GM ratio was 41.06 (SD 42.9)/142.6 (SD 104.8); the corresponding result from normal CD34" on aplastic stroma for CFU-Bi:CFU-GM was 103.1 (SD 30.4)/361.7 (SD 91.3) and similar to control progenitors off normal adherent layers at 117 (SD 20.4)/335 (SD 56.8) (p = 0.0009). Furthermore, when results of adherent and nonadherent aplastic colonies were combined as a total clonogenic potential and compared to the normal composite, diseased CD34" cells had significantly lower colony output (combined mean 185.8 vs. 447.1; p = 0.0009, exact two-tailed test).

These data indicate that both stroma adherent and nonadherent progenitors were decreased in aplasia and that alterations in the adhesion to the stroma were not a significant cause for reduction in the CFU-BI in this disease.

Discussion

In aplastic anemia, an overall activation of the immune system has been described, with increased bone marrow suppressor cell activity from CD8" Fcy' lymphocytes [25], in vitro elevation in interferon-γ, neopterin, and tumor necrosis factor (TNF) [19,44] levels by the bone marrow cells, and enhanced spontaneous secretion of these cytokines.

A few studies have suggested that the mechanisms of the pancytopenia originate from abnormalities in the marrow microenvironment [17,18,26,27,30,44], with marrow-suppressive effects and specific alterations in certain cell populations being demonstrable, both in the acute presentation and following immunosuppressive therapy [19,25,45]. When tested, however, these stromal cells secrete adequate amounts of G-CSF, GM-CSF, and IL-6 constitutively and after induction with IL-1 [46]. These observations are consistent with two recent studies [15,16] that suggest that defects at this level are rare in this disease.

Our initial work demonstrated that the stroma marrow aplasia adequately supports clonogenic progenitors [34]. Because of the marked reduction in progenitor cells obtainable from untreated patients, however, it was felt that with currently available methodology, extensive investigations into this population would be unsuccessful. Accordingly, subsequent work was directed into studying the clonogenic defect in the marrow that restores hematopoiesis after ALG therapy. To examine the interactions between the progenitors and the adherent layers, we have employed a CD34"-rich population using a short-term blast colony assay [31–33], since this provides a sharp endpoint in the form of quantifiable CFU-BI. Additionally, the adhesive interactions between the CD34" and the stroma could also be tested by analyzing, in clonogenic assays, the selected stroma nonadherent population and determining its proportions.

For this analysis, myeloid progenitors were obtained from the sternum of controls and the iliac crest of aplastic patients. Although variations in the cell populations obtained from different origins may occur, stromal cultures revealed no significant distinctions; clonogenic assays were based on selected precursors with purities and efficiencies that were also similar for both groups. Thus the source from which the material was obtained is not considered to affect these results.

In this study, the percentages of nonhematopoietic cells, such as endothelium and fibroblasts or B lymphocytes in the CD34"-selected population, were not determined [47]. However, these nonmyeloid cells from normal suspensions did not appear to affect the behavior of the aplastic stroma, as demonstrated by the comparable growth of control CFU-BI on normal or aplastic SI. We were unable to rule out the possibility that such populations present in the aplastic suspension could have had inhibitory effects on their own myeloid precursors, but this was thought improbable due to the low cell numbers remaining adherent to the stroma.

The original method was modified in that the irradiation of the allogeneic stroma was omitted to avoid damage to the possible presence of radiosensitive cells of the immune system that in vivo may modulate the aplastic hematopoiesis and to avert the release of burst growth factors that follows this physical insult [3,48].

Upon confluence, in situ morphological inspection of the cultures failed to demonstrate significant differences between normal and diseased stroma. Cytochemistry of the trypsinized and fixed SI showed similarity in the cell populations when
macrophages were stained with Sudan Black, fat cells with Oil Red O, and fibroblasts as well as reticulum cells with acid or alkaline phosphatase.

In the current analysis, we confirm that the myeloid stroma in aplastic anemia sustains normal hematopoiesis appropriately, with a clonogenic output that is no different from that of control layers. These data suggest that the prevailing levels of negative regulators are not functionally higher than those of control layers, since normal CFU-GM formation was well supported.

Of greater relevance is that in this disease, selected CD34+ precursors formed significantly fewer colonies on normal stroma, and the colonies generally showed suboptimal development. Furthermore, when nonadherent CD34+ cells were cultured in semisolid systems supplemented with PHA-LCM, CFU-GM colonies were proportionately similar but significantly lower in the disease group than in the controls (Fig. 1). These observations provide additional evidence that the fraction of dividing cells among the adherent and nonadherent populations is markedly reduced in this disease and that the decreased CFU-GM is not related to alterations in the adhesiveness to the stroma. These results are consistent with the hypothesis that the predominant hematopoietic defect lies within the progenitors. Whether similar mechanisms are operative during the acute presentation or this abnormality is only characteristic of the escape population that survives the initial aggression, remains unclear.

In an attempt to clarify this issue, we have studied these patients further in clonogenic assays, employing marrow fractions highly enriched for the CD34+ antigen and exposed to various combinations of growth factors belonging to the G protein and tyrosine kinase receptor superfamilies. Analysis of the data suggests that the derangement resides in the stem cells, at either the receptor or signal transduction level (unpublished observations).

We therefore conclude that the clonogenic defect of the marrow that restores hematopoiesis following ALG immunosuppression resides in the stem cell, while the levels of negative regulators in the stroma are not functionally higher than in normal marrow.

In aplastic anemia progenitor cells have a reduced sensitivity to the effects of growth factors

Abstract: We have recently shown that in patients with aplastic anemia (AA) recovering following immunosuppressive therapy, the persistent reduction in the bone marrow clonogenic potential is unrelated to suppressive effects of the myeloid stroma and intrinsic to the hematopoietic progenitors. We examined the mechanisms of this defect by determining the response of the aplastic CD34+ clonogenic precursors to proliferative signals induced by hematopoietic growth factors and comparing their results with those of a control population. Light density bone marrow mononuclear cells were lymphocyte and monocyte depleted and enhanced for the CD34+ progenitors by immunomagnetic selection. Selected progenitors were then cultured in the mixed colony assay with incremental concentrations of combinations containing erythropoietin (Epo), granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-3 (IL-3) and c-kit ligand. Bone marrow from aplastic patients had significantly fewer light density cells displaying the CD34 antigen (mean 0.63%, SD 0.35 vs. 1.62%, SD 1.4; p = 0.002). Dose response studies on aplastic CD34+ cells demonstrated that at low concentrations of Epo, IL-3 and GM-CSF, clonogenic growth was significantly impaired but achieved normal values at concentrations giving plateau growth in control cultures. However, for all colony types, responses to effective concentrations of c-kit ligand corresponded with those of controls. These data suggest abnormalities at the receptor or signal transduction levels.

Despite significant advances in the therapy for aplastic anemia, little is known about the causes of bone marrow failure. While evidence suggesting primary stem cell abnormalities accumulates (1, 2), the inhibitory roles of the immune system and the bone marrow environment remain controversial (3, 4). To clarify these interacting mechanisms we had previously employed the blastoid colony forming units (CFU-BL) assay (4, 5) and found that, in patients who recovered after immunosuppressive therapy, the bone marrow stroma supports normal CFU-BL adequately (2, 6–8). This evidence confirmed results previously obtained with the long-term bone marrow culture system (LTBMC) (9, 10). It also indicated that in the aplastic microenvironment, the level of negative regulating peptides did not exceed that of control stroma. However, none of these studies provided further evidence regarding the possible mechanisms for bone marrow dysfunction.

Clinical experience indicates that some patients with aplastic anemia (AA) respond to therapy with pharmacological doses of erythropoietin (Epo) (11), granulocyte-macrophage colony-stimulating factor (GM-CSF) (12) or granulocyte-colony stimulating factor (G-CSF) (13). This suggests that, despite intense pancytopenia, under appropriate stimulation, amplification of the terminal elements is still
Novitzky & Jacobs

possible, with consequent clinically significant improvements in blood values. These, however, are transient and only directed at the cell line under stimulation.

Studying the pathological lesion further, we exposed to combinations of growth factors, progenitors enriched for the CD34 antigen from patients with aplasia in partial or complete response to immunosuppressive therapy. Results of these studies demonstrate that the proliferative potential in these precursors is retained, but a significantly reduced sensitivity in these cells to the tested combination of peptides causes the reduced clonogenic response.

Materials and methods

In a pilot investigation patients with acute aplasia or subjects with this disease who were recovering after immunosuppressive therapy were studied and their results compared to a control population (8). In that study no CD34+ progenitor cells were detectable in the untreated group, so the current analysis was restricted to only those patients who had responded to anti-lymphocyte globulin therapy.

The present cohort has been comprehensively described elsewhere (6, 8, 14). Briefly, we investigated 15 subjects of median age 30 (range 18–61) presenting with acute aplasia (15) who had responded to anti-lymphocyte globulin (ALG), or, in the case of three, to additional cyclosporine immunosuppression. They were studied at a median of 4 yr from the initial treatment (range 1–8). Another patient in partial recovery, after therapeutic abortion for hypoplasia, was also tested. Their hematological data are presented in Table 1. Morphologically, variable degrees of dysplasia were evident in the blood and the bone marrow in all but one patient. Two developed a positive Ham’s test and clinical features of paroxysmal nocturnal hemoglobinuria at 2 and 4 yr after presentation.

Patients’ bone marrow was aspirated from the posterior iliac crest under 1M pethidine hydrochloride (1 mg/kg) analgesia, given 30 min before the local anesthesia. Seven hematologically normal individuals undergoing sternotomy for cardiac surgery under general anesthesia comprised the control population. While the anatomical source of marrow of the two populations differed, possible variations in the frequency of myeloid precursors were not considered likely to affect the in vitro culture results significantly, as only progenitors enriched for the CD34+ membrane antigen were employed for these clonogenic assays. All consented to donate bone marrow according to institutional guidelines of the University of Cape Town and Groote Schuur Hospital.

Selection of the hematopoietic progenitor cells

Methods employed for purifying and selecting the progenitor cell population have been described in detail elsewhere (8). Briefly, control or aplastic mononuclear cells were recovered from a density gradient (1.077 g/mL, Histopaque, Sigma, USA), monocyte and lymphocyte depleted by 2 h adherence on plastic dishes and incubation with CAMPATH 1 M and complement (16). The resulting monocyte- and lymphocyte-poor concentrates were labelled at 4 °C with 0.02 mL/10⁷ cells of anti-human CD34 antigen murine monoclonal antibody (Anti HPMA-1, My 10, Becton and Dickinson, Sunnyvale, California). Labelled cells were washed and exposed at 4 °C to paramagnetic beads covalently bound to affinity purified goat IgG (M-450, product no. 125.01, Dynal, Oslo, Norway) (17). This target population was then harvested with a magnet applied to the sides of the tube (MPC-1, Dynal, Oslo, Norway). Cells were freed from beads by re-suspension in 0.1 mL of phosphate buffered saline (PBS) containing 0.01 mL of a polyclonal murine immunoglobulin (Detchahead, Dynal, Oslo, Norway) (18). Their viability was determined, cells were counted in a hematocytometer and their numbers were adjusted to a concentration of (1–5) × 10⁶/mL.

Aliquots of cells obtained from the initial density gradient and from the final separation were incubated overnight at 37 °C in medium containing 15% foetal calf serum (FCS). They were washed twice, dripped onto multitest slides (Highveld Biologicals, Transvaal, South Africa), air-dried over 4–6 h and frozen to −80 °C for immunophenotyping.

Hematopoietic growth factors

Recombinant human (rh) cytokines (Amgen Thousand Oaks, California, USA); rh-IL 3 (specific activity of 10⁷ U/mg), rh GM-CSF and c-kit ligand (specific activity 1 x10⁶ U/mg each), at protein concentrations of 0.5, 0.5 and 2 mg/mL, respectively, were diluted to 10² ng/mL and stored at 4 °C.
Poor sensitivity to growth factors of progenitor cells in aplastic anemia

Epo was donated by Bioclones (Sandton, Transvaal), and once reconstituted, was kept at 4°C at a concentration of 1000 U/mL.

Clonogenic assays

Normal or aplastic selected CD34 progenitors were cultured in vitro for 14 d at 37°C, at a cell density of (1–5) x 10³ in Iscove's Modified Dulbecco's Medium (Gibco BRL, Life Technologies, Paisley, Scotland) (IMDM), supplemented with l-glutamine, 30% FCS, 5 x 10⁻⁵ M 2-mercaptoethanol, 0.3% agar (final concentration) and incremental concentrations of growth factors. The selected cytokines were four concentrations of Epo in the presence of IL-3 10 ng/mL; increments of IL-3 with Epo 2 U/mL, of GM-CSF in combination with Epo 2 U/mL and of c-kit ligand in association with Epo 2 U/mL and IL-3 10 ng/mL. Dose responses were constructed based on a pilot study in normal individuals, where starting growth factor concentrations represented 25–50% of maximal clonal efficiency. The highest dose usually expressed concentrations well above plateau growth values for the cytokines tested. All cultures were performed in duplicate and their averages then subjected to statistical analysis.

Cultures were fixed in 10% glutaraldehyde and stained with May-Grünwald-Giemsa for permanent recording. Granulocyte-macrophage colony forming units (CFU-GM) were defined as myeloid aggregates (granulocytic, monocytic-macrophage or mixed) containing more than 40 cells. Erythroid colony forming units (CFU-E) were described as erythroid clusters of 4–99 cells, while burst forming units-erythroid (BFU-E) were expressed as colonies containing more than 100 cells or aggregates of 3 or more subclusters.

Immunofluorescence studies

Frozen multiwell slides of light density and selected cells from normal subjects or patients with aplasia were thawed and air dried overnight, fixed in 100% acetone, and labelled with CD34 (0.01 mL Anti-HPCA, My 10, Becton Dickson, USA) for indirect studies. A fluoresceine conjugated second rabbit antibody (Dakopatts) was then added. Positive (19) and negative (monoclonal antibody against beta galactosidase, Professor E. B. Dowdle, Department of Clinical Sciences, University of Cape Town) controls were always included. Slides were mounted and read under ultraviolet illumination at 50 nm with a mercury gas lamp.

Statistical analysis

Raw values of colony scores were subjected to logarithmic transformation with the formula \( Y' = \ln(Y + 1) \) because of the marked dispersion of the data. Percent increment (%) in colony numbers of 4 growth factor combinations were compared by the formula \( \%Z = (Y'X/100) - 100, \) where \( Y \) represented the colony number under investigation and \( X \) the colony values obtained with the combination IL-3 10 ng/mL+Epo 2 U/mL. Means, standard deviations and confidence intervals were calculated and a two-way analysis of variance was employed to determine the significance of differences between groups of cultures or a single culture versus a control group. Multivariate analysis was performed to define correlation between sets of observations, discriminant functions and clustering of data (20).

Results

Progenitor cell selection

Immunofluorescence studies on unselected light density cells from patients with aplasia resulted in a median of 0.65% CD34+ (SD 0.39) cells, which were significantly fewer than in normal controls at 1.62% (SD 1.40) (two way t-test \( p=0.002 \)). Although immunofluorescence studies were not performed on the unselected population, the efficiency of the procedure was calculated from the initial CD34 reacting population within the mononuclear cell fraction and the cells obtained after immunomagnetic selection, resulting in 62% recovery.

Morphological and immunophenotypic examination of the selected fraction revealed no obvious difference in the cell content. Morphologically, undifferentiated blasts represented a median of 81 and 87% in each group. Immunofluorescence studies for the CD34 antigen showed that 80% (SD 4.97) and 82.5% (SD 5.79), respectively, were reactive, while monocytic cells were always <2%.

Erythropoietin (Epo) (Fig. 1)

Dose response with incremental concentrations of Epo at 0.2, 2, 10 and 100 U/mL in the presence of IL-3 10 ng/mL showed increased numbers of BFU-E in both patients and controls (Table 2). In the normal group the maximal clonogenic efficiency for erythroid bursts was reached at 10 U/mL. Optimal CFU-E growth was already achieved at the lowest concentration, while no significant effects were induced on myeloid clones by erythropoietin at any dose.

In the aplastic group, however, compared to normal CD 34+ cells, BFU-E numbers were

Fig. 1. Comparative results in the clonogenic growth between patients with aplastic anemia and normal individuals. Values in the vertical axis are expressed as results of mean colony numbers from $5 \times 10^5$ normal and aplastic CD34+ progenitors while those in the horizontal axis denote the concentration of the growth factor under investigation. Dose response to Epo 0.2, 2, 10 and 100 U/mL in the presence of IL-3 10 ng/mL and GM-CSF 0.1, 1, 10 and 50 ng/mL in the presence of Epo 2 U/mL are shown. Results are expressed as mean of $Y = \ln(Y + 1)$. With Epo, differences at 0.2 and 2 and 10 U/mL were significant for BFU-E colonies ($p < 0.05$). With GM-SCF differences at 0.1 and 1 ng/mL were significant for BFU-E and CFU-GM colonies ($p < 0.05$).

significantly lower at 0.2, 2 and 10 U/mL ($p < 0.001$, 0.001 and 0.05). Erythroid burst numbers from the patients continued improving significantly even at 100 U/mL (0.2 and 2 U/mL vs. 100 U/mL; $p = 0.01$), approaching control values, without achieving plateau growth, in contrast to the control group. The CFU-E numbers at all concentrations were less numerous in the patients than in normal samples but this difference in the results did not achieve significance ($p > 0.05$). CFU-GM were unaffected by changes in Epo concentration.

Granulocyte-macrophage colony stimulating factor (Fig. 1)

Control and aplastic progenitors were cultured with Epo 2 U/mL and GM-CSF at concentrations of 0.1, 1, 10 and 50 ng/mL. Erythroid bursts from normal marrow peaked at the lowest concentration and appeared inhibitory at higher doses, while CFU-E numbers were not affected by higher growth factor concentrations. Significant improvements in CFU-GM followed increments in the concentrations of this cytokine between 0.1 and 50 ng/mL ($p = 0.04$).

In the patients with aplasia, the numerical increment in BFU-E was significant from the lowest concentration of GM-CSF to 10 ($p < 0.05$) and 50 ng/mL ($p < 0.01$). Compared to the control population, BFU-E numbers were significantly lower than those of normal cultures at 0.1 and 1 ng/mL ($p < 0.001$ and 0.001). For CFU-E, GM-CSF was already at saturating concentrations at the lowest dose and no further improvement in colonies was experienced. When the concentrations were increased from 0.1 to 50 ng/mL, GM-CSF significantly stimulated the proliferation of aplastic myeloid colonies ($p = 0.01$). Compared to control values, at concentrations of 0.1 and 1 ng/mL, CFU-GM numbers were significantly lower ($p < 0.023$ and 0.01) but colony scores continued rising when supplemented with 50 ng/mL, at this concentration approaching control values.

Interleukin 3 (IL-3) (Fig. 2)

Bone marrow selected cells were cultured with Epo 2 U/mL and IL-3 at 1, 10 and 50 ng/mL. In the normal precursors IL-3 also gave a maximal clonal expansion at 10 ng/mL for all colony types, while at 50 ng/mL some inhibitory action on the erythroid colonies was noted.

In the aplastic group, increments in the numbers of all colony types were again observed. BFU-E numbers were significantly higher in cultures containing 50 ng/mL than in the lowest concentration ($p < 0.05$). Compared to control values, colony numbers from aplastic clones were significantly lower for BFU-E at 1 ng/mL ($p = 0.001$) and at 10 ng/mL ($p = 0.001$) but matched normal samples at the top concentration. CFU-E numbers were not significantly changed by increments in IL-3. CFU-GM proliferation was well preserved, showing elevation in colony numbers matching the results obtained by the control progenitors (Fig. 2).

Stem cell factor (c-kit) (Fig. 2)

Normal and aplastic progenitors were cultured with Epo 2 U, IL-3 10 ng/mL and stem cell factor at concentrations of 1, 20 and 200 ng/mL. In the normal assays, the addition of incremental concentrations of c-kit ligand to the basic IL-3 + Epo combination showed insignificant improvements in the BFU-E and CFU-GM numbers, while CFU-E development was not affected.
Poor sensitivity to growth factors of progenitor cells in aplastic anemia

</table>

Values from individuals with aplasia were significantly lower than those from the control group only for BFU-E at 1 ng/mL (p < 0.05), as at this concentration the prevalent effects were provided by the basic IL-3 + Epo combination (21). At effective c-kit ligand concentrations (≥20 ng/mL), results improved to values not significantly different from those of control cultures (Table 2 and Figs. 2 and 3). CFU-E numbers were not altered by changes in SCF concentration. CFU-GM numbers also improved but did not differ significantly at the three concentrations or from control values.

The effect of saturating concentrations of IL-3, GM-CSF, Epo and stem cell factor on the basic IL-3 10 ng/mL and Epo 2U/mL were studied by determining the percent increment of absolute colony numbers in each group. As Fig. 3 shows, with all combinations, aplastic precursor cells had a proportionally higher increment in colony numbers. This was most significant for the combination containing maximal concentrations of c-kit ligand leading to enhancements in CFU-GM and BFU-E by 330% and 263% (p < 0.05 and 0.01), for these colonies (Fig. 3).

In summary, results of dose responses in the mixed colony assay showed that compared to those of the normal population, aplastic CD34 + progenitors displayed a significantly reduced sensitivity to Epo, GM-CSF and IL-3. By contrast, exposure of aplastic precursors to effective concentrations of c-kit ligand (≥20 ng/mL) led to significant BFU-E and CFU-GM enhancement, superior to saturating concentrations of any other growth factor. Resultant increments were proportionally higher than those of normal cultures (Fig. 3), approaching values not significantly different from those of normal precursors.

Multivariate analysis segregated the results for all three-colony types of cultures supplemented with c-kit ligand at biologically effective concentrations (≥20 ng/mL) from the remaining studies. Interpretation of these data would suggest that cultures containing c-kit ligand were affected by independent interactions from those induced by the other cytokine combinations.

Discussion

We have previously shown (6) and confirmed (8) that the bone marrow stroma in aplasia supported hematopoiesis adequately, suggesting that the primary defect lay within the hematopoietic stem cell (7, 8). The objectives of the current investigation were to determine in dose response studies, the proliferative state of selected aplastic CD34 + progenitors greatly depleted of accessory cells.
Motivations for the choice of growth factors for the study were four-fold. Firstly, some of these cytokines had been shown to be clinically useful in vivo (11–13, 22). Secondly, these combinations had already been tested in studies containing unfractionated marrow cells (22–25), furthermore they included peptides belonging to both the cytokine and tyrosine kinase receptor super-families (26–30). Lastly, these culture combinations included early and late acting cytokines with pleiotropic functions that included erythroid burst promoting activity such as IL-3 and GM-CSF and stem cell factor (21, 26, 28).
Poor sensitivity to growth factors of progenitor cells in aplastic anemia

induce the release of TNF (27), or other negative regulators, limiting the proliferative effects of growth factors on the hematopoietic progenitors.

These experiments have also documented that, despite a sub-optimal response to the more restricted stimulators (Epo 2 U/mL and IL-3 10 ng/mL), adding effective concentrations of c-kit ligand significantly corrected the inferior colony development. c-kit ligand has little clonogenic activity on its own (21), but at appropriate concentrations it was synergistic with other cytokines. Furthermore, in aplastic progenitors, the proportional increment (% change) in the colony numbers of cultures containing this cytokine was superior to that of control studies. It exceeded the basic IL-3 10 ng/mL + Epo 2 U/mL by 563.3% for erythroid and myeloid colonies together, leading to the highest scores for BFU-E and CFU-GM (Fig. 3). This resulted in clonogenic yields not significantly different from those of control cultures, supporting the view that in this disease the clonal potential remains preserved. Multivariate analysis revealed a segregation of cultures supplemented with effective concentrations of c-kit ligand, from those grown with other GF combinations, suggesting independent interactions affecting the cultures containing this growth factor. In this context, other investigators had reported similar results (24, 25, 33).

We have previously shown, with the CFU-bl assay, that cells in the aplastic stroma do not exert excessive inhibition on control CD34+ progenitors (7, 14). In the current analysis, we have documented that appropriate response to certain growth factors are observed only at high growth factor concentration or in the presence of c-kit ligand, suggesting alterations in the signaling pathways for cell division. Reduced response to growth factors may result from abnormalities in the receptor densities or affinities for the ligand, leading to sub-optimal clonogenic growth. Alternatively, IL-1 or IFN, which enhance Fas receptor expression, may inhibit colony formation through induction of apoptosis (34, 35).

However, in this study, the described derangement in the responses to GF ranged widely over three cytokines, indicating alterations in shared structures or in pathways signaling for cell division. Since cooperation and integration of signals between pathways are important in the mitogenic response (30), supplementation of cultures with c-kit ligand may lead to correction of the signals relayed and to correction of the cellular proliferation. This may have important therapeutic implications.

It is concluded that in patients with aplastic anemia treated with ALG in combination with HDMP, intrinsic abnormalities in the CD34+ population result in subnormal clonogenic growth. Whether during the initial presentation, a more profound abnormality of the same pathways leads to the severe pancytopenia, or whether this derangement is a characteristic of the escape population surviving the original attack, remains to be determined.

Acknowledgements

Our gratitude is extended to Professor L. Wilson for extensive discussion; and to Dr. S Iuscu for the comprehensive statistical analysis.

bone marrow aspiration revealed a hypercellular bone marrow with M:E 25:1 and marked increase in granulocytopoiesis. The differential count was: neutrophils 12%, blasts 1%, metamyelocytes 13%, myelocytes 51%, promyelocytes 14%, basophils + mast cells 10%, erythropoiesis was mildly megaloblastic without any features of dyserythropoiesis. A severe degree of dysgranulopoiesis was present. There were many abnormal promyelocytes and mononuclear promyelocytes, Pelger-Huet anomaly and neutrophils with ring nuclei were seen. Many blasts had Auer rods. An occasional megakaryocyte was seen. There was focal increase in plasma cells in the particles. There was a marked increase in tissue mast cells in the bone marrow. Mostly these cells were located in the particles, besides being present in clumps or in isolated form (Fig 1). Many of them were fusiform and other were oval or round. The cytoplasm contained numerous metachromatic granules, which covered the nucleus and the cytoplasm. The relatively small nuclei were mostly bi-lobed with an occasional mast cell having a single lobed nucleus. Most of them were loaded with granules, but some were deprived of granules or showed sparse granulation. Cytochemically these mast cells were strongly positive for toluidine blue and acid phosphatase, positive for Sudan black B, periodic acid-Schiff (PAS) and naphthol AS-D chloroacetate and negative for myeloperoxidase and leucocyte alkaline phosphatase. On the basis of these findings the diagnosis of MDS-RAEB-t with malignant mastocytosis was established. The patient was neither available for treatment nor follow-up.

Among several reports on the association of neoplastic haematological disease with mast cell disorders, the occurrence of MDS seems to have been missed till the observation by Travis et al (1988) in systemic mastocytosis. This might be due to the fact that MDS is generally accepted to cover a rather ill-defined group of disorders of haemopoietic stem cells (Dash et al., 1991). Although it is generally accepted that prognosis in these cases is determined by the associated haematological disease rather than mastocytosis, the cases of MDS reported by Travis et al. (1988) lead an aggressive course. Nine out of 10 died of which five (55-5%) had developed acute leukaemia. This incidence is much higher than that usually reported in MDS.

MARROW STEM CELL AND STROMA CELL FUNCTION IN APLASTIC ANAEMIA

Using a modification of the long-term bone marrow culture assay (Dexter et al., 1977) Marsh et al. (1991) have recently provided data that CD34 positive myeloid precursor cells derived from patients with aplastic anaemia have a significantly lower cloning efficiency than normal progenitors thereby suggesting an intrinsic defect in this population.

Preliminary data from a parallel and ongoing study in our department provides support for this observation. Thus, in an

Br J Haematol 1991; 79: 531-533
assay that exploits the adhesive properties of undifferentiated blasts colonies designated 
CDFUu (Gordon et al. 1987) we have examined the growth-promoting properties of stroma 
derived from both patients with aplastic anaemia and normal 
volunteers in addition to the cloning efficiency of their respective bone marrow stem cells in cross-culture 
experiments. Furthermore, we have measured the response of the same population, once depleted of accessory cells, to recombinant growth factors.

After informed consent had been obtained haematologically 
normal individuals undergoing thoracotomy, or su-
jects with aplastic anaemia, donated 30–40 ml of bone 
marrow which, following separation on ficoll-hypaque gra-
dient with a specific gravity of 1.077 g/ml the harvested light-
density cells were separated into two fractions.

Stromal cultures were established from normal and aplas-
tic subjects by suspending 5 x 10^6 cells in alpha minimum 
esential medium containing 12.5% horse serum, 12.5% 
feetal calf serum, 10^-4 M hydrocortisone and culturing these 
in 30 mm petri dishes at 37°C in 5% carbon dioxide and high 
humidity. Medium was changed weekly and upon confluence 
the layers were irradiated at 75 cGy/min to a total of 15 Gy 
(Fig 1).

The second fraction was monocyte depleted by 2 h 
incubation in 90 mm plastic petri dishes and 5 x 10^6 cells 
overlayered on the performed normal and aplastic stromal 
cultures for 2 h at 37°C for adhesion to take place. Cells not 
adherent to the stroma were removed by standardized 
washing with tissue culture medium and the presence of 
progenitors in the effluent medium quantitated in the 
GM-CFUc assay. Stromal adhesive precursors were imobi-
lized in 0-3% agar and cultured for 5 d at 37°C in a high 
carbon dioxide and humid atmosphere. CFUu were scored as 
colonies when aggregates contained more than 20 cells.

The remaining monocyte-poor marrow cells were incu-
bated with anti-CD34 (My 10 Becton Dickinson) at 4°C for 30 
min, excess antibody washed off and the labelled cells exposed to 
5–15 x 10^6 paramagnetic particles coated with high-
affinity goat anti-mouse immunoglobulin (Magnetic Insti-
tute, Boston, Mass.). A positive selection was achieved by a 
magnetic field applied to the sides of the tube.

Target populations were enumerated, characterized morphologically and by immunofluorescence, after which 
between 5 x 10^5 and 5 x 10^6 cells were cultured using a 
mixed colony assay in the presence of 2 units erythropoietin, 
50 μg/ml rh recombinant human interleukin 3 (II3) or 
granulocyte-macrophage colony stimulating factor (GM-
CSF), mercaptoethanol, 30% FCS in 0-3% agar. All results 
were corrected and expressed as colonies/10^5 cells.

To date, five normal controls, two patients with untreated 
aplastic anaemia (UA) and three with this disease in partial 
response following antilymphocyte globulin (TAA) have 
been studied. There was no morphological difference between 
normal stroma and that derived from patients with TAA 
whilst that from UA showed a marked reduction in macro-
phages.

Both normal and aplastic stromal layers supported the 
formation of CFUu to an equal extent. There was, however, a 
marked difference in the number of colonies generated from 
the marrow of patients with TAA when grown over normal 
stroma, in addition to which these were small and poorly 
defined. No clonogenic growth occurred from progenitors 
derived from patients with UA.

When the population of cells not adherent to stroma was 
cultured to GM-CFUc were present in the normals whereas 
16–40 colonies were formed in the TAA patients.

The CD34 positive population was quantitatively de-
creased in TAA. However, cultures of the accessory-poor cell 
fraction, defined as containing less than 2% CD3, CD19, 
CD14 positive cells, and positively selected to a purity greater than 
80% showed a marked reduction in the colony growth 
using the GEMM:CFU assay when compared to normal 
precursors in response to recombinant IL3 and GM-CSF 
(Fig 2).
As Dr Marsh and her colleagues point out, there is growing evidence of intrinsic abnormality in the haematopoietic progenitor cell function at least in some of the patients and this is reflected in our experience that included atypical blast colony formation over pre-formed stroma, decreased adhesiveness and impaired response to recombinant growth factors. It is therefore not surprising that the mature blood elements may be quantitatively abnormal in this disease (De Planque et al., 1989). Although our own data is still inconclusive, a hypothesis could be proposed that in some cases of aplastic anaemia the haematopoietic defect may be present before the onset of the pancytopenia which is the result of an immunologically mediated surveillance mechanism mounted to suppress the abnormal haematopoiesis. Biological immune response modulation, with antilymphocyte globulin, leads to an improvement in the peripheral blood count values as well as in marrow cellularity but is unlikely to correct the underlying defect.

PROGNOSTIC VALUE OF CD34 EXPRESSION IN DE NOVO ACUTE MYELOBLASTIC LEUKAEMIA

In a recent paper by Geller et al. (1990) the expression of CD34 by leukaemic cells of patients with acute myeloblastic leukaemia (AML) was found to be significantly associated with resistance to remission induction therapy. Consequently, CD34-positive patients had a clearly lower complete remission (CR) rate. Cases expressing CD34 also had a much higher incidence of secondary AML (sAML) and a history of antecedent haematological disorder (AHD). As in the experience of other investigators (Borowitz et al., 1989), patients with sAML or AHD were also more likely to fail induction remission treatment. By using multivariate analysis and adjusting for other clinically relevant covariates, Geller et al showed that the prognostic value of CD34 expression tended to be independent (P=0.066).

In an attempt to further clarify the prognostic importance of CD34 expression in AML, we have analysed its possible relationship with leukemic resistance in a series of 27 patients with de novo AML. Response was assessed by a bone marrow aspirate performed on day 15 after chemotherapy and weekly thereafter. CR status was defined by standard criteria. Patients who died before response could be properly evaluated were considered ineligible for the purposes of this study.

Induction remission therapy consisted of one cycle of a conventional 3+7 regimen including daunorubicin 60 mg/m² or mitoxantrone 12 mg/m² and cytarabine (200 mg/m²/d). As in Geller’s study, CD34-positive cases were defined as those with more than 10% blast cells showing reactivity with CD34 monoclonal antibody (My10). The main clinical and haematological characteristics of patients according to CD34 expression are depicted in Table I. CR rate was clearly related to CD34 (P=0.058) and myeloperoxidase (MPO) reactivity (P=0.030). All 14 CD34-negative cases entered CR as did all 12 cases with more than 40% MPO reactivity.

SUMMARY

The in vitro culture of bone marrow is an established method for the study of normal and abnormal haematopoiesis. In a semi-solid agar system, marrow progenitor cells (CFU) of the granulocyte and macrophage lines will clone in the presence of specific colony-stimulating factors (CSF) and appear in the matrix as clusters (6-50 cells) or colonies (more than 50 cells). Growth is not normally obtained from peripheral blood unless this is first concentrated. To characterize the morphology of these cells in situ, a method has been developed in which the entire plate is fixed and mounted on a slide. After drying, this preparation is well suited to staining with a variety of biological dyes and furthermore provides a permanent and detailed record of the entire culture.

Analysis of 414 studies in a variety of clinical conditions forms the basis of this communication. In a 35-mm Petri dish normal marrow grows 30 colonies (SEM ± 2,49) and 30 clusters (SEM ± 3,59) at 12 days of culture resulting in a colony:cluster ratio of 1:1.3. The technique was found useful in our bone marrow transplantation programme where scanty growth in culture identified those donor grafts containing a paucity of stem cells, which is one explanation for the failure to obtain haematopoietic reconstitution. In preleukaemia only 2.76 colonies (SEM ± 0,85) and 15 clusters (SEM ± 4,24) were obtained.

In overt leukaemia, whether arising ab initio or following relapse, plating efficiency was similarly reduced to 5,2 colonies (SEM ± 1,34) although 64 clusters (SEM ± 12,54) were found resulting in a colony:cluster ratio between 1:5 and 1:12. With successful therapy this pattern returns to normal, but reappearance of disturbed growth or aberration of colony:cluster ratio signals a relapse or the presence of minimal residual disease, a pattern that may occur when peripheral blood and marrow are still morphologically normal. In the myeloproliferative syndrome CFU become demonstrable in the peripheral blood as the disease progresses, and metastasize to either the accelerated phase or to blastic transformation results in changes similar to those found in leukaemic marrow.

These studies illustrate the potential practical value of this technique. Further applications include the exploration of aetiological mechanisms in patients with neutropenia and bone marrow aplasia, or in elucidating humoral or cellular factors inhibiting growth in patients with tumours such as myeloma. In vitro culture systems have diagnostic potential in haematology, and further evaluation will define their role in current practice.

The mechanisms controlling the orderly proliferation and maturation of haematopoietic cells within the bone marrow are complex and they have proved difficult to analyse because, until recently, there was no practical way of examining the influence of the individual regulating factors. Liquid suspension cultures of marrow suffer from many of the same limitations as in vivo experiments in that relatively small segments of the whole process cannot be isolated for study. Appreciating the need for alternative analytical techniques, Pluznik and Sachs' and Bradley and Metcalf' extended the experience of virologists that transformed cells will grow in vitro by attempting to culture tumour cells using similar methods. The two groups tried independently to obtain clonal growth in agar using mouse leukaemia or AKR lymphoid leukaemia cells respectively, but both were initially unsuccessful. Further experiments were based on the technique described by Puck and Marcus' in which feeder layers of various cells were employed to obtain colony formation. However, although growth did occur, analysis of the cell aggregates showed that these were composed of neutrophilic granulocytes and macrophages derived from the underlayer and not of tumour origin. Nevertheless, these and other studies' established that a specific growth factor was necessary for colony formation and that this was supplied by cells from the underlayer.

Rapid progress has been made from these important initial observations. Thus, Pike and Robinson's successfully applied the double-layer technique to the study of human bone marrow, while Chervenick and Boggs' substituted methylcellulose for agar as the matrix to support cell growth. Subsequently, Axelrad et al.' demonstrated that erythroid colony formation could be obtained in the presence of erythropoietin. Metcalf et al.3,9 have been prominent in much of the development of semi-solid agar systems including isolation and purification of colony-stimulating factors' and the use of mitogen-stimulated lymphocytes to support the growth of eosinophils as well as megakaryocytes. Furthermore, it was observed that B and T lymphocytes and haematopoietic stromal cells could be successfully cultured in the system.
containing 2-mercapto-ethanol. These various achievements have been reviewed by Metcalfe and it is clear that the basic technique may, with modifications, provide a practical approach to the analysis of the various physiological processes that govern cell growth, including the relationship between haematopoietic cells and supporting stroma.

The same approach has been used to explore functional differences that may be recognizable between normal and neoplastic cells. In the case of leukaemia it has been reported that the tumour cells may be distinguished from their normal counterparts in culture, and this important observation is presently being further evaluated. The most obvious deviation that samples of leukaemic marrow show from normal are alterations in plating efficiency and disturbances in colony : cluster ratio. The latter is presumed to reflect, at least in part, profound suppression of normal haematopoietic populations. Other explanations are that leukaemic progenitor cells are inherently unable to mature normally, or that their response to regulatory factors may be defective. A variety of other malignancies have been examined by in vitro culture of bone marrow and most of this material has recently been analysed and reviewed by Metcalfe. It is evident that these methods provide a means for the examination of a host relationship with the neoplasm; a chance to define tumour kinetics and provide at least one way of testing cytotoxic regimens.

One of the major limitations of the agar culture system is the difficulty in defining morphological detail of constituent cells within the colonies or the clusters, and this difficulty is reflected in the variety of techniques used for their study. The latter extend from phase-contrast microscopy through a variety of supravital techniques to those which necessitate aspiration of the colony from the matrix for mounting and subsequent staining. None of these approaches is really practical for the study of cells in situ, nor do they offer a permanent record of the entire culture for later comparative studies. Furthermore, although described methods will allow a degree of morphological recognition, this is achieved at the cost of disrupting cellular relationships. We have recently developed a technique which makes it possible to realise these objectives.

In recent years there has been a steadily increasing application of the in vitro culture of marrow for studying the physiological and pathological features of haematopoiesis, and improvements in methodology regularly appear in the literature. We have analysed our experiences with this assay system and report these in the context of clinical applications of the method.

**MATERIAL AND METHODS**

The 414 studies which were carried out are analysed in Table I. Underlayers were prepared each week in 35-mm Petri dishes (Falcon 3001) containing 1 × 10⁶ normal leucocytes/ml of 0.5% agar (Difco). Marrow or blood cells to be studied were harvested from dextran sedimentation and overlaid as a monocellular suspension in 0.5% agar at a concentration of 2 × 10⁶ cells/ml. Petri dishes were incubated at 37°C in a humidified atmosphere containing a final concentration of 5% carbon dioxide. All studies were done in triplicate and included control cultures using NIH-conditioned medium derived from human embryonic kidney (J. M. Bull — personal communication). The plating efficiency was determined by counting the colonies and clusters on days 10, 12 and 14, using either an inverted microscope with phase-contrast illumination or preferably a stereoscopic dissecting microscope with an incident light source. Parallel cultures were set up in agar without underlayer or additional conditioned medium to

monitor the spontaneous growth rate and the colony:cluster ratio. Marrow cells from patients with myeloma were washed in tissue culture medium and then cultured in either autologous or AB serum to demonstrate the presence of humoral inhibitors to in vitro growth.

At the completion of the culture period, the mean number of colonies and clusters for each plate was determined and the ratio recorded. The entire Petri dish was then flooded with fixative; the agar discs were freed and transferred to a watch glass with excess fixative. After separation from the underlayer, which was discarded, the overlayer was mounted on a glass slide, air-dried and stained using a variety of biological dyes and cytochemical reactions. Morphological screening was done using Romanowsky, haematoxylin-eosin and methyl green-pyronin stains. When indicated, esterase, Sudan black B or myeloperoxidase reactions were employed. For ultrastructural studies, colonies were selected from plates that had been fixed in 3% glutaraldehyde (pH 7.2); these were processed and sectioned at 400 Å on an ultramicrotome. Grids were viewed on a Siemens electron microscope and appropriate fields were photographed.

**RESULTS**

The results of the 414 studies at the 12-day period of culture are seen in Table I and Fig. 1. From normal marrow a mean of 29.9 colonies (SEM ± 2.49) and 39.1 clusters (SEM ± 3.59) was found; the colony:cluster ratio is 1 : 1.3. As the culture ages, the morphological features of the cells change from neutrophils (Fig. 2) to a period when macrophages are also present, until finally only macrophages are found (Fig. 3).

Samples obtained from bone marrow transplant donors gave results in the normal range. However, in two cases a marked decrease in plating efficiency was found and neither of the recipients achieved engraftment despite the presence of adequate numbers of nucleated cells, the latter being the usually accepted criteria for graft adequacy.

In patients with preleukaemia there is a marked reduction in overall plating efficiency reflected in the colony count of 2.75 (SEM ± 0.85) and clusters of 15 (SEM ± 4.24). The colony:cluster ratio may initially be within the normal range but typically a disproportionate number of clusters grow, resulting in the abnormal ratio of 1 : 5.5.

In patients with acute non-lymphoblastic leukaemia, both plating efficiency and colony formation are markedly reduced. Colony formation was 5.2 (SEM ± 1.34), but abundant cluster formation, 63.94 (SEM ± 12.54), was seen.

---

**Fig. 2.** Granulocyte colony (× 1000). The cytoplasm is finely granular and stains a delicate pink using the methyl green-pyronin method. Seven-day culture from normal human marrow.

**Fig. 3.** Macrophage colony (× 1000). Note nuclear detail and granular cytoplasm due to phagocytosis of the agar. This granularity appears as a brilliant orange colour in methyl green-pyronin-stained preparations. Fourteen-day culture from normal human marrow.
resulting in profound disturbance in the colony: cluster ratio. A similar pattern was seen in acute lymphoblastic leukemia, where subnormal colony and cluster formation was found (8.17 ± 2.59 and 23.83 ± 3.6 respectively). For the two morphological variants the ratios were 1:12.3 and 1:3 respectively. These deviations from normal are statistically significant (P<0.05).

Patients with adult acute leukemia, whether non-lymphoblastic or lymphoblastic, who had achieved and maintained complete remission, are characterized by normal mean colony counts of 30.87 (SEM ± 2.85) and 22.43 (SEM ± 2.99) respectively. Similarly, cluster counts were 56.02 (SEM ± 3.86) and 47 (SEM ± 6.63) for the two leukemic variants. Colony:cluster ratios for the two groups of leukemic patients in remission were 1:1.8 and 1:2.1. None of the values deviates significantly from normal (0.04<P<0.05).

In one patient with acute non-lymphoblastic leukemia, a transient marked increase in overall growth with abundant colonies preceded the more usual changes in ratio by 3 months (Fig. 4) and the patient subsequently relapsed. This pattern may be another manifestation of occult disease and should alert physicians to the possibility of impending deterioration. The change in growth pattern was associated with an alteration in the character of the colonies, which were large and loosely packed with cells, a feature that is quite distinct from the usual density encountered during remission.

In patients with the myeloproliferative syndrome the pattern did not initially differ significantly from the normal; no growth was obtained from blood while marrow yielded mean counts of 42.55 colonies (SEM ± 10.85) (0.7<P<0.8) and 46.3 clusters (SEM ± 8.94) (0.6<P<0.7). However, with progression of the disease, a marked contrast from normal peripheral blood emerged. Normally unconcentrated blood grows virtually no colonies or clusters, whereas in the myeloproliferative syndrome 26.32 colonies (SEM ± 3.54) and 41.47 clusters (SEM ± 8.38) were found. The onset of accelerated phase or blastic transformation was characterized by a decrease in plating efficiency in the blood and a prominent disturbance in colony:cluster ratio, a finding that closely parallels that obtained from leukemic marrow.

In myeloma, colony formation is generally depressed to a level of 17.61 (SEM ± 2.12) while cluster counts are normal at 34.08 (SEM ± 4.19). It is noteworthy that no significant difference is demonstrable when washed marrow cells from patients with myeloma are cultured in either autologous or in AB serum, indicating that humoral inhibition of granulocyte:macrophage colony formation is unlikely to be found in the patient's serum.

In neutropenic subjects, colony:cluster ratio was not significantly different from normal, with values of 12.8 (SEM ± 2.87) and 35.83 (SEM ± 1.78) respectively. These observations indicate that peripherally acting mechanisms were present in our patients rather than production defects in the stem cells, where poor growth would have been anticipated.

In aplastic anemia, colony formation was markedly depressed to 2.63 (SEM ± 1.15) with cluster counts of 23.38 (SEM ± 5.71), findings characteristic of a stem cell lesion. It was not, however, possible to exclude the possibility that these findings may reflect inhibition occurring on the basis of cell-to-cell interaction taking place in the culture.

**DISCUSSION**

The demonstration that progenitor cells (CFU) of the granulocyte:macrophage lines derived from samples of bone marrow have the capacity to clone *in vitro* gave considerable impetus to the use of this technique for the study of both normal and abnormal haematopoesis. Before the availability of semi-solid agar culture methods, the complex nature of the regulatory mechanisms operating within the intact bone marrow and the difficulty of isolating segments of the differentiation sequence made analytical studies almost impossible. Although liquid cultures were used, they had many of the same limitations that applied to the *in vivo* experiments. For example, the effects of any manipulation were seen only at the end of a chain of related events, and it was difficult to segregate and manipulate individual phenomena occurring during haematopoietic proliferation and maturation. In contrast, the suspension of progenitor cells in a viscous matrix makes it possible to explore some of these physiological processes and their regulation at cellular and humoral level.

The current technique has been developed from the early studies of Puuzlik and Sachi and Bradley and Metcalf, with subsequent adaptation of the method to human material by Pike and Robinson. Further refinements have followed with the preparation of the colony-
stimulating factor (CSF) from a variety of different tissue sources, and standardization can be achieved by titrating varying quantities of this material against fixed numbers of CFU from bone marrow that has been previously characterized and then stored. The regular use of such dose-response curves and the inclusion of an international standard (J. M. Bull — personal communication) will provide quality control and enable the results between laboratories to be compared.

In physiological terms the culture of bone marrow in agar has been instrumental in demonstrating that a relationship exists between the granulocyte and the macrophage: monocyte system, and this, in turn, has led to the enunciation of a hypothesis for the homeostatic regulation of granulocyte mass.8,9 Basically it appears that macrophages elaborate a CSF that promotes granulopoiesis and as the granulocyte pool expands it produces increasing quantities of a second humoral factor or chalone, having colony-inhibiting activity (CIA) which, in an adequate concentration, will suppress granulopoiesis.8,10 Since this is a dynamic system, a critical point will be reached where the balance between these two factors again alters, with the result that macrophage-derived CSF becomes dominant and CFU favours neutrophil production. It has also been suggested8 that bacteria may play a pivotal role in granulocyte production by serving as a stimulus to increase in CSF elaboration, and as the newly formed cells remove the antigen, the CSF level falls and the neutrophil generation decreases. More recently it has been shown that a similar negative feedback loop may be mediated by macrophage-derived prostaglandin E production. From these studies it is evident that in vitro bone marrow culture has an important role to play in elucidating the mechanisms that interact to control granulopoiesis.

In bone marrow transplantation graft rejection occurs in a number of patients, and this is usually on the basis of prior exposure to blood products with sensitization and iso-antibody formation. Alternatively, it is possible that insufficient numbers of stem cells may be infused and, here also, engraftment will not be achieved. It is a simple matter to culture a sample of the donor graft and thus ensure that this does not happen. We have found at least one clear example and a second probable case where the patient received an adequate graft on the basis of numbers (3.2 x 10^6 nucleated cells/kg), but very poor growth was obtained in culture, and haematopoietic reconstitution did not occur. In vitro studies are thus a simple precaution to recognize those marrow donations where a paucity of stem cells may be expected to produce suboptimal results.

The study of pathologically disordered cell regulation is exemplified by the haematological malignancies. In the patients with preleukaemia there is a variable but usually marked reduction in plating efficiency accompanied by a disturbance in colony: cluster formation. The cytological detail of the individual cells in the aggregates and their ultrastructural examination remains an area for further development. Despite the apparent diagnostic value of culture studies in the preleukaemic patient, their place remains controversial, since clinical progression of the disease is still considered the essential criterion for initiating therapy. Nevertheless, if it can be shown that the combination of culture and morphology, perhaps combined with cytogenetics, will reliably predict the development of leukaemia, then the approach to treatment may be expected to change.

Similarly, bone marrow obtained from patients with acute leukaemia, both untreated and during relapse, grows with a characteristic pattern in agar. There is a marked reduction in overall growth or plating efficiency, colony formation is depressed and a variable number of clusters is evident. These findings are more prominent in lymphoblastic than in non-lymphoblastic leukaemia. It is notable that morphological relapse may only become evident many months after these abnormalities are manifest in culture, and the latter frequently appear at a time when the patients are clinically and haematologically normal. In this context we have encountered a leukaemic patient who, in complete remission, demonstrated a transient period of generalized acceleration in growth, evident many months before even colony: cluster ratio was disturbed, and without any pathological blasts being demonstrated in the blood or marrow; overt disease became obvious 6 months later. The explanation for this finding is uncertain; it might theoretically represent rapid expansion of the leukaemic clone or, alternatively, the response of normal progenitor cells to markedly enhanced humoral drive. The latter finding is favoured since the colony: cluster ratio was maintained, which contrasts with the more usual situation in leukaemia where the cells grow poorly or not at all, and tend to form clusters rather than colonies.

The best method of culturing leukaemic cells remains controversial, and despite reports that this is possible,11 there is no uniformity of agreement that the tumour cells will consistently grow in culture. Clearly, such an achievement would potentially provide a most sensitive measurement for the detection of residual leukaemia and be vital in defining early relapse. The scope of the method can be expanded by using methods to display the distinctive morphological features and the kinetic behaviour of leukaemic cells as compared with normal CFU. Detailed examination of cellular content within the clusters and the colonies as they exist in situ has been difficult, largely because no simple method has been available for this study, although recent experience with a different technique12 may help to resolve the problem. Similarly, the ability to store and maintain the viability of leukaemic bone marrow progenitor cells offers a practical opportunity to examine the influence of these cells in a number of different ways. For example, it should be possible to quantitate and characterize their production of CSF and to define its influence on normal CFU in culture. Conversely the response of these malignant cells to exogenous stimulating factors remains of interest. In addition, more sophisticated control mechanisms can be tested, such as interaction of the cellular level between normal and leukaemic cells using co-culture systems.

A third group of haematological neoplasms explored with this technique are those of the myeloproliferative syndrome. The pattern by which the marrow growth
changes as the disease evolves is now well defined and in chronic granulocytic leukaemia and myelofibrosis it is characterized by dislocation of the progenitor cell population from the marrow to the peripheral blood, a time sequence that has distinct diagnostic possibilities. Furthermore, a defect in plating efficiency and a change towards a leukaemic type of colony: cluster ratio develop as acceleration or blastic transformation occurs. Of equal interest is the potential of this technique to display the interrelationship between haematopoietic and stromal cells in vitro, thus providing a model with which to characterize myelofibrosis and perhaps to understand better the controversy about its pathogenesis.3 This argument has recently been given sharper focus by reports that stromal changes are secondary to the development of the haematopoietic lesion and are not part of the primary neoplasm.

The application of in vitro marrow culture to demonstrate humoral inhibitors is illustrated by examining marrow from patients with myeloma plated in either autologous or AB serum. Failure to depress colony formation excluded a humoral inhibitor as a major cause of the pancyclopenia that may be present in these patients at diagnosis. The concept that defective haematopoiesis may be on the basis of cell:cell interaction can be tested by co-culture experiments. The latter possibility has its basis in the possibility that sub-sets of T lymphocytes may possess suppressor activities which will be reflected in pancyclopenia or marrow hypoplasia.

Cloning techniques are helpful in formulating a functional or kinetic classification of the neutropenia. Thus it is possible to separate defective production clearly from situations where accelerated loss of mature cells occurs peripherally, as in classic immune neutropenia. In the latter situation, culture of the bone marrow shows normal or enhanced plating efficiency with retention of a normal colony: cluster ratio. This information is of relevance to the clinician who must direct investigation and therapy quite differently in the two groups of patients.

The application of in vitro culture systems to the study of patients with aplastic anaemia may help to unravel aetiological mechanisms in this heterogeneous group of diseases. In patients with a stem cell defect, poor plating efficiency is typical and is usually accompanied by a disturbance of colony: cluster ratio; here bone marrow transplantation remains the preferred therapy. In theory, any purely humoral cytotoxic factors could be identified by comparing cultures of progenitor cells in AB serum with those in autologous serum after initial washing to free the CFU of attached antibody. In the light of recent studies showing that immunologically mediated suppression of haematopoiesis may involve a subpopulation of patients with bone marrow aplasia requiring only immunosuppressive therapy, the ability to select these correctly by in vitro culture may come to assume still greater diagnostic importance. Clearly, then, the current objectives are to separate immunological lesions from those due to defective stem cells and to clarify the role of the micro-environment in the pathogenesis.

It is concluded that in vitro culture systems for the study of bone marrow have substantial clinical potential but require further development. Technically, there is the need to standardize methodology and refine morphological and infrastructural studies of the cells and combine these with more sophisticated techniques such as cyto genetics. Physiologically, these methods provide a practical approach to the isolation and study of cellular and humoral effects in haematopoiesis, including interactions between stromal and haematopoietic stem cells. In clinical practice they have a role to play in the characterization of bone marrow grafts and form part of the current diagnostic tests for a range of haematological malignancies, including pre-leukaemia, early leukaemic relapse or the presence of minimal residual disease. Similarly in patients thought to have the myeloproliferative syndrome, the demonstration of CFU in the peripheral blood is a valuable ancillary to the diagnosis and provides one means of monitoring possible leukaemic transformation. The further applications of this method are numerous and include characterization of patients with neutropenia and bone marrow aplasia.

Bone Marrow Culture in vitro.
A Technique for Analysis and Permanent Recording of Cellular Composition

PETER JACOBS, DANIEL DUBOVSKY, SUSAN SMITH,
GAIL RANDALL & MONA BRACHER

Received 1 July, accepted for publication 29 November 1978

The in vitro cloning of haematopoietic progenitor cells derived from blood or bone marrow is now an established technique for the study of normal and abnormal blood formation. In semi-solid agar the results are conventionally recorded as the number of clusters or colonies that grow on the plate under controlled culture conditions. However, the demonstration of detailed morphology within these cellular aggregates remains unsatisfactory. Aspiration techniques are cumbersome and invariably disturb cellular relationships within the supporting matrix while supravital staining is limited by variable uptake of dye by the agar.

We describe a method in which the entire cell-containing layer is removed from the Petri dish, fixed, and after mounting on a glass-slide, is air-dried. This preparation stains well with a wide variety of biological dyes, is minimally influenced by background colouration of the culture medium and excellent demonstration of morphologic detail is possible. A permanent record of the cellular composition of the culture is easily obtained by mounting the stained agar disc.

Key words: CFU colony morphology – colony composition

Cloning techniques for the in vitro study of bone marrow were initially attempted in mice (1, 2) and shortly thereafter applied to the study of haematopoiesis in humans (3). Subsequently, many of the technical details have been defined, including the characterization of the conditions necessary for culture of the different haematopoietic cell lines and the identification of a variety of effective colony stimulating factors (4). Nevertheless, the method is limited by lack of a simple method for the study of cellular morphology as it exists on the plate. Phase contrast or supravital staining can be used, but resolution of cytologic detail is poor and differential staining not practical. Alternatively, colonies or clusters may be aspirated with a pipette and following concentration on a slide, using a cytocentrifuge, are stained and examined (5, 6). These techniques are cumbersome and disturb the relationship of the cells within the supporting matrix.
Furthermore, most of the methods in use are affected by marked absorption of the stain by the wet supporting matrix.

We have developed a technique in which the complete agar disc containing the colonies and the clusters is removed from the Petri dish and fixed, mounted on an albumin-coated slide and, air-dried. This preparation is suitable for staining with a wide variety of biological dyes resulting in excellent demonstration of morphologic detail while maintaining intact cellular relationships within the supporting matrix. The method is simple and has the additional advantage in that mounting will provide a permanent record of cellular composition and growth pattern of the entire culture as it occurs in situ.

METHODS

Culture technique

The method is based upon that of Pike & Robinson (3) in which underlayers are prepared fresh each week from normal leucocytes. 1 x 10⁷ white cells are suspended in 9 ml McCoy's tissue culture medium containing 20% foetal calf serum, 100 µg penicillin, 100 µg streptomycin and 1 ml of 5% agar (Difco). 1 ml of this mixture is pipetted into a 35 mm Petri dish (Falcon 3001) providing 1 x 10⁷ normal leucocytes in 0.5% agar.

1 ml of 0.3% agar containing 2 x 10⁷ cells is pipetted onto the feeder layer and the plate incubated at 37°C in a fully humidified atmosphere containing 5% carbon dioxide in air. Cultures are set up in triplicate and read at 7, 10, 12 and 14 days using either an inverted or a stereoscopic dissecting microscope. Plating efficiency is expressed as the average number of colonies or clusters on the three plates at each of the time intervals and recorded as a ratio.

Fixation

The entire plate is flooded with fixative and underlayer and overlayer separated from the edge of the Petri dish by simple rotation. In the event that the two layers adhere peripherally, a 32 mm disc is cut free, using a cork borer of suitable diameter. The underlayer and overlayer are transferred with excess fixative to a 10 cm watch glass where they are easily separated and the underlayer discarded. The overlayer is allowed to fix for 1 hour at 22°C; the fixative varies and is determined by the particular staining technique that will subsequently be employed. Three percent glutaraldehyde in 0.1 M cacodylate-hydrochloric acid buffer at pH 7.2 is used for Romanowsky, haematoxylin-eosin and methyl green-pyronin staining. After removal from the glutaraldehyde the agar disc is rapidly dehydrated and air-dried. Zenker's fluid gives equally good fixation but its use is time-consuming in that removal of mercuric chloride and subsequent bleaching introduce additional steps and add little to the quality of the glutaraldehyde fixed preparations. Analytical grade methanol provides a practical alternative when methyl green-pyronin, periodic-acid Schiff or myeloperoxidase staining are used. Where chloroacetate or non-specific esterases are to be demonstrated, buffered formalin to acetone is preferable and for Sudan black B a 10% formalin ethanol gives optimal results. After fixation the agar disc is mounted on an albumin-coated glass slide and air dried at 22°C overnight.

Stains

Romanowsky staining is satisfactory when the dried slides are immersed for 6 hours in phosphate buffer at pH 6.8 containing a final concentration of 1% stain. Giemsa, Wright or May-Grünwald may be used independently but we have found that an equal mixture of the three gives better results. After 4–6 hours the slides are removed from the dilute stain, rinsed in buffer and rapidly dried on a blood spinning centrifuge, although a small hand operated hair dryer is adequate. Granule differentiation can be modified by increasing the staining time up to 18 hours and then differentiating in ethanol containing 0.5% rosen and 0.05% acetic acid (Coleman, personal communication 1975) before air drying as above. To retain tinctorial characteristics passage through alcohol for dehydration should be avoided. The dry preparation is rinsed in xylol and mounted under DPX (BDH Chemicals, Poole, UK).

Haematoxylin-eosin, methyl green-pyronin, periodic-acid Schiff and toluidin blue stains are carried out according to standard histochemical procedures (7).

Cytotoxic and histochemical studies include Sudan black B (7), acid and alkaline phosphatase (7), chloroacetate and non-specific esterase (8, 9) and myeloperoxidase (10).
Electron microscopy

Material for ultrastructural study is selected under direct vision following gluteraldehyde fixation and the 2 mm discs containing the colonies are cut free from the matrix using a core borer, removed from the plate, rinsed in 0.1 M phosphate buffer, pH 7.2, overnight and post-fixed in 1% osmium tetroxide in veronal buffer at pH 7.2 for 15 minutes. After washing in 0.1 M phosphate buffer for 1 hour, the discs are pre-stained with 2% uranyl acetate in 10% acetone, dehydrated and embedded in Spurr’s resin (TAAB laboratories, Reading, UK) at 70°C overnight. The sections are cut on an ultra-microtome at 400–500 Å, stained with saturated solution of uranyl acetate, rinsed, post-stained with 0.2% lead acetate and viewed on a Siemens microscope; suitable fields are then selected and photographed.

RESULTS AND COMMENTS

The preservation of the entire plate is easy to achieve and a linear relationship demonstrated to exist between the number of colonies and clusters present in unfixed culture and those subsequently seen on the stained preparations.

The fixatives were of importance and 3% gluteraldehyde was found to be the most practical*. Zenker’s solution also gives good preservation of cellular detail but is cumbersome and was not found to be superior to gluteraldehyde. Methanol generally produced high quality plates but was less predictable in its penetration and fixing characteristics so that cell margins were often indistinct, and granules less well preserved than with either gluteraldehyde or the more tedious Zenker fixation. Methanol was, however, particularly effective with methyl green-pyronin staining. The use of special fixatives for the cytochemical stains does not differ substantially from standard methods employed in the study of blood or bone marrow.

The Romanowsky stains were consistently the most useful since they allow direct correlation with the original samples. Combined with gluteraldehyde fixation the cells were easily recognised in that cytoplasmic and nuclear outlines were distinct and granules were prominent. Variations in the concentration of dye, the staining period and the use of differentiation allowed accentuation of individual characteristics. However, for routine use, a 1% final concentration of mixed Romanowsky dyes and an exposure time between 4 and 6 hours, without differentiation, was adequate. It is important to avoid dehydration in the alcohols since this results in less satisfactory preparations than rapid air drying before mounting.

Haematoxylin and eosin staining was useful in demonstrating nuclear detail, but cytoplasmic structures were less clearly defined. Thus, granule demonstration, although feasible, compared unfavourably with the Romanowsky stains.

Methyl green-pyronin provided a good general stain in that it combined excellent demonstration of morphologic features and distinct differences in staining. Macrophages (Figure 1) stained brilliant orange with prominent cytoplasmic material while the granulocytes (Figure 2) stained a delicate shade of pink although individual granules were poorly appreciated. The macrophages characteristically contained ingested agar and this substance probably accounts for the distinctive colour produced with pyronin.

On the basis of our experience this simple battery of three stains appears suitable for most of the screening, but in certain circumstances additional cytochemical studies are helpful. To ensure uniformity of sampling the plate is divided into quadrants so that comparable portions can be examined with the different techniques.

Myeloperoxidase, chloroacetate ester-
ase and non-specific esterase are a useful combination facilitating differentiation between granulocytes and cells of the monocyte with macrophage line. In addition sudan black B is easily applicable to the fixed material and will broaden the scope for morphologic study. Periodic-acid Schiff provides acceptable staining characteristics but is of limited value apart from demonstrating basic morphologic features in another way. Similarly, toluidin blue can be employed to show granules or phagocytosed agar in macrophages.

Of note is the fact that most of the staining methods used with this technique are not markedly influenced by background staining and this contrasts with experience where unfixed or wet matrix is present. Any staining that does occur can be diminished in intensity by relatively minor modifications in dye concentration. Under these circumstances colour photographic recording rather than preservation of this disc is an alternative means of securing a permanent record of the culture.

In certain circumstances more detailed examination of the cells may be required and here electron microscopy will provide an excellent preparation (Figure 3) to complement the morphologic and cytochemical studies. For example, attempts to clone mouse lymphocytes yielded cells which could not be confidently distinguished from monocytes; ultrastructural studies resolved this dilemma.

The technique is also well suited to more sophisticated examination of the cells including demonstration of specific immunoglobulin production by means of peroxidase: anti-peroxidase technique and kinetic studies using autoradiography.
result in excellent demonstration of morphologic detail within the cellular aggregates as they exist in situ. A further advantage is that the stained plate provides a permanent record of the culture and is suitable for exchange of information between centres.

(Received 19 January 2005; accepted 21 February 2005)

Abstract
Cytosine arabinoside and anthracycline-containing regimens induce remission in upwards of 60% of previously untreated patients with adult acute myeloid leukaemia (AML). Despite this, in addition to primary drug resistance, the majority of these patients relapse. Reliable methods for uniformly recognising these two subgroups at presentation do not exist and therefore a further attempt has been made to relate in vivo toxicity, using a clonogenic assay, to clinical outcome. In 10 normal controls and 12 chemotherapy naïve cases, mononuclear cells harvested by density gradient separation were re-suspended at a concentration of 2 x 10⁶/ml and quadruplicates of 250 μl per well cultured in methylcellulose containing foetal calf serum and phytohaemagglutinin stimulated leucocyte conditioned medium. Cell kill was determined for cytosine arabinoside, daunorubicin and etoposide either singly or in combination using both a pulsed and continuous exposure. Aggregates were scored after seven days and three distinct patterns recognised. The patients all received the same drugs in a standard protocol and achievement of complete remission correlated with growth pattern. The survival of normal marrow colony-forming cells or GM-CFUc and the leukemic equivalent designated L-CFUc were assessed and a sensitivity index (SI) determined as a ratio of these two values in which more reproducible results were found when the drug was continuously present. It is concluded that the microculture technique is feasible and clearly demonstrates chemotherapy effect but no correlation was demonstrated with clinical outcome. This is a negative pilot study and, as a means of recognising drug sensitivity or resistance, should be discarded in favour of currently available molecular techniques.

Keywords: Cell cycle, cytosine, acute myeloid leukaemia, sensitivity index

Introduction
A significant number of patients with acute myeloid leukaemia (AML) will achieve complete remission with currently employed treatment regimens typically containing cytosine arabinoside with maximum effect on cell cycle during nucleic acid synthesis and anthracycline antibiotic intercalating adjacent base pairs and inhibiting DNA and RNA with subgroups of patients having further benefit from the epipodophyllotoxin inhibiting topoisomerase II in a cell cycle dependent manner with specificity in late S and early G II phases [1–3]. Despite careful selection of cases, using a variety of prognostic factors [4], a number will have primary drug resistance [5] and the majority will randomly relapse in the post chemotherapy period often having achieved morphologic complete remission [6]. While no standard clinical or laboratory features reliably predict this event [7] increasing attention is being given to immunophenotyping [8], gene rearrangement with much of
the early work focussed on the lymphoblastic tumours [9,10] as well as minimal residual disease [11,12].

Past attempts have also examined in vitro assays for clonogenic cells particularly those reflecting the leukaemic lineage and designated CFUc-L [13,14]. This approach has the potential to define proliferate capacity, growth requirements and drug sensitivity of occult disease [15,16]. To further explore this application, the previous observation of poor leukaemic growth in agar has been compared to methylcellulose as the matrix [17,18]. Secondly, the agents were tested singly and in combination at different incubation times [19,20]. Drug sensitivity was defined by results after continuous exposure in comparison to sensitivities determined at 1h pulse and both correlated with initial clinical response in individuals with acute myeloid leukaemia.

Materials and methods

Patients

Twelve untreated patients with newly diagnosed AMLs, classified according to the French–American–British criteria were contrasted to 10 hematologically normal controls [21,22].

Treatment

Patients received a 7-day continuous infusion of cytosine arabinoside (100 mg/m²), 7 days of etoposide as a half-hour bolus (100 mg/m²) and daunorubicin on the first 3 days (45 mg/m²). Complete remission was defined as the disappearance of blasts from the peripheral blood and normal haematopoesis in the bone marrow. Non-responders were individuals who had residual disease after two courses of induction therapy.

In vitro culture assay

Bone marrow was aspirated from the posterior iliac crest into preservative-free heparin and mononuclear cells (MNC) recovered following density gradient separation by Ficoll-Hypaque (Sigma catalogue No 1077-1, density 1.077 g/ml), washed twice with Iscove’s Modified Dulbecco’s medium (IMDM- Gibco, UK) and re-suspended with IMDM with 30% foetal calf serum (FCS) (Delta Bioproducts, SA). Based on previously described methods [23,24] 2 × 10⁵ MNC/ml, contained in 2 ml of IMDM and having a final concentration of 0.9% methylcellulose, (Sigma, UK), 20% FCS and 10% phytobhaemagglutinin-leucocyte condition medium [25] (PHA-LCM) (Welcome, UK) were plated in 250μl per well in quadruplicate (NUCC Multidish Catalogue No. 176740, Denmark) and the mean value of the four micro wells reported. The cultures were incubated at 37°C in a humidified atmosphere containing 5% carbon dioxide for 7 days and then scored using an inverted microscope. Aggregates of greater than 40 cells were defined as colonies and between 10 and 40 as clusters.

In an attempt to further enhance sensitivity growth patterns were reassessed by dividing them into type A containing <20 colonies and <200 clusters, type B with <20 colonies and between 200 and 400 clusters and type C with >20 colonies and >200 clusters identified subgroups requiring additional courses of induction chemotherapy.

Drug preparation and cytotoxicity testing

These agents were freshly prepared immediately before culture and had been shown to be stable at −70°C for 3 weeks [26,27]. Final concentration with cytosine arabinoside [28] (Upjohn, UK) was 12.5 μmol/l and etoposide (Bristol Myers/Squibb, SA) 20 μg/ml. These concentrations approximate those previously established as being optimal for in vitro chemotherapy testing [29].

In pulse experiments, 6 × 10⁵ MNC/ml were pre-incubated in liquid suspension culture with the appropriate concentrations of each respective agent or drug-free control media. After 1h the cells were washed twice with IMDM, re-suspended with 20% FCS in IMDM. After which cells counts performed and viabilities determined by trypan blue exclusion. 2 × 10⁵/ml of cells were then plated at 250 μl in methylcellulose as the immobilising agent.

In continuous exposures, 2 × 10⁵/ml of cells were plated directly into the methylcellulose containing the drug and incubated for 7 days. Control cultures containing patients’ cells without drugs were set up simultaneously. Patterns derived from normal marrows were used to establish survival in the GM-CFUc assay from the leukemic cells and so obtain a sensitivity index (SI) [30].

Calculations

Using an inverted microscope, the cultures were scored on day 7, defining the number of surviving colonies, percentage inhibition from the leukaemic aspirates compared to controls without the drugs [31] and the SI determined when the two groups were compared based on the mean value of the 10 normal marrows.

\[
\% \text{ survival} = \frac{\text{cell survival after drug exposure}}{\text{cell survival with no drug exposure}}

CR: Complete remission, is defined as disappearance of all morphological evidence of disease in peripheral blood and <5% blasts in bone marrow; BMTX: Bone marrow transplant; FAB: Morphological classification according to the French–American–British co-operative group.

* Patient died during induction therapy. ^ Patient relapsed.

each drug was determined:

\[
SI = \frac{\% \text{ cells killed from group 1 (average of controls)}}{\% \text{ cells killed from group 2 (individual cases)}}
\]

In preliminary studies, the percentage survival of cells was low and the percentage of cells killed was found to be a more reproducible endpoint. Thus, a sensitivity index of 1.0 is defined as no difference in drug sensitivity between GM:CFUc and CFUcL. If the CFUcL shows greater killing or sensitivity to the drug than GM:CFUc, the SI was less than 1 and the converse applied when the SI was greater than 1.

Results

Of the 12 cases enrolled (Table I) in vitro studies of marrow cells and types of growth formed by their cells in culture (Table II) were correlated with subsequent response to therapy.

Of these 3 with the type A proliferation pattern achieved complete remission and 2 are alive. Type B was found in 1 a single individual who entered remission and another 2 who died. The former patient required 2 induction courses to reach the status, but subsequently relapsed and demised. Type C was found in 6 of whom 3 entered remission, and in whom two needed a second course of chemotherapy. There were two failures to respond to treatment regimen and one died during this process.

In summary, of the 12 individuals having acute myeloid leukaemia, all with type A growth achieved complete remission. Of those with type B and C aggregates in the clonogenic assay 4 achieved complete remission but were more resistant to the therapy regimen and all needed two courses to clear recognisable blasts.

Discussion

The in vitro growth patterns of leukaemic cells in agar or methylcellulose appears to yield prognostic information that is clinically useful and this can be

obtained prior to the treatment in patients presenting with acute myeloid variant when comparison is made to GM-CFUc from normal donors. Thus the number of clones produced under these circumstances by the neoplastic clone (CFUc) is more variable, and there is a preponderance of small-sized colonies defined as clusters of fewer than 40 cells. These growth characteristics appear to be independent of the FAB sub-type, the patient’s age or sex and cytogenetic status of the marrow cells [32,33].

In the groups A and B, 4/6 patients did initially responded to therapy and achieved remission. Two died, one during induction, and one which was acute progranulocytic sub-type or M3 during induction and a second one after completing this phase of the chemotherapy. In group C, 3/6 also achieved remission but two needed a second induction course. Of the 3 patients that failed 2 did so during the initial cytotoxic drug infusion.

In this feasibility study, in vitro growth of marrow from patients with acute myeloid leukaemia has been the sole criterion for attempts to recognise distinctive patterns that may have predictive value for chemotherapy regimens. In groups A and B where proliferation in the clonogenic assay was poor prognosis appeared better. This is in contrast to studies by Curtis and colleagues [34–36], who were unable to correlate their findings with success or failure of remission induction. Conversely McCulloch and associates [37], and Brown and Carbone [38] have demonstrated that their culture method, which is similar to ours, does provide a predictive value in this context.

In the cytotoxicity assay normal human marrow colony-forming cells have nearly the same sensitivity as their leukaemic counterparts for each of the agents used individually or in combination [39]. The exposure for 1h may be too brief to reveal the sensitivity of cells to the drug regimen (Figure 1). In fact a prolonged contact time may be critical for all cell cycle-dependent drugs exemplified by a Cytosine arabinoside and etoposide (Figure 2). Thus it was found that when tested either individually or in combination the pattern for continuous exposure had similar cytotoxic effects on all the patients, and this was particularly true when used together. The figures further illustrate that response was significant in ex vivo but, in the same individuals, there was substantial difference in clinical outcome.

Clonogenic assays, as an approach to testing for drug sensitivity, have a number of limitations [39–41]. Taking these in consideration, coupled with the outcome in this feasibility study, it is concluded that they failed to reliably predict response in vivo. This may, in part, be a limitation of the small number of correlations presently reported. Also, dose response curves were not used but rather concentrations employed that had been established from prior publications. Taking all the available information together and in the context of other experience this assay cannot be recommended as a reliable predictor for correlating laboratory results with response in clinical setting.

The Secretion of Plasminogen Activators by Human Myeloid Leukemic Cells In Vitro

By E. Lynnette Wilson, Peter Jacobs, and Eugene B. Dowdle

Peripheral blood cell preparation from 23 normal subjects and 72 patients with acute and 32 patients with chronic myeloid leukemia were cultured in vitro and released plasminogen activators were analyzed. The quantity of plasminogen activator secreted by leukemic cells varied widely and could not be correlated with the clinical severity of the disease. Immunochemical and electrophoretic techniques have been used to show that normal peripheral blood granulocytes released exclusively urokinase-like plasminogen activator, whereas leukemic cells secreted either urokinase or a tissue activator-like enzyme. The molecular species of enzyme released by acute myeloid leukemic cells may serve as a diagnostic marker of relevance to the management of this disease, since patients with acute myeloid leukemia whose cells released only tissue plasminogen activator did not respond to combination chemotherapy. Tissue plasminogen activators released by leukemic cells may display an unusual electrophoretic pattern that resembles that shown by urokinase. Immunochemical procedures are therefore essential for the correct identification of these enzymes.

ALTHOUGH the chemotherapy of leukemia is based on sound pharmacologic principles, it remains empirical to the extent that individual patients may respond very differently to a particular chemotherapeutic regimen in terms of induction of remission, maintenance of remission, or incidence of undesirable side effects. It would therefore, be of value if additional laboratory criteria were available that could be used in conjunction with clinical and conventional histologic procedures to predict response to therapy.

It has recently been noted that plasminogen activator synthesis and release are inducible cellular functions that are subject to modulation by hormones, drugs, and other agents, many of which affect expression of the transformed phenotype. For this general reason, it seemed to us possible that the study of plasminogen activator synthesis in vitro would prove of value for the further characterization of human leukemic cells. Two recent observations have provided a more particular justification for this investigation. First, it has been demonstrated that normal granulocytes synthesize plasminogen activator; and second, it has been shown that human cells release plasminogen activators of two distinct immunological types—one similar to urokinase and the other similar to tissue activator. It was therefore of interest to determine (A) whether leukemic myeloid cells released both types of enzymes and, if so, (B) whether the molecular species of plasminogen activators released by myeloid leukemic cells differed in a way that would be nosologically useful.

In this article we present results of a series of studies showing that peripheral blood cells from patients with myeloid leukemia released plasminogen activators when cultured in vitro. Differences in molecular species of enzyme released by leukemic cells were observed. These differences appeared to have prognostic significance.

MATERIALS AND METHODS

Subjects

Normal blood samples were obtained from 23 healthy persons working in the laboratory. Leukemic blood samples were obtained from 72 patients with acute myeloblastic leukemia (AML) and 32 patients with chronic myeloid leukemia (CML) who attended the hematology service at Groote Schuur Hospital.

Diagnoses were based on histologic and histochemical examination of peripheral blood and bone marrow specimens. Romanowsky-stained preparations, cytochemical stains, and ultrastructural features were used to classify each specimen according to the French-American-British recommendations.

Fifty-eight patients with acute myeloblastic leukemia were treated with combination chemotherapy that included the epipodophyllotoxin, VP-16-213, cytosine arabinoside, and Adriamycin. Response to therapy was assessed by aspiration and trephine-biopsy of the bone marrow on the tenth day following completion of the cytotoxic chemotherapy. Induction of remission was judged to have been successful if marrow hypocellularity was achieved with subsequent regrowth of blast-free marrow that remained apparently normal for at least 4 wk.

Of the 58 patients treated in this way, 27 went into complete remission, 15 failed to enter remission, and 16 died before response to therapy could be assessed.

The 14 remaining patients that are identified in Table 1 as having had palliative or alternate therapy are individuals who, by virtue of their advanced age or associated clinical conditions, were judged to be unsuitable for combination chemotherapy.

Cells

Blood was taken by sterile venipuncture into tubes containing preservative-free heparin (Thromboliquine, Organon Teknika, Holland) to give a final concentration of 5 U/ml. Cells were fractionated by centrifugation with RPMI 1640 medium and centrifugation on a layer of Ficoll-Hypaque. Leukemic blast cells were harvested from the plasma-Ficoll interface and contaminating red blood cells removed by incubation for 5 min in 0.83% ammonium chloride (pH 7.4).

Cells were washed once by centrifugation and resuspension in RPMI and were then resuspended in RPMI containing 3% fetal calf serum (FCS) to give 4 \times 10^6 cells/ml. One milliliter aliquots of this suspension were incubated in 35-mm Falcon plastic tissue culture Petri dishes at 37°C in a humid atmosphere of 5% CO₂ in air. After 24 hr of incubation, the cells were suspended in fresh medium and the incubation was continued for a further 24 hr. At the end of this second period, the medium (harvest fluid) was collected by centrifugation and analyzed quantitatively and qualitatively for plasminogen-dependent proteases as described below.

In some cases, a caseinolytic plaque assay was used to obtain a rough estimate of the number of individual cells that synthesized plasminogen activators. In this procedure, the cells were washed and mixed with appropriate prewarmed solution to provide a final suspension of 6 \times 10^5 cells/ml in RPMI containing 0.8% agar, 1.3% solution of commercial instant non-fat dry milk powder, and 160 µg/ml purified human plasminogen. This suspension was run into prewarmed moulds formed from glass microscope slides separated by short lengths of thin wire. The preparations were then allowed to set at room temperature, when the slides were carefully separated and the gels incubated at 37°C in a humid atmosphere for plaques of lysis to develop (Fig. 1).

Plasminogen Activator Assay

Plasminogen activator in harvest fluid was assayed by measuring the plasminogen-dependent release of soluble radioactive fibrin degradation peptides from insoluble 125I-labeled fibrin-coated Linbro multwell plates. This was done exactly as previously described, save for the addition of 4 µg of plasminogen to each well instead of 2 µg.

Rabbit Antibodies to Human Urokinase and Tissue Plasminogen Activator

Rabbits were immunized by subcutaneous injection of commercially purified human urokinase or human tissue plasminogen activator secreted into the medium of a human melanoma cell line. The IgG antibody fractions from immune sera were prepared as pre-

Fig. 1. Plasminogen-dependent caseinolysis by leukemic cells. Acute myeloid leukemic cells were suspended at a concentration of 6 \times 10^5 cells/ml in agar gels containing casein. Gel A was supplemented with 160 µg/ml of plasminogen; plasminogen was omitted from gel B. Plaques of caseinolysis seen in gel A were photographed after 8 hr of incubation at 37°C.
Electrophoretic and Immunochemical Analysis of Plasminogen Activators

Molecular species of plasminogen activators present in harvest fluids collected from normal and leukemic cells were analyzed by 3 procedures previously described in detail.19

1. Harvest fluid samples were electrophoresed in 11% polyacrylamide gel slabs containing 0.1% SDS. The gels were then washed in 2.5% Triton X-100 to remove the SDS, and the bands of plasminogen activator activity were detected by plasminogen-fibrin-agar zymography in which plasminogen-dependent fibrinolysis was evident as clear lysis zones in the opaque fibrin indicator slab (Fig. 4).

2. Harvest fluid samples were assayed for residual plasminogen activator activity after treatment with serial dilutions of rabbit antibody to urokinase or to tissue plasminogen activator (Fig. 5).

3. Plasminogen activator in any given harvest fluid could be analyzed by a combined electrophoretic and immunochemical procedure in which specific antibody was added to a trough cut in the plasminogen-fibrin-agar indicator layer. The polyacrylamide gel slab containing electrophoresed plasminogen activators was then carefully layered over the indicator layer in such a fashion that adjacent electrophoretic tracks lay parallel to and on either side of the antibody-containing trough. Specific inhibition of individual activator bands could be seen in the antibody-rich agar adjacent to the trough (Figs. 6 and 7).

RESULTS

Fibrinolytic Activity Released by Cells Cultured In Vitro

When caseinolytic or fibrinolytic activity was released by normal or leukemic cells, this was invariably and completely plasminogen-dependent. This was evident as plaques of proteolysis in the casein-agar system (Fig. 1A) that were not seen when plasminogen was omitted from the indicator gel (Fig. 1B). Similarly, release of 125I-fibrin degradation peptides in the solid-phase radioenzymatic assay system was dependent on the presence of plasminogen.

Fig. 2. Inhibition of urokinase and tissue plasminogen activator by specific rabbit IgG antibodies. Samples of urokinase and tissue activator secreted by human melanoma cells were incubated with antibodies to urokinase (–—–), tissue activator (–—–), and ovalbumin (–—–) and assayed for residual enzyme activity in the 125I-fibrin plate assay. Undiluted antibody solutions contained 5 mg/ml of purified IgG.

Fig. 3. Release of plasminogen activator by cultured myeloid cells isolated from peripheral blood samples of patients with acute myeloid leukemia (AML) and chronic myeloid leukemia (CML). Each point represents the mean result obtained from three cultures prepared from a peripheral blood sample obtained from a different patient. Immunochemical and electrophoretic techniques were used to identify the enzyme as urokinase-like (●), tissue-activator-like (□), or mixed (●).
Normal mononuclear cell preparations that remained on top of the Ficoll-Hypaque layer (i.e., lymphocytes and monocytes) released too little plasminogen activator for accurate quantitation or characterization.

Normal neutrophils that centrifuged through the Ficoll-Hypaque layer released easily measurable amounts of plasminogen-dependent fibrinolytic activity for purposes of molecular identification. Unfortunately, however, these cells survived poorly in culture.

The lack of a stable viable cell population over the duration of the experimental period made it impossible to express the quantity of enzyme released on the basis of cell number for purposes of comparison with leukemic cells.

Leukemic cells fared well in culture and, by the end of the 48 hr, more than 85% were still viable. These cultures therefore provided data that could be used both to determine the amount of enzyme released and the molecular species of enzyme that was synthesized.
four leukemic cell culture fluids. These were compared with urokinase (A) and tissue activator (F). The enzymes present in leukemic cell harvest fluids, B, D, and E, were electrophoretically similar to urokinase. Leukemic cell harvest fluid, C, contained plasminogen activators of three electrophoretically distinct types—one similar to tissue activator, one similar to urokinase, and a third gave a band of fibrinolysis corresponding to a mol wt of 100,000.

Antibody titrations showed that enzymes secreted by leukemic cells could be immunochemically identified as urokinase or tissue activator (Fig. 5). In this experiment, cells from one leukemic subject secreted urokinase-type activator (Fig. 5C), while cells from a second leukemic subject released enzyme that was exclusively tissue activator in type (Fig. 5D).

The immunochemical identity of the enzymes in cell harvest fluids could be more definitely identified using the combined immunochemical and electrophoretic procedures illustrated in Fig. 6. As shown in this example, one sample of leukemic cell harvest fluid contained activators that were completely inhibited by

---

**Release of Plasminogen Activators by Leukemic Cells**

Cell preparations from 61 patients with AML and 32 patients with CML were cultured in vitro, and harvest fluids were taken for measurement of plasminogen activators released during the second 24 hr period. The results are presented in Fig. 3, from which it can be seen that the quantity of enzyme secreted varied widely over a 10,000-fold range from 0.001 U/10^7 cells/24 hr to 22.4 U/10^7 cells/24 hr. In 9 cases (7 AML and 2 CML), leukemic cells secreted too little enzyme to be detected in the fibrin plate assay.

**Molecular Species of Plasminogen Activators Released by Normal and Leukemic Cells**

Representative results of an electrophoretic analysis of the plasminogen activators released by cultured cells are given in Fig. 4, which shows a fibrin-agar indicator gel that was used to identify the enzymes present in

**Fig. 7. Inhibition of a 60,000 mol wt plasminogen activator secreted by cells from a patient with acute myeloid leukemia by anti-tissue-activator antibody added to a trough (Ab) cut in a fibrin agar indicator gel. Tracks 1 and 2 contain plasminogen activator secreted by cells from an individual with acute myeloid leukemia, and tracks 3 and 4 contain tissue plasminogen activator.**
antibody to urokinase (tracks A and B), whereas the harvest fluid from a second leukemic cell preparation (tracks C and D) contained one activator species of mol wt 60,000 that was inhibited by the antibody to urokinase, whereas the activators with mol wt of 70,000 and 100,000 were unaffected by the antibody to urokinase.

These procedures were used to show that cells from 15/72 patients with AML secreted tissue activator, cells from 45 patients secreted the urokinase-type enzyme, and cells from 5 patients secreted a mixture of urokinase- and the tissue-type activator. Cells from 7 patients with acute myeloblastic leukemia secreted too little enzyme for the activator to be identified with certainty (Table 1).

Cells from 32 patients with chronic myeloid leukemia were studied. Of these, 13 secreted urokinase, 12 secreted tissue activator, 5 secreted a mixture of urokinase and the tissue-type activator, and cells from the remaining 2 patients secreted too little enzyme to identify.

Neutrophils isolated from 23 normal subjects invariably released only the urokinase-type enzyme.

It is of interest to note that, in two cases, a plasminogen activator was observed that migrated electrophoretically as a single enzyme band with a molecular weight corresponding to that of urokinase. It was, however, unaffected by antibody to urokinase and completely inhibited by antibody to the tissue activator (Fig. 7).

Therapeutic Correlations

Cells from 72 patients with AML were studied with a view to defining the molecular species of plasminogen activator they released and correlating these with responses to therapy. The combined results are presented in Table 1, from which it can be seen that, taken overall, cells from 15 cases released tissue activator and those from 45 cases released the urokinase-type enzyme. In 5 instances, a mixture of tissue activators and urokinase was released, and in 7 cases the amount of enzyme released was too low for reliable identification.

This general tendency for approximately 20% of AML patients to have cells that released tissue activator was apparent in each of the three major therapeutic subdivisions. Thus, blasts from 4/14 patients who received palliative therapy, 3/16 patients who were treated with standard combination chemotherapy but who died before evaluation could be completed, and 8/42 patients in whom results of therapy could be assessed released tissue activator.

If, however, one considers only the 42 patients in whom the therapeutic response could be determined, it can be seen that in 81% of (25/31) patients whose cells released the urokinase-type enzyme, a remission was satisfactorily induced. In contradistinction, all 8 patients whose cells released tissue activator alone failed to enter remission.

In this limited series, therefore, there was a significant correlation (χ² = 17.8 p < 0.001) between the release of tissue activator alone and a poor response to the cytotoxic regimen that was used.

Since it has been reported by others that age and white blood cell (WBC) count at the time of presentation are adversely related to prognosis, patients whose cells released tissue activator and urokinase type enzymes were compared with respect to these parameters. Although differences were found, in no case were these statistically significant. Mean values ± SE of mean for patients whose cells released tissue activator were: age, 47 ± 3.9; total WBC, 33 ± 14.2. Corresponding values for those whose cells released urokinase were: age 37 ± 2.8; total WBC, 46 ± 9.1.

DISCUSSION

As previously observed with fibrinolytics released by other human cell types cultured in vitro, we have found that when fibrinolytic or caseinolytic activity was released by human peripheral blood leukocytes of the myeloid series, this was invariably plasminogen dependent. One is therefore justified in regarding these enzymes as plasminogen activators. This was true for both leukemic and normal cells and confirms the observations made by Granelli-Piperno et al. for normal human polymorphonuclear leukocytes.

The amount of plasminogen activator secreted by leukemic cells in culture varied widely and could not be correlated with the clinical severity of the disease. Although blasts isolated from the peripheral blood of patients with AML tended to release more plasminogen activator than did CML cells, there was a considerable overlap between these groups.

Using antibodies to urokinase and tissue activator in combination with electrophoretic analysis, we have shown that normal peripheral blood granulocytes released exclusively urokinase-like plasminogen activator, whereas leukemic cells secreted either a urokinase-like enzyme or a tissue-activator-like enzyme. The data therefore allow the tentative conclusion that the detection of tissue plasminogen activator release by peripheral blood cells is indicative of the leukemic state.

In most cases, cells isolated from any given leukemic blood sample generally secreted only one molecular species of plasminogen activator. This observation merits additional comment in the following three respects.
First, patients with AML whose peripheral blood leukocytes released exclusively activator of the tissue type tended to have a worse prognosis in terms of their susceptibility to induction of remission than did patients whose cells released enzyme of the urokinase type. If more extensive studies confirm this correlation, the molecular species of plasminogen activator released by AML blast cells may serve as a diagnostic marker of relevance to the management of this disease.

Second, we have isolated cells from 5 patients with AML that released both the urokinase-type and the tissue-type of plasminogen activator. In these cases, the cells appeared to be exclusively blastic and of leukemic type, suggesting that certain leukemic clones may develop that synthesize and release both forms of plasminogen activators. The report of a cloned cell line that produces two immunochemically unrelated forms of plasminogen activators provides precedent for this suggestion.

Third, our previous experience with plasminogen activators released by human cells has led us to believe that the electrophoretic finding of a 60,000 mol wt plasminogen activator, and the absence of a 70,000 mol wt enzyme in the same track, was sufficient to identify the enzyme as being of the urokinase type. The results we have obtained with two leukemic cell isolates have provided the exception that invalidates the generality of this assumption. We can now say with confidence that it is possible to observe tissue plasminogen activators that cannot be distinguished by electrophoresis from the urokinase type of enzyme. Immunochemical procedures are therefore essential for the correct identification of these enzymes.

The Effects of Dexamethasone and Tetradecanoyl Phorbol Acetate on Plasminogen Activator Release by Human Acute Myeloid Leukemia Cells

By E. Lynnette Wilson, Peter Jacobs, and Eugene B. Dowdle

This investigation was undertaken to examine the extent to which leukemic cell functions are susceptible to regulation in vitro and to investigate their heterogeneity in this regard. Since plasminogen activator release is known to be a modulatable cellular function that can be influenced by antinflammatory steroids and tetradecanoyl phorbol acetate (TPA), the effect of these two compounds on the secretion of urokinase- or tissue-type enzymes by leukemic cells was studied. The release of both enzyme species could be stimulated or suppressed by these substances by mechanisms that were inhibited by actinomycin-D and hence required transcription of new mRNA. Plasminogen activator release by cells from 41/45 patients with AML was either stimulated or inhibited by $10^{-7}$M dexamethasone, implying that most AML cells possess glucocorticoid receptors. In 26/45 cases, the enzyme was inhibited by this steroid to less than 25% of control values. Pronounced inhibition of this degree was not encountered with normal polymorphonuclear leukocytes. Plasminogen activator secretion by AML cells was profoundly inhibited in 20/41 cases by 1 ng/ml TPA and stimulated in 8/41 cases. Leukemic blasts varied considerably in their response to dexamethasone and TPA. Plasminogen activator release should prove a sensitive means of monitoring the responses of AML cells to biologically active compounds.

Peripheral blood leukocytes from patients with myeloid leukemia release serine proteases that function as activators of the plasma zymogen, plasminogen. In a recent study of this phenomenon, we have observed that leukemic cells derived from different patients were dissimilar with respect to plasminogen activator release, both qualitatively in terms of the rate of enzyme secreted per cell, and quantitatively in terms of the molecular species of plasminogen activator that was secreted. Leukemic cells secreted either the urokinase-type or the tissue-type plasminogen activator. In acute myeloid leukemia (AML), cellular tissue-type plasminogen activator release was associated with an unfavorable prognosis for induction of remission.

In most other systems that have been studied, synthesis and release of plasminogen activators have been found to be inducible cellular functions that can be modulated by hormones, retinoids, and other compounds that affect expression of the malignant phenotype. It therefore seemed possible that an in vitro study of the effects of pharmacologically active substances on the synthesis of plasminogen activators by leukemic cells would provide a quantitative means of estimating the susceptibility of these cells to genetic modulation. Such information would contribute to the knowledge of the biology of the leukemic cell and might provide a rational basis for the classification and treatment of leukemias.

In this article we record our observations on the effects of the antiinflammatory steroid, dexamethasone, and the tumor promoter, tetradecanoyl phorbol acetate (TPA), on plasminogen activator release by AML cells incubated in vitro. These two compounds were chosen for their ability to influence plasminogen activator release in other systems. Furthermore, TPA has been shown to induce differentiation in the human promyelocytic cell line HL-60 and in cells from patients with AML.

MATERIALS AND METHODS

Subjects

Blood samples were obtained from 15 healthy laboratory workers and 45 patients with AML. All diagnoses of leukemia were based on histologic and histochemical examination of peripheral blood and bone marrow specimens. Romanowsky-stained preparations, cytochemical stains, and ultrastructural features were used to classify specimens according to the French-American-British recommendations.

Cells

Blood was taken by sterile venipuncture into tubes containing preservative-free heparin (Thrombolykin, Organon Teknika, Holland) to give a final concentration of 5 U/ml. Cells were fractionated by dilution with RPMI 1640 medium and centrifugation on a layer of Ficoll-Hypaque. Leukemic blast cells were harvested from the plasma-ficoll interface and freed of contaminating erythrocytes by incubation for 5 min in 0.83% ammonium chloride (pH 7.4). Polymorphonuclear leukocytes (PMN) were isolated from the blood of normal individuals as described by Granelli-Piperno et al.

Blood, Vol. 61, No. 3 (March), 1983
Experimental Protocol

Cells were washed once by centrifugation and suspension in RPMI 1640 and were resuspended in RPMI 1640 containing 3% fetal calf serum (FCS) to give $4 \times 10^6$ cells/ml. One-milliliter samples of this suspension were added to 35-mm Falcon plastic Petri dishes, and dexamethasone or TPA were added to give concentrations covering the ranges $0-10^{-5} M$ and $0-10$ ng/ml, respectively. Dexamethasone (Sigma Chemical Co., St. Louis, Mo.) and TPA (Dr. P. Borcher, Minn.) were kept as stock solutions in absolute ethanol at $10^{-7} M$ and 100 ng/ml, respectively. These were diluted in RPMI 1640 containing 3% FCS so that the addition of 10 μl to each 1 ml of medium gave the desired final concentration. The dishes were incubated for 24 hr at 37°C in a humid atmosphere of 5% CO₂ in air. At the end of this period, the medium was harvested by centrifugation and replaced with fresh medium containing compounds at the same concentration as before. At the end of this second period, the medium was again collected by centrifugation. The medium samples, referred to as harvest fluids, were stored at −80°C for analysis of plasminogen activator activity.

Cells were inspected under phase contrast microscopy after 24 and 48 hr of in vitro incubation. Cellular viability was assessed by Trypan blue exclusion.

Plasminogen Activator Assay

Plasminogen activator activity in harvest fluids was assayed by measuring plasminogen-dependent release of soluble radioactive fibrin degradation products from insoluble ¹²⁵I-fibrin-coated multiwell tissue culture plates (Linbro, Cat. no. FB-16-24, Flow Labs). This was done as previously described,²² save for the addition of 4 μg of plasminogen per well instead of 2 μg. Results were calculated in terms of urokinase units by reference to urokinase standards assayed simultaneously.

Immunohistochemical Analysis of Plasminogen Activators

Molecular species of plasminogen activators present in harvest fluids released by normal and leukemic cells were identified as urokinase-type or tissue-type using specific inhibitory antibodies to these enzymes. Harvest fluid samples were incubated for 1 hr at 4°C with serial twofold dilutions of purified rabbit antibody and assayed for residual activity using the ¹²⁵I-fibrin assay. All procedures have previously been described in detail.²²

Effect of Compounds on DNA Synthesis

Cells ($4 \times 10^6$) were suspended in 1 ml of medium containing dexamethasone or TPA at the required concentration and incubated for 18 hr before adding ³H-thymidine to give a final concentration of 5 μCi (1 μg)/ml. After a further 8 hr of incubation, 1 ml of ice-cold 10% trichloroacetic acid was added to each culture dish and dishes were set at 4°C for 30 min. The precipitate was then collected on a Whatman GFC filter and washed with 30 ml of 5% ice-cold trichloroacetic acid. The filter was dried and counted in Liquifluor-toluene in a Packard liquid scintillation spectrometer.

RESULTS

Normal granulocytes and cells from patients with AML differed markedly in their ability to survive in culture. At the end of 48 hr, at least 85% of leukemic cells were still viable, whereas only approximately 60% of normal granulocytes survived for 24 hr, and by 48 hr, this figure dropped to 30%. The limited capacity for in vitro survival shown by granulocytes has necessitated our confining our observations on these cells to the first 24-hr period of incubation. Since maximal effects of TPA and dexamethasone on plasminogen activator release by AML cells were observed during the second 24-hr period of exposure to these compounds, the results obtained during this period are presented.

We present the effects of TPA or dexamethasone on plasminogen activator release in terms of suppression or stimulation relative to control values observed in the absence of these compounds. For the sake of brevity and descriptive convenience, we have arbitrarily graded these effects as follows: pronounced suppression—less than 25% of control value; moderate suppression—25%-80% of control value; insignificant effect—80%-140% of control value; stimulation—greater than 140% of control.

Effects of TPA and Dexamethasone on Cellular Morphology and Viability

During the first 48 h of in vitro culture, TPA at 0.1 ng/ml, 1 ng/ml, or 10 ng/ml had no adverse effects on

the viability of AML cells. In contrast, TPA at 1 ng/ml was moderately toxic to normal granulocytes, and at 10 ng/ml it was uniformly lethal within 24 hr.

As reported by Pegoraro et al., TPA induced a striking change in the morphology and adherence of AML cells in culture. At 10 ng/ml, TPA caused the cells to adhere to the plastic surface as clusters or as spread macrophage-like cells. Adherence was also frequently observed at 1 ng/ml but was usually not noted at 0.1 ng/ml.

Dexamethasone had no effect on the morphology of normal or leukemic cells. At $10^{-6}M$, this hormone occasionally caused viability to decrease during the first 48 hr of in vitro culture; at $10^{-7}M$ this effect was not seen.

**Plasminogen Activator Release by Normal or Leukemic Cells**

Enzyme secretion by leukemic cells of the 45 patients included in this study ranged from 0.001 to 22.1 urokinase units/10^6 cells/24 hr. Of these cells, 32 secreted plasminogen activator of the urokinase-type and 11 secreted plasminogen activator of the tissue-type. In two cases, both enzymes could be detected.

Neutrophils from normal subjects released from 0.006 to 0.3 urokinase units/10^6 cells/24 hr. In all cases this enzyme was of the urokinase-type. These results have previously been reported. 1

**The Effects of Dexamethasone on Cellular Plasminogen Activator Release**

Dexamethasone was added to cultures of normal granulocytes and AML cells to give final concentrations ranging from 0 to $10^{-6}M$, and harvest fluids were assayed for plasminogen activator content. The results observed when cultures were treated with $10^{-7}M$ dexamethasone are presented in Fig. 1, where each point represents the average of the results for duplicate cultures expressed as a percentage of the average of results from triplicate control cultures to which steroid was not added.

In 12/13 cultures of normal PMN, $10^{-7}M$ dexamethasone caused moderate suppression of plasminogen activator release. In the remaining case, the steroid had little effect.

The effects of dexamethasone on AML cells were more complex and in many cases more striking. Dexamethasone at $10^{-7}M$ either stimulated, had relatively little effect, or inhibited plasminogen activator release. Typical examples of these 3 responses are shown in Fig. 2.

In most cases, the effects of dexamethasone were time-dependent (being more obvious after 48 hr than they were after 24 hr) and concentration-dependent, being maximal or very nearly so at $10^{-7}M$. These
relationships are illustrated in Fig. 3. Two unusual responses were observed in which the steroid caused pronounced inhibition of plasminogen activator release at $10^{-4} M$, whereas it stimulated at $10^{-7} M$.

There was a tendency for the release of the tissue-type plasminogen activator to be inhibited to a greater extent than release of urokinase but this was not statistically insignificant. In 6/45 cases, $10^{-7} M$ dexamethasone stimulated plasminogen activator release, and in 35/45 cases, significant suppression was observed. Dexamethasone had an insignificant effect on cells from the remaining 4 cases (Fig. 1). In 26/45 cases, plasminogen activator release by leukemic cells was inhibited to less than 25% of control values. Pronounced inhibition of this degree was not encountered with any of the preparations of normal PMN studied at any of the concentrations of dexamethasone.

Results obtained with $10^{-8}$ and $10^{-4} M$ dexamethasone were similar to those obtained with $10^{-7} M$, whereas $10^{-8} M$ dexamethasone had significantly less effect on plasminogen activator release.

The effect of dexamethasone on plasminogen activator secretion could be prevented if actinomycin-D (1 µg/ml) was added to the cultures together with the dexamethasone, indicating that transcription of new mRNA was required for its inhibitory or stimulatory effect to manifest itself.

**The Effects of TPA on Plasminogen Activator Secretion**

Leukemic and normal cells were treated with TPA at concentrations of 0.1, 1, and 10 ng/ml and harvest

---

**Fig. 3.** AML cells were treated with the indicated concentrations of dexamethasone for two consecutive 24-hr periods as described in Materials and Methods. Harvest fluids from untreated (Con) and steroid-treated cells were then assayed for plasminogen activator activity.

**Fig. 4.** The effect of 1 ng/ml TPA on plasminogen activator secretion by AML cells and PMN. Each point is derived from a different subject and represents the average of the results for duplicate cultures expressed as a percentage of the average of the results from triplicate control cultures to which TPA was not added. Each point represents results obtained from a separate individual. Urokinase-like enzyme (○); tissue activator-like enzyme (●); mixed urokinase-like and tissue activator-like enzymes (□).
fluids were collected for plasminogen activator assay as described for steroid-treated cells. The results were compared with those obtained with the same cells were incubated under identical conditions without TPA. The data obtained with 1 ng/ml TPA are presented in Fig. 4, where each point represents the average of the results for duplicate cultures expressed as a percentage of the average of results from triplicate control cultures to which TPA was not added.

When added to normal neutrophils, TPA at 1 ng/ml caused a moderate suppression of plasminogen activator release in 2/15 cases; in 5/15 cases it had no significant effect, and in 8 cases it stimulated between 2 and 10-fold.

The effects of TPA on AML cells varied considerably. When added at 1 ng/ml, the compound caused profound inhibition of enzyme release in 20/41 cases and stimulated in 8/41 cases. Cells that released urokinase showed a tendency to be inhibited by TPA, whereas cells that synthesized tissue activator were stimulated. This difference was not significant when examined by the Mann-Whitney U test. In all cases where inhibition was seen, viable cell counts excluded the trivial explanation of a cytotoxic effect of the TPA.

Results obtained with 10 ng/ml were essentially similar to those obtained with 1 ng/ml, while 0.1 ng/ml had a less marked effect.

The effects of TPA on plasminogen activator release could be prevented by actinomycin-D in a similar manner to that described previously for dexamethasone.

Combined Effects of Dexamethasone and TPA on Plasminogen Activator Release and DNA Synthesis

Although it had been established that, as used in our experiments, neither TPA nor dexamethasone diminished the viability of leukemic cells, we felt it important to exclude cytotoxicity as an explanation for our observations in a more definitive experiment. This was accomplished by the simultaneous measurement of DNA synthesis and plasminogen activator release as a function of dexamethasone and TPA concentration in the same leukemic cells. Results of such an experiment showed that dexamethasone caused inhibition of plasminogen activator release yet had no effect on DNA synthesis. Conversely, TPA at 10 and 1 ng/ml stimulated plasminogen activator release, yet inhibited DNA synthesis.

DISCUSSION

In this article we have shown that dexamethasone and TPA modulated the rate of release of plasminogen activators by normal and leukemic cells cultured in vitro. These effects were not due to nonspecific toxic phenomena and required the transcription and translation of new mRNA for their manifestation.

Although, as observed by Granelli-Piperno et al., dexamethasone suppressed and TPA tended to stimulate plasminogen activator release by normal granulocytes, these effects were generally less marked than those observed when AML cells were treated with these compounds at the same concentrations. Differences between AML cells and normal PMN in these respects may have been due to differences in their neoplastic status or in the extent to which they had differentiated. Normal bone marrow myeloblasts would have been a preferable control cell population to have used and such studies are currently in progress. Furthermore, PMN cells survived poorly in culture, so that it was difficult to design experimental protocols that could be used to draw valid comparisons between AML cells and normal granulocytes. For these reasons we do not wish to suggest that differences between normal granulocytes and AML cells that we have observed necessarily identify differences between normal and leukemic cells.

By most clinical and laboratory criteria, the leukemias comprise a group of well defined disorders. Within each diagnostic category, however, one frequently observes patients whose disease differs strikingly in its presentation, progress, and response to therapy. The results in this article provide further examples of this phenotypic diversity.

Plasminogen activator release by AML cells incubated in vitro differed between patients both in terms of the type and the amount of enzyme secreted and in terms of the extent to which this secretion could be modulated by dexamethasone or TPA. The regulation of plasminogen activator synthesis and release has proved to be a genetically controlled cellular function in all cells studied to date. Our data provide good reason to believe that the same holds true for AML cells and that the phenotype of each myeloid leukemic cell clone is uniquely governed by the action of genes that vary in the degree to which their expression can be modulated. Sufficient data are not yet available to allow significant correlations to be drawn between modulation of plasminogen activator release, other criteria of cellular differentiation and clinical features of this disease.

Since cells from 41/45 patients with AML showed a significant change in the rate of plasminogen activator secretion in response to 10⁻³ M or 10⁻⁴ M dexamethasone, one might infer that the great majority of AML cells possess glucocorticoid receptors. Using techniques that measure binding of radioactive steroid, Lippman et al. and Gailani et al. found that 20%–30% of disrupted AML cell specimens possessed glucocorticoid receptors. However, when intact cells were used for receptor measurement, leukemia blasts from all patients were found to contain glucocorticoid
receptors. Our results tend to confirm the need for intact cells for receptor measurements. The most sensitive and informative assay may be the indirect enzymatic one that we have used, in which the effects of steroid-receptor engagement are amplified many-fold by effects on cellular plasminogen activator release.

Most studies of the effects of dexamethasone on plasminogen activator synthesis have reported inhibition of enzyme release by this steroid. Roblin has recently suggested that the synthesis of the urokinase-type enzyme is inhibitable by dexamethasone, whereas that of tissue plasminogen activator is not. Our observations with leukemic cells show that this is not a general rule. The release of both tissue-type and urokinase-type plasminogen activators were susceptible to the effects of dexamethasone, and in these cells, both enzyme species could be inhibited or stimulated by this steroid (Figs. 1 and 2). Therefore, it is the cell type rather than the species of enzyme that is the final determinant of dexamethasone responsiveness and, unlike other cell types studied, AML cells may show stimulation of plasminogen activator secretion in response to this glucocorticoid.

Although TPA is best known as a promoter of carcinogenesis and for its ability to enhance expression of the transformed phenotype, it has been shown to induce differentiation in leukemic cells. Similarly, TPA usually induces the synthesis of plasminogen activator when added to other cells cultured in vitro, yet as shown by our studies, this compound usually inhibits release of this enzyme when applied to leukemic cells (Fig. 4). In these two respects, therefore, AML cells respond to TPA in an anomalous fashion. The reason for this and its significance must await further study.

In conclusion, we feel it appropriate to emphasize the usefulness of the measurement of plasminogen activator synthesis as a sensitive means of monitoring cellular responses to biologically active compounds. The implications of this conclusion for rational approaches to the management of AML are obvious. It is hoped that further studies will justify this conclusion and will establish the characterization of plasminogen activator release as a useful procedure for predicting prognosis and optimal therapeutic options in this disease.

Bone Marrow Transplantation

Bone marrow transplantation has emerged as the preferred form of treatment for certain clinical situations exemplified by immunodeficiency diseases, and for patients with severe acute aplastic anaemia. The place of this procedure in the treatment of individuals with acute leukaemia is less clearly defined, although a small number of long-term survivors has established it as justifiable when conventional methods have failed. In view of the steady progress in understanding the principles of bone marrow transplantation, and the availability of this service in the Republic, it is timely to review the current status of this form of management.

The transfer of marrow from one individual to another is not new, and its feasibility was demonstrated in animal studies more than a quarter of a century ago. Transplantation in humans was initially abortive, and the poor results obtained in these early studies restricted its clinical application. However, from 1970 the principles of tissue typing have been better appreciated, and this knowledge, coupled with advances in immunosuppressive therapy, has led to a number of long survivals, so that bone marrow transplantation may now be regarded as both practical and realistic. Nevertheless, a number of problems remain unresolved, and it is important to place in perspective what can be achieved with this procedure, in order to define current indications and to identify those diseases which require further study before transplantation can be included among the therapeutic options.

In severe combined immunodeficiency disease, morbidity and mortality are high, and transplantation of bone marrow from a suitably matched sibling is the treatment of choice. In this situation it is noteworthy that haematopoietic function is usually intact, and only immunological reconstitution is necessary. Accordingly, multiple small infusions of marrow, or even of fetal liver, may be effective in reversing the lesion. The severity of the immunological defect limits capacity for rejection, making engraftment relatively simple, even when minor histocompatibility differences exist and unrelated donors are used. However, graft-versus-host disease remains an unpredictable and formidable problem.

In bone marrow hypoplasia, results have been clouded by the lack of clear definition of the indications. However, criteria are now established for the selection of individuals who will have a significantly improved survival compared with that of matched patients who receive only supportive and conservative therapy. These include platelet counts of less than 20 000/μl, granulocytes less than 500/μl and reticulocytes of less than 1% when corrected for anaemia, together with a loss of haematopoietic cells from a bone marrow trephine biopsy specimen.

The fact that the majority of patients with severe bone marrow hypoplasia can have their marrow successfully reconstituted in this way is evidence in favour of the defect's being in the stem cell rather than in the micro-environment. However, some patients have rejected the graft, but have nevertheless recovered, with regrowth of autologous marrow. The latter findings support the concept that, at least in some individuals, severe acute aplasia may involve a lesion other than that of the stem cell.

In aplastic anaemia, the longest period of survival after a transplant from a monogygotic twin is 16 years, while the 3 patients treated in Seattle are presently alive and well. The same series, 31 of the 73 HLA-matched patients who received transplants from siblings are presently alive, the longest survival being 5 years. Essentially similar data have been reported by the international co-operative study group of which the investigators from Cape Town are members.

Against this background is important to note that such patients, immediately upon diagnosis, should be transferred to a transplantation centre so that they can be evaluated for what is currently considered the preferred form of treatment. Any delays in this diagnosis have been established, in anticipation of spontaneous resolution, and particularly when blood is administered, may compromise the success of later transplantation attempts. Conservative treatment should be reserved for patients with severe acute aplastic anaemia, in whom transplantation is, for one reason or another, not feasible.

In patients eligible for transplantation, success is statistically related to the adequacy of the number of donor cells infused and the absence of prior antigen sensitization. Second transplantsations from the same or an alternative donor can further increase the chance of success.
