relapse. DLs were either ineffective or led to toxicity from GVHD in all but one of the patients treated. This is not surprising, because the response rate in relapsed AML is low and there are few data to show that DLs are effective in inducing remissions in patients with aggressive lymphomas.23-25 Only a single patient with multiple myeloma has achieved CR following DL therapy.

The use of this conditioning regimen has been very effective in a group of patients that had many high-risk features: patients who had prior high-dose therapy, patients with renal or cardiac impairment, or patients with high-risk diagnoses for allogeneic SCT such as Hodgkin disease or multiple myeloma. Indeed, allogeneic transplantation using myeloablative conditioning following failed autologous transplantation has been associated with a treatment mortality ranging between 50% and 80%.23,26 Undoubtedly, such a high mortality rate may offset a potential for cure, and therefore conventional transplants have generally been avoided in such patients. In our study, 19 patients received a second transplant, and only 3 patients (17%) died of transplantation-related complications, demonstrating that this nonmyeloablative approach could be attempted if a second transplant has to be considered.

While a conditioning regimen containing fludarabine and melphalan appears to have been active in tumor control, particularly in patients with Hodgkin disease and NHL, the follow-up period is still very limited and all patients remain at risk of relapse.

In such a high-risk group of patients, any conditioning regimen is likely to be associated with a significant relapse risk, and therefore the survival curves shown in Figure 2 should be interpreted with caution. This is particularly so in some hematologic malignancies, such as acute leukemia, where the GVL effect of DLI for the treatment of relapse is of limited efficacy.23 However, the antitumor responses seen with the conditioning regimen might allow the use of DLI to be delayed until 6 to 12 months post-transplantation, when this intervention might be associated with less GVHD.21,24

In summary, our results show that our nonmyeloablative regimen facilitates allogeneic engraftment, with a low incidence of GVHD and TRM. The long-term antitumor activity of this regimen remains unknown, however, if used in combination with the prophylactic or pre-emptive use of DLI, prolonged remissions might be obtained in some types of hematologic malignancies.

Acknowledgments

We thank the staff members of the Therapeutic Antibody Centre, University of Oxford, for their contributions to the production of CAMPATH-1H antibody.

Background
CAMPATH-1 (CD52) Abs have been used in stem-cell transplants for the prevention of GvHD and graft rejection. These complications can effectively be prevented by depletion of T lymphocytes from both donor and recipient. However, donor lymphocytes might contribute to an anti-leukemia effect and lymphocyte depletion may exacerbate problems with immune reconstitution. There is a fine balance between the risks of GvHD and host-versus-graft reactions, relapse and infection.

Methods
Clinical outcomes for 4264 patients were reported to a central registry and analyzed by univariate and multivariate methods to determine the superior protocols. Various protocols of lymphocyte depletion were tested, using either CAMPATH-1M (lgM) plus complement or CAMPATH-1G (lgG2a) to treat the donor BM ex vivo and CAMPATH-1G in vivo to treat the recipients. The humanized antibody CAMPATH-1H has recently replaced CAMPATH-1G. A meeting of the clinical collaborators was convened to discuss the results and to review the experiences of individual centers.

Results
Interest focused on the use of mobilized PBSC for transplantation and on the use of reduced-intensity conditioning regimens ('mini' or 'non-myeloablative' transplants). These approaches are likely to become increasingly important in the future and will allow transplant procedures to be used for relatively older patients. The use of CAMPATH-1G or CAMPATH-1H was associated with a low incidence of GvHD or rejection, though there were some differences that might be related to the longer half-life of the humanized antibody. An unexpected and apparently paradoxical effect of post-transplant CYA was observed — it appeared to reduce the risk of dying from infection after 6 months. Although part of the benefit could be explained by a reduction in GvHD, the effect was still evident when patients with GvHD or graft rejection were excluded from analysis.

Discussion
CAMPATH-1H appears to have a useful role in the prevention of graft rejection and GvHD, particularly in patients who are at high risk of these complications. It can equally well be used by admixture with the infused stem cells, or by administration to the patient prior to the transplant. Future studies will seek to understand the mechanism of the CYA effect and to improve the quality of immune reconstitution.

Introduction

International clinical investigators met in Oxford UK in September 2000, to review the results of clinical studies using CAMPATH-1 Abs for immunosuppression in stem-cell transplantation. They had previously submitted updated results to the CAMPATH Users’ registry and this report summarizes the statistical analysis of those data and discussion that took place at the meeting. This is a registry-type analysis and, as such, has the advantages and drawbacks inherent in that type of study [1]. By pooling data from many centers it is possible to answer questions that it would be hard to address even by very large prospective randomized trials. However, this approach requires accurate and complete data collection and there is a risk that variables will be confounding, leading to erroneous conclusions about causal relationships. The CAMPATH users have made strenuous efforts to provide complete and up-to-date data for analysis, and we have developed algorithms for multifactorial analysis of this type of dataset.

The Campath family

The group has worked with three different CAMPATH-1 Abs [2]. They all recognize the same epitope on the CD52 Ag, a small lipid-anchored glycoprotein that is found on almost all lymphocytes. The original CAMPATH-1M (rat IgM) is the most efficient for complement activation and has been used exclusively in vitro for treatment of donor stem cells with exogenous complement. CAMPATH-1G (rat IgG2b) does activate complement, but also binds human Fc receptors and lysed cells very effectively in vivo. It has been used both in vivo, to treat the recipient before and/or after the transplant, and also in vitro, to treat the stem cells. When lymphocytes are coated with CAMPATH-1G, there is a small and variable degree of lysis, probably depending on the amount of residual plasma in the cell suspension, but most of the cells are presumed to be lysed when the mixture is infused into the patient. A key feature of this treatment is that excess CAMPATH-1G is also likely to deplete residual recipient lymphocytes. CAMPATH-1H is a humanized IgG1, created from CAMPATH-1G by genetic engineering [3].

Antibody protocols

The main protocols for using CAMPATH-1 Abs are shown in Figure 1. In protocols 01–04 the donor BM is depleted of T cells in vitro, with or without CAMPATH-1G in vivo to control rejection. In protocols 06–07, CAMPATH-1G has been used in vivo alone, before and/or after the transplant. Since 1997, CAMPATH-1H has been used to replace CAMPATH-1G in protocols 03, 04, 06 and 07, and one object of the analysis was to see whether the clinical results were comparable.

Conclusions from previous meetings

The following topics were not discussed in detail since the current analysis generally confirms earlier published results [4,5].

- T-cell depletion of donor BM with CAMPATH-1M or CAMPATH-1G results in:
  - Reduction in risk of GvHD;
  - Increase in risk of graft rejection;
  - Increase in risk of relapse (a large effect in CML, small in acute leukemia).

The risk of graft rejection can be reduced by additional immunosuppression, including:

- Additional conditioning with TLI;
Additional conditioning with CAMPATH-1G.
- Post-transplant CYA.

Attempts to prevent or treat relapse by:
- Adding back small numbers of donor T cells increases GvHD with a marginal effect on the risk of relapse.
- Pre-emptive donor lymphocyte infusions can be very effective in treating CML following molecular or cytogenetic relapse, but there is a risk of severe GvHD.

Combination of CAMPATH-1 Abs in vivo and in vitro can sometimes delay engraftment.

Patients and methods
Patient recruitment: exclusion and inclusion for analysis
The registry collects basic enrolment and outcome data for all patients who receive treatment with CAMPATH-1 Abs as part of conditioning or GvHD prophylaxis for stem-cell transplants. From the correlation between antibody distribution records and registry returns, we estimate that the database includes at least 98% of all patients treated during 1982–99. Between April and August 2000, updated data were received from all of the 38 currently active transplant centers, representing 88% of the patients in the registry.

A total of 4764 allogeneic transplants have been reported. Of these, 202 were excluded from analysis, mostly because of short follow-up (< 100 days), or because CAMPATH-1 was used in conjunction with other methods for T-cell depletion, or they were from centers contributing only one or two patients. Sixty-one centers contributed to the final dataset of 4062 transplants, of which 3922 were first allogeneic transplants and 140 were second or subsequent (Table 1).

No attempt was made to classify the degree of HLA matching for unrelated donor transplants, since precise information was not available for all the patients, especially those transplanted before the era of molecular genotyping. Notwithstanding the likely effects of HLA matching on the outcomes, all of the unrelated donor transplants have been considered together. All types of graft failure, early, late or partial, whether or not successfully treated, were included together and percentages were calculated as a fraction of patients at risk (i.e. survived long enough to be evaluable for engraftment). To calculate the risk of GvHD, patients who suffered graft failure without GvHD were considered not evaluable and, again, the percentages were calculated as a fraction of those 'at risk'. Only hematologic relapse was analyzed; for patients with CML there was no account of molecular or cytogenetic relapse since the diagnostic criteria have changed over the time scale of these studies.

Univariate statistical analysis
Treatment groups were compared using the χ² test for categorical variables and the Wilcoxon two-sample test for continuous variables. Life-table analyses were carried out by the standard method using the LOGRANK computer software specially developed for this purpose (Steve Cobbold, unpublished work). This program can display the estimated standard error of the survival curves at each event point [6], which allows a simple visual estimation of significance. It is empirically determined that if there is 'daylight' between the error zones of two curves, then the difference is usually statistically significant (at least

Multivariate statistical analysis
The dataset of 3922 first-transplant patients was analysed by Cox multivariable regression model, using the custom software package COXSURV (Steve Cobbold, unpublished work) to automatically carry out the necessary iterations. First, the data were coded appropriately, either binary (male/female, in vivo antibody/no in vivo antibody etc.) or in numeric groups (e.g. age, log cell dose etc.). Data were checked for confounded variables and, as expected, several were found (e.g. total irradiation dose + number of fractions). The worst of these were eliminated from subsequent analysis. The factors that remained are shown in Table 2. The first univariate iteration was carried on each of the covariates. The factor with both the highest relative risk (i.e. making the biggest contribution to the outcome) and a significant probability value was then fixed and all other variables recalculated. This was repeated until there were no more significant variables. The program can plot 'corrected' survival curves. These were modeled for any particular variable, or pairs of variables, allowing for the contribution of all other significant variables. In a standard life-table, group survival is calculated thus

\[ P_n = \frac{P_{n-1} (AtRisk_n - \text{events}_n)}{(AtRisk_n - \text{Censored events}_n)} \]

where:
\[ AtRisk_n = N - \sum_1^n \text{events} \]
\[ N = \text{total number of patients in the group} \]

In the multivariable model, accumulated risk exposure replaces accumulated patients numbers and is calculated as follows:

\[ P_n = P_{n-1} \frac{(AtRisk_n - \text{Risk}_n)}{(AtRisk_n - \text{Censored Risk}_n)} \]

where:
\[ \text{Risk}_n = \text{the product of individual risk factors, i.e. the sum of the Log_e(Risks)} \]
\[ \text{i.e.:} \]
\[ \text{Risk}_n = E + \beta_1(a_n - mn[a]) + \beta_2(b_n - mn[b]) + \ldots \]
\[ E = 1 \text{ if an event occurs. } E = 0 \text{ if there is no event} \]
\[ a, b, \ldots \text{ are significant variables included in the model} \]
\[ mn[a], mn[b], \ldots \text{ are the means of } a, b, \ldots \]

βₐ is the covariate coefficient from the Cox model associated with variable a
β for the variable(s) being investigated are set to zero.

\[ \text{AtRisk}_n = \sum_{i=1}^{N} \text{Risk}_i - \sum_{i=1}^{n} \text{Risk}_i, \]

i.e. accumulated risk exposure replaces accumulated patient numbers.

To handle missing data points, unknown variables are set to the mean and the risk from patients where the variable of interest is not known is distributed equally between the two groups. Risk factors can be estimated for each variable as:

\[ \text{Riskfactor}_i = e^{(\beta_i \times \text{mean})}. \]

**Results — univariate analysis**

**Overview**

Results for each protocol were divided into two groups: with and without post-transplant CYA (± MTX). As became apparent, there was often a substantial difference between them. Outcomes were classified according to protocol, disease, source of stem cells (BM or blood) and type of donor (HLA-identical sibling or unrelated). The numbers of mismatched family donor transplants were too small for detailed analysis by protocol.

**HLA-matched siblings — BMT**

Total data for all diseases are presented in Table 3. There is some bias because different protocols may have been used for different diseases. Therefore, separate analyses were carried out for non-malignant diseases (Table 4), patients with acute leukemia in first CR (Table 5), and CML in first chronic phase (Table 6). Relatively few patients had received CAMPATH-1H, so these were pooled with the corresponding CAMPATH-1G data in most cases. However, comparison of CAMPATH-1H and CAMPATH-1G was possible for Protocol 07 (CAMPATH-1G/1H pre-transplant), where it appeared that the results were essentially similar whichever was used (Table 4).

The protocols that gave the best control of both GvHD and rejection, and the lowest transplant mortality, were Protocol 02 (CAMPATH-1G plus CAMPATH-1M) and Protocol 03 (CAMPATH-1G ‘in the bag’). Post-transplant CYA gave a reduction in transplant mortality that often seemed to be greater than its effect on GvHD or rejection. This effect was predominantly due to a difference in deaths from infection that occurred between 6 months and 2 years, and was still evident even when patients who suffered any GvHD or graft rejection were excluded from analysis (Figure 2).

Results from three centers who used Protocol 02 to treat patients with AML in first remission were published [7]. Comparison with case-matched controls treated with conventional CYA/MTX GvHD prophylaxis, as reported to the International Bone Marrow Transplant Registry (IBMTR) showed that the CAMPATH-treated group did significantly better. It is not possible to continue with this approach due to lack of commercial interest in production of the rat Abs.

The use of CAMPATH-1G or CAMPATH-1H pre-transplant (Protocol 07) with post-transplant CYA, gave a low incidence of acute and chronic GvHD, comparable with the other protocols. Antibody levels have been measured in a small number of patients transplanted from unrelated donors, and these results suggest that there is sufficient antibody in the recipient at the time of marrow infusion to deplete the donor T cells. CAMPATH-1H may have a longer half-life than CAMPATH-1G in this context, since it was still detectable for several days post-transplant [8].

**HLA-matched siblings — PBSC transplants**

Most patients have followed Protocol 03 (CAMPATH-1G/1H in the bag) — generally with full conditioning including TBI. A significant number of patients were treated using Protocol 07 (CAMPATH-1G/1H pre-transplant) — most of these were ‘mini’ transplants where fludarabine/melphalan were used as conditioning agents.

1 Despite the apparently good control of GvHD and rejection, there was a high proportion of deaths from infection in the CAMPATH-1G/CAMPATH-1M group. Many of these patients had received additional chemotherapy with thiopeta, as well as conventional cyclo/TBI.

Data for Protocol 03 were analyzed in 1999 and the results published together with technical details of the transplants [9]. They were updated for this meeting (Table 7). Recovery of CD34+ cells following the in vitro incubation with CAMPATH-1G or CAMPATH-1H was close to 100%. Comparison of CAMPATH-1G and CAMPATH-1H shows some differences, which seemed to be clinically very apparent, but it is not clear whether they are statistically significant. There was more chronic GvHD using CAMPATH-1H without CYA. Although it was reported as limited, teams at Cape Town and Ulm found it to be a significant clinical issue. Transplant-related mortality was a little higher (not significant) with CAMPATH-1H and there were more deaths from infections. However, these problems seemed to be reduced with the use of post-transplant CYA. Overall, the results of PBSC transplants did not seem as good as for BM (compare Tables 3 and 7).

Transplant-related mortality was higher for PBSC, despite the favorable characteristics of these transplants: a high proportion of good-risk patients, rapid engraftment and very little graft rejection or GvHD (Figure 3). However, comparison of PBSC and BM over all protocols in the multivariate analysis showed reduced transplant-related mortality for the blood stem cells (see later).

In Protocol 07 (CAMPATH-1G/1H pre-transplant) only 19 patients received CAMPATH-1G so it was hard to compare the outcome with CAMPATH-1H (38 patients) (Table 7). Nearly all received post-transplant CYA. With CAMPATH-1H there was a very low rate of graft rejection or GvHD. Transplant-related mortality appeared high at 2 years (36 ± 27%) but few patients had been followed long enough for a reliable estimate. Many of these were poor-risk patients who received reduced intensity conditioning because they were deemed to be unsuitable for a standard transplant.

Unrelated donor transplants
As a general rule, adults have been treated according to Protocols 06 or 07, whereas children have been treated according to Protocol 02 (Tables 8–10). Good results were obtained with Protocol 02 so long as post-transplant CYA was given. However, this has been discontinued due to difficulties with the supply of rat antibodies.

Comparison of CAMPATH-1H and CAMPATH-1G using in vitro (Protocols 06, 07) showed a significant advantage for CAMPATH-1H in terms of rejection, transplant-related mortality and leukemia-free survival. Whether this is due to the antibody itself, or some other concurrent improvement in the transplant procedures, is impossible to tell. For example, the Hammersmith Hospital added an extra fraction of TBI at about the same time as introducing CAMPATH-1H. The results indicate that the humanized antibody is no worse in this setting, although there was more Grade II acute GvHD in patients treated on Protocol 06. However, at the meeting the Hammersmith team raised a note of caution, reporting a high incidence of relapse in the CML patients who received CAMPATH-1H. Since these relapses were mostly diagnosed by molecular or cytogenetic techniques, and were often successfully treated by donor lymphocyte infusions, they do not appear in the database.

The results with CAMPATH-1H pre-transplant (Protocol 07) were at least as good, if not better than CAMPATH-1H given pre- and post-transplant (Protocol 06). Engraftment was faster, rejection and GvHD were very low, and the 1-year survival data are excellent so far. The humanized antibody persists in the patient for at least 5 days, and is probably sufficient to deplete any donor T cells. Avoiding post-transplant antibody might be beneficial by favoring more rapid reconstitution of lymphocytes and other cells.

Conclusions from univariate analyses

- In general, CAMPATH-1H is at least as good as CAMPATH-1G, though there is more chronic GvHD (in the absence of CYA).

</table>
The best practical protocols appear to be CAMPATH-1H in the bag (02) or CAMPATH-1H pre-transplant (07).
- Deaths from infection are significant in some settings — notably PBSC transplants.
- Addition of post-transplant CYA always seemed to improve the outcome.

**Results — multivariate analysis**

Ratios are expressed in this table.

Almost all factors analyzed appeared to significantly affect the rate of engraftment (Table 11). The dominant ones were: faster with high cell dose ($p < 10^{-6}$), faster with PBSC rather than bone marrow ($p < 10^{-9}$, even allowing for effect of cell dose) and faster with post-transplant cyclosporin ($p < 10^{-7}$).

**Transplant-related mortality (TRM; all patients):**

The most significant factors influencing TRM were match (less was bad), age (older was bad), and disease status at time of transplant (more advanced was bad) (all $p < 10^{-9}$) (Table 12). In addition, higher total dose of TBI was good ($p < 10^{-5}$), CAMPATH-1M alone (Protocol 01) was bad ($p < 10^{-5}$), CAMPATH-1H was good ($p < 10^{-4}$), male donor was good ($p < 0.001$), MTX

</tbody>
</table>
was bad \((p < 0.001)\), CAMPATH-1G was good \((p < 0.01)\), male patient may be good \((p = 0.04)\), CYA may be good \((p = 0.04)\) and blood stem cells may be good \((p = 0.02)\).

Note that, because total dose of TBI was confounded with number of fractions and dose rate, it is not possible from these data to reach any definitive conclusions about the merits of particular radiation regimens.

**Relapse (acute leukemia)**

The analysis of relapse was limited to 1717 patients with acute leukemia (Table 13). The most significant factor was status at time of transplant \((p < 10^{-6})\). Apart from this, the only factors to emerge as significant were: a higher dose of TBI may be good \((p < 0.02)\), a female donor may be good \((p < 0.02)\) and a good match may be good \((p < 0.05)\). T-cell depletion with any antibody or T-cell add-back had no significant effect on relapse in this subclass of patients.

**Leukemia-free survival (acute leukemia)**

Significant factors were status at time of transplant (more advanced was bad) \((p < 10^{-6})\), match (poor was bad) \((p < 0.001)\), age (older was bad) \((p < 0.01)\) (Table 14). Of the factors that can be controlled, higher dose of TBI was good \((p < 0.001)\), MTX was bad \((p < 0.01)\), CAMPATH-1H may be good \((p < 0.02)\).

In summary, the use of either CAMPATH-1G and CAMPATH-1H was associated with better outcomes in these analyses, especially in reduced TRM, and no obvious increase in relapse resulting in improved leukemia-free survival. An example of a 'corrected' actuarial analysis of transplant-related mortality is shown in Figure 4. This simultaneously illustrates the benefits of better donor-recipient matching and of using CAMPATH-1H in the protocol, whilst allowing for the influence of the other significant covariates.

**Results — individual centers**

Representatives from several of the principal transplant centers presented and discussed their individual results:

University Hospital, Cape Town, South Africa

Nicolas Novitsky summarized the experience using Protocol 03 (CAMPATH-1G or CAMPATH-1H 'in the bag'). A total of 79 BM transplants and 66 PBSC transplants were carried out (all Protocol 03). CAMPATH-1G was used in 106 and CAMPATH-1H in 39 cases (all PBSC). Based on the mononuclear cell number in the graft and using approx 0.05 mg antibody per 10⁶ cells, the

| CAMPATH-1H | 0.26 | 1.03 | 0.02 |
Figure 4. Multivariate analysis of transplant-related mortality (all patients). The risk of dying from causes other than relapse is plotted, taking into account all other significant factors identified in the multivariate analysis. Four groups are illustrated here: less well matched donors (unrelated or mismatched family members) and better matched donors (HLA-identical siblings or HLA-identical other family members). Each is subdivided into patients who received CAMPATH-1H for GvHD prophylaxis and patients who received other CAMPATH antibodies.

A typical dose of CAMPATH-1H was 20–40 mg. Usually no post-transplant immunosuppression was given, but following the occurrence of chronic GvHD in the CAMPATH-1H group, prednisone (or occasionally CYA) was administered up till Day 90. Due to the referral patterns to hospital, CYA therapy was not always practical, as it required frequent visits by patients for monitoring. To date, in the 20 patients treated with prophylactic prednisone post-transplant, mild chronic GvHD was still seen, but delayed. This complication was not seen in subjects treated with CYA. Patients are now routinely given septrin and penicillin.

Individuals treated with CAMPATH-1G showed a rather poorer outcome for PBSC compared with BM, although there were no significant differences in early (< 30 day) or late mortality between CAMPATH-1G and CAMPATH-1H. The main observations on moving to CAMPATH-1H were a higher rate of CMV reactivation (not fatal, but sometimes leading to other complications, e.g. graft failure and sepsis), and a higher rate of chronic GvHD (42%). Although chronic GvHD was generally responsive to steroid treatment, this therapy could lead to infection complications. Some patients in the CAMPATH-1H group who had recovered hematopoiesis developed overwhelming sepsis with meningococcal or staphylococcal pneumoniae, which had not been observed previously.

Roel Willemeze and Grant Prentice remarked that a high rate of CMV reactivation was to be expected and possibly may be seen earlier after PBSC transplants compared with BM transplants. High dose acyclovir is used as CMV prophylaxis at the Royal Free Hospital, with twice-weekly monitoring by PCR and pre-emptive therapy given following two consecutive positive PCR results. Deaths from CMV disease were rare, but nevertheless viral reactivation remains a substantial issue.

Recovery of lymphocyte subsets post-transplant was studied at Cape Town, and the outcome following allologeneic BMT, autologous and allogeneic PBSC compared. Some of this work has been published [10]. The main findings were as follows:

- Despite an increase in colony-forming units granulocyte–macrophage (CFU-GM), there was no significant difference in the reconstitution of lymphoid subsets between BM and PBSC transplants.

- Although memory T cells (CD2*CD45RA*) were expanded, the naive population remained low during 12 months follow-up — this was most obvious in the CD4*CD45RA+ subgroup. Adoptive immunotherapy is unlikely to correct this and ways to improve thymic recovery need to be reviewed.

- CD95 (Fas — normally characteristic of activated cells) was over-expressed during the follow-up period by all transplant groups.

University Hospital, Ulm, Germany

Donald Bunjes described the results obtained between 1989 and 1997 for 43 patients with AML in first remission transplanted according to Protocol 02 (CAMPATH-1G
and CAMPATH-1M) following standard conditioning with Cyclo/TBI. Median follow-up is now 7 years. There was no rejection and the median time to reach 0.5 × 10⁹ neutrophils/L was 23 days. There was no acute GVHD > Grade II and only 9% chronic GVHD. Only four patients had any immunosuppression post-transplant and the long-term DFS is 66%.

Since then, 48 patients have been treated according to Protocol 03, all with CAMPATH-1H (20 mg). This cohort was older, had higher-risk disease and included about 20% non-HLA-identical related donors. Thiopeta was added to the conditioning regimen for some of the patients. No post-transplant CYA was given. Again, there was no graft failure. Engraftment (0.5 × 10⁹ neutrophils/L) occurred by Day 11. In contrast with the previous results, there was a 60% incidence of acute GVHD (all < Grade 2) and 30% chronic GVHD. Although the GVHD was not severe, it did require treatment, which Donald did not find acceptable. The transplant-related mortality in this cohort was 38%, about double that of the previous trial — though the patients were worse risk. CMV reactivation occurred in about 90% of patients at risk (i.e. seropositive before transplant) and one died of CMV pneumonitis. CMV reactivation and its subsequent treatment was likely to predispose to other infectious complications. Overall, immune reconstitution was seen as the biggest outstanding problem.

Two suggestions were proposed to modulate the incidence of GVHD:

- Add CYA post-transplant;
- Add in vivo antibody pre-transplant.

Stephen Mackinnon commented that at the Memorial Sloan Kettering Institute, the combination of thiopeta and CYA had proved to be very toxic. Donald Bunjes replied that since January 2000, CYA has been introduced at Ulm and thiopeta dropped. Nicolas Novitzky suggested that the relatively high incidence of chronic GVHD with little acute GVHD may be related to the relatively high proportion of ‘TH2 type’ (i.e. IL6⁺, IL2⁻) CD8⁺ cells in PBSC compared with BM. Donald Bunjes answered that a relatively high number of cases of autoimmune disease (cytopenias and thyroiditis) had been seen following PBSC transplant, compared with BM, perhaps consistent with this hypothesis.

University Hospital, Leiden, The Netherlands
Roel Willemsje presented the data on PBSC transplants at Leiden using Protocol 03. So far, none of the patients has received post-transplant CYA. To date, 33 patients had received stem cells treated with CAMPATH-1G and 24 with CAMPATH-1H. The incidence of acute GVHD > Grade I was 11% (CAMPATH-1G) or 29% (CAMPATH-1H). The total incidence of chronic GVHD was 17% (CAMPATH-1G) or 34% (CAMPATH-1H). Although there was more GVHD in the CAMPATH-1H group there was not yet a significant difference in transplant-related mortality. Possibly the results would be improved by introduction of post-transplant CYA, but it was correctly pointed out that this had not previously been advocated since one of the principal benefits of T-cell depletion had been the avoidance of post-transplant immunosuppression.

Royal Free Hospital, London, UK
Grant Prentice described the results using CAMPATH-1H both in vivo pre-transplant and in the bag (Protocol 04). A total of 28 patients, aged up to 57 years (median 36 years), suffering from various diseases (including high-risk) were transplanted from various donors, including 21 alternative donors, mostly unrelated and many partly HLA-mismatched. Sixteen received BM treated with 10 mg CAMPATH-1H ‘in the bag’ and 12 received PBSC treated with 20 mg CAMPATH-1H. The conditioning regimen originally contained TLI and busulfan, but more recently a protocol of fludarabine, cyclophosphamide, TBI and CAMPATH-1H (5 days) has been used. HLA-matched patients (whether related or not) did not receive post-transplant immunosuppression; others had CYA.

Two patients transplanted from unrelated donors did not engraft; however lab tests on the pre-transplant BM samples showed viability but no growth in CFU-GM culture. There was no acute GVHD > Grade II, six had limited chronic GVHD and one extensive chronic GVHD. As observed by other centers, there was a high degree of reactivation of CMV, but CMV disease was prevented by monitoring and pre-emptive therapy, as described earlier. One patient who suffered Grade II acute GVHD later died of adenovirus infection. CD4⁺ T cells had risen to > 200/µL by about 9 months post-transplant — this was not delayed compared with previous patients at the Royal Free Hospital. T-cell recovery was a little faster for
sibling donors compared with unrelated donors. In conclusion, CAMPATH-1H was well tolerated, there was little GvHD, but a high degree of CMV reactivation.

Heartlands Hospital, Birmingham, UK

Donald Milligan reported the results for two groups of patients — the first received 'mini' transplants using fludarabine, melphalan and CAMPATH-1H for conditioning with T-replete stem cells (Protocol 07, 14 patients). The second group received conventional conditioning with cyclophosphamide and TBI (sometimes with etoposide as well) and PBSC treated with CAMPATH-1H (Protocol 03, 14 patients). All of the patients received post-transplant CYA. There was little or no graft failure or GvHD in both groups, but an issue of significant concern in the mini-transplant group was the incidence of viral infections, particularly CMV (8/9 patients at risk, one died), adenovirus (7/14 patients at risk, one died) and polyomavirus (6/14 patients at risk). The frequency of other viral infections, including EBV and HSV, were similar and low in both groups. In total, despite the small numbers of patients, there were significantly more virus infections in the mini-transplant group. Lymphocyte counts, including CD4 T cells and cytotoxic T-cell responses were lower in the mini-transplant group than in the conventional-transplant group. Could these differences be due to the different total dose of CAMPATH-1H, or some other factor, such as the use of fludarabine, or differences in the patient population? A proposed strategy is to use just 10 mg of CAMPATH-1H 'in the bag' instead of in vivo with the mini conditioning regimen.

University College Hospital, London, UK

Stephen Mackinnon presented data on mini-transplants updated since a recent publication [11]. The basic protocol consisted of 5 × 20 mg CAMPATH-1H from Day −8 to Day −4, fludarabine from Day −7 to Day −3, melphalan on Day −2 and CYA post-transplant, originally for 6 months, but now for 1–3 months. CAMPATH-1H was included to prevent rejection, but it also resulted in a low incidence of GvHD, which allowed the CYA to be reduced. This protocol has been used with a variety of high-risk patients unsuitable for conventional transplants owing to age or a previous transplant. HLA-identical siblings (mostly PBSC) and unrelated donors (mostly BM) were included. Of 64 patients analyzed, 14 had been transplanted in relapse or with refractory disease and 30 were second transplants. One patient died before engraftment, one suffered graft rejection and the other 62 all engrafted. There were typically 5–7 days of neutropenia. Chimerism was measured by mini-satellite analysis and it was found that about 50% were fully donor type at first analysis. About 25% were mixed chimeras in all lineages and the remaining 25% were mixed chimeras for T cells and full in others.

Only five patients suffered any acute GvHD and none was > Grade II. There was almost no chronic GvHD, even when CYA was stopped early. Transplant-related mortality at 1 year was 17%. Engraftment was good even among the 20 patients transplanted from unrelated donors, including eight who were partly HLA-mismatched. However, the follow-up was an average < 1 year and all patients were still at risk of relapse. They were not routinely given donor lymphocytes, but these were started at 6 months if there was mixed chimerism and evidence of residual disease. Lymphocytes were given cautiously, starting with 10⁴ per kg and even this has produced some GvHD (other groups have used 10 times more). It is estimated that a safe dose for T cells is of the order of 10⁵/kg at the time of transplant, but may rise to 10⁶/kg after several years. Older patients such as these may not tolerate GvHD.

As in other studies, immune reconstitution was slow, with also a high frequency of CMV reactivation, causing a logistical problem with the need for frequent testing and pre-emptive treatments. One possibility might be the adoptive transfer of CMV-specific donor T cells. Following infusion of about 10⁷/kg CMV-specific donor T cells in 2–3 weeks there was a huge proliferation, despite the continued administration of CYA, and these cells could be followed in vivo by using CMV-specific HLA-peptide tetramers.

The possibility of disordered immune reconstitution was discussed. Donald Milligan described one patient who died from severe autoimmune hemolytic anemia, and one other who died from tuberculosis in the spleen. Other published mini-transplant protocols have mentioned similar problems. However, Stephen Mackinnon pointed out that the transplant-related mortality in the patients who received CAMPATH-1H is still lower than for other protocols, for example in a European study (including the UK data as about one-third of the dataset), the transplant-related mortality at 100 days was 11% and
at 1 year was 30%. GvHD was a common complication in the European study, perhaps partly because donor lymphocytes were being given too early.

Herman Waldmann asked whether there was any evidence for an adjuvant effect of CAMPATH-1H in preventing relapse in lymphoid malignancies. The patients were too heterogeneous and the data too early to answer this question, but at 3 months post-transplant most were in complete or partial remission (having generally been transplanted in relapse or with resistant disease), suggesting that the regimen gives good disease control, at least initially.

Discussion
CAMPATH-1G and CAMPATH-1H appear to be generally similar in activity for depleting T lymphocytes to prevent GvHD and rejection. However, differences were reported. On the one hand, there was a significant advantage in leukemia-free survival associated with the use of CAMPATH-1H in unrelated donor transplants (Protocols 06, 07). On the other, there was an increased incidence of chronic GvHD and possibly poorer transplant-related mortality in PBSC transplants where CAMPATH-1H was used to treat the stem-cell infusion (Protocol 03). All of these comparisons are with retrospective historical groups and there have been no prospective randomized trials, it is therefore impossible to tell for certain whether the differences are related to the change in the Ab, or some other factors. One factor is that the humanized antibody could have a longer half-life in vivo and this might have an impact on the pattern of lymphocyte regeneration in the weeks following a transplant. Some preliminary studies in unrelated donor transplants suggest that this might be the case [8].

It is undisputed that T-cell depletion is the most effective way to prevent GvHD, but it is difficult to balance this benefit against the possible loss of graft versus tumor activity and delay in immune reconstitution. There is no doubt that the numbers of T cells in the blood, particularly CD4+ cells, recover more slowly after a T-cell depleted transplant. However, it is less clear whether there is a corresponding functional impairment in immunity. Many lines of evidence are suggesting that the initial expansion derives from donor memory cells, which may lead to a relatively restricted oligoclonal repertoire. Emergence of new naïve T cells from the thymus is very slow, but there is no reason to suppose it will be diminished by T-cell depletion of the donor graft — on the contrary, it has been suggested that the relative lack of peripheral lymphocytes may facilitate that process.

An unexpected finding was the significant benefit of post-transplant CYA in virtually every protocol. It was not remarkable that this might further reduce the incidence of GvHD and rejection and thus reduce transplant-related mortality, but the effect appeared to persist even when these factors were allowed for. An important benefit of protocols containing CYA appeared to be in the reduction of deaths from infections during the period from approx. 6 months to 18 months post-transplant (during a time when most patients would already have discontinued the drug). There was much discussion at the meeting about the possible explanations. For example, CYA might prevent sub-clinical GvHD, which would otherwise compromise the fragile immune system. Alternatively, perhaps the patients who received the immunosuppressive CYA were monitored more effectively, or were given better prophylactic antibiotic regimens. Maybe cyclosporin has a counter-intuitive favorable influence on immune reconstitution after T-cell depleted transplants. Unfortunately, we do not have the data to address these questions.

At the end of all the analysis, Protocols 03 and 07 were commended for further study, with particular emphasis on elucidating the role of post-transplant CYA in this context. The group will continue to follow up the existing cohorts of patients for long-term effects and outcomes. However, it seems that with the likely wider availability of CAMPATH-1H, it is time for prospective randomized trials to be carried out to establish the real utility of this treatment in stem-cell transplantation, and to compare it directly with more conventional approaches.

Acknowledgements
We thank everyone who contributed to this meeting, including not only the speakers and discussants, but also the many members of transplant teams who contributed data for analysis as well as the organizations that have provided funding over the years for supply of CAMPATH antibodies: UK Medical Research Council, The Wellcome Foundation Ltd, Leukosite Inc, Millennium Pharmaceuticals Inc., the Kay Kendall Foundation and the EP Abraham’s Trust.

Blood concentrations of alemtuzumab and antilglobulin responses in patients with chronic lymphocytic leukemia following intravenous or subcutaneous routes of administration

Geoff Hale, Peppy Rebelo, Lee R. Brettman, Chris Fegan, Ben Kennedy, Eva Kiniby, Mike Leach, Jeannette Lundin, Håkan Mellstedt, Paul Moreton, Andy C. Rawstron, Herman Waldmann, Anders Österborg, and Peter Hillmen

Alemtuzumab is a humanized anti-CD52 antibody licensed for refractory B-cell chronic lymphocytic leukemia (B-CLL), when given intravenously at 30 mg thrice weekly. However, the intravenous route is associated with infusion-related reactions and is inconvenient. We measured blood concentrations in 30 relapsed patients treated with intravenous alemtuzumab and in 20 patients from a previously untreated group who received similar doses subcutaneously. Highest trough samples in the intravenous group were less than 0.5 μg/mL to 18.3 μg/mL (mean 5.4 μg/mL). The cumulative dose required to reach 1.0 μg/mL was 13 mg to 316 mg (mean 90 mg). Higher blood concentrations correlated with the achievement of better clinical responses and minimal residual disease. The highest measured concentrations in the subcutaneous group were similar (0.6 μg/mL to 24.8 μg/mL, mean 5.4 μg/mL). However, the cumulative dose to reach 1.0 μg/mL was higher: 146 mg to 1106 mg (mean 551 mg). No antilglobulin responses were detected in 30 patients given intravenous alemtuzumab whereas 2 of 32 patients given subcutaneous alemtuzumab made substantial anti-idiotypic responses. Thus, subcutaneous alemtuzumab achieved concentrations similar to those for intravenous alemtuzumab, although with slightly higher cumulative doses. Subcutaneous alemtuzumab is more convenient and better tolerated but may be associated with some patients forming anti-alemtuzumab antibodies, particularly those patients who were previously untreated. (Blood. 2004;104:948-955)

© 2004 by The American Society of Hematology

Introduction

Alemtuzumab (CAMPATH-1H, Campath; ILEX Pharmaceuticals, San Antonio, TX) is a humanized immunglobulin G1 (IgG1) antibody that recognizes the CD52 antigen, a lipid-anchored glycoprotein, on lymphocytes.1,2 Alemtuzumab is exceptionally lympholytic and has been tested as an immunosuppressive agent in transplantation and autoimmune diseases. It is active against a range of lymphoid malignancies and in 2001 was approved for the treatment of B-cell chronic lymphocytic leukemia (B-CLL) in patients who have been treated with alkylating agents and who failed fludarabine therapy. This was based largely on a trial in 93 patients, most of whom had advanced disease with an extremely poor prognosis.4 After a short dose escalation, alemtuzumab was given intravenously at 30 mg thrice weekly for 4 to 12 weeks. This gave an overall response rate (complete remission [CR] + partial remission [PR]) of 33%. Other trials in chemoresistant CLL reported comparable response rates of 42% and 29% respectively.5,6

The dose regimen was developed empirically without the benefit of detailed pharmacodynamic or pharmacokinetic studies. Alemtuzumab often causes substantial first-dose reactions, and although the reactions can now be minimized by appropriate premedication, they are the reason why an initially escalating dose was followed by frequent small doses. This regimen is not the most convenient for patients or physicians. Therefore, the subcutaneous route has been studied in an attempt to reduce side effects and make the treatment more manageable.7,8 The different routes of administration can be compared by analysis of the biodistribution of antibody, on the principle that treatments that give comparable blood concentrations should produce similar clinical effects. Some information is available about the pharmacokinetics of intravenous alemtuzumab in patients undergoing stem cell transplantation who have no substantial leukemic burden.9,10 The terminal half-life was estimated to be approximately 15 to 20 days. However, in patients with advanced CLL, tumor cells could absorb antibody from the circulation.

The humanization of alemtuzumab reduced the risk of antilglobulin responses.11 However, the antigen binding sites are still potentially immunogenic. The ability to provoke a response depends on the target antigen, the immune status of the patient, the use of immunosuppressive drugs, and other factors, perhaps including the route of administration. There is a suggestion that subcutaneous administration might be more immunogenic than...
intravenous administration in patients with rheumatoid arthritis, though it is well known that such patients are particularly able to make anti-lymphocytes.

Here we measured blood concentrations of alemtuzumab and anti-lymphocyte antibodies against it during 2 different clinical trials. In the first, alemtuzumab was administered intravenously to patients who had previously failed alkylating agents and fludarabine as in the licensed indication. In the second, alemtuzumab was administered subcutaneously to patients who required therapy but had received no prior treatment. We compared the blood concentrations and anti-lymphocyte antibodies and investigated the possible relationship between alemtuzumab concentrations and clinical responses.

Study design: A second study

An open-label phase 2 trial was conducted at 4 clinics in the United Kingdom and in Stockholm, Sweden. The primary objective was to assess the efficacy of alemtuzumab administered subcutaneously. Patients were eligible if they had a diagnosis of R-CLL, were 18 years of age or older, had a WHO performance status of 1 or less, life expectancy at least 12 weeks, required treatment and had not been treated previously. Other details were similar to the first study except the treatment regimen. Alemtuzumab was administered from the Therapeutic Antibody Centre, Oxford, United Kingdom (patients 1-29) or from MedPartners (patients 30-41). The 2 preparations were similar although the formulations were slightly different and the antibody from the Therapeutic Antibody Centre was stored frozen. On days 1, 3, 5, 7, and 9, alemtuzumab was administered subcutaneously in the thigh. If well tolerated, 10 mg was given on day 3 and 30 mg (in 2 injection sites) on day 3. In the event of thrombosis or edema, the same dose was repeated until well tolerated. After dose escalation, most patients self-administered the antibody. The 30-mg dose was given thrice weekly for up to 18 weeks. If treatment was interrupted for more than 7 days the dose was reinitiated at 3 mg or 10 mg. Therapy was stopped if patients achieved a complete remission (CR) or fulminated NCI criteria for progressive disease (PD).

Measurement of alemtuzumab in patient serum

Serum samples were collected before doses and at various times afterward and stored at -70°C until analysis by immunoassay. Test samples were incubated at 50°C for 30 minutes to inactivate complement, then incubated with HUT-78 cells at room temperature for 30 minutes. The cells were washed and resuspended in fluoroscein isothiocyanate (FITC)-labeled polyclonal anti-human IgG Fe domain (F-9512; Sigma, Poole, United Kingdom), incubated for 30 minutes, washed and fixed with formaldehyde prior to flow cytometry. Alemtuzumab concentrations were calculated from the median fluorescence intensity on a standard curve. The lower limit of quantitation was 0.5 μg/ml (allowing for 2-fold sample dilution), overall precision was µ±10%, and overall accuracy was 100%. There was no interference by normal or patient control sera and no reactivity with F(ab')2 fragments of alemtuzumab.

Measurement of anti-lymphocyte antibodies

Antibodies to alemtuzumab were measured in serum samples by sandwich enzyme-linked immunosorbent assay (ELISA) as previously described with some modifications. Microtiter plates were coated with alemtuzumab (M&K Pharmaceuticals) and blocked with dextran (phosphate-buffered saline [PBS] containing 2% bovine serum albumin [BSA]). Standards, quality-control samples, and test samples were added, incubated for 1 hour at room temperature, and rinsed 4 times with wash buffer (PBS containing 0.05% Tween 20). Biotin-labeled alemtuzumab was added to each well, incubated for 1 hour, and rinsed as before. The assay was developed withextravidin-peroxidase (E-2886; Sigma) and ortho-phenylenediamine. Color development was measured at 450 nm for 20 minutes by Genesis II software (Thermo Life Sciences, Basingstoke, United Kingdom). The standard was Y1D1, a monoclonal anti-idiotypic specific for alemtuzumab. One U/ml of anti-lymphocyte activity is the signal equivalent to 1 mg of Y1D1 reference standard. The limit of detection (LOD) and lower limit of quantitation (LLQ) were 488 U/ml (allowing for 2-fold sample dilution), overall precision was ±10%, and overall accuracy was 100%. There were no false positives or interferers by normal or patient control sera. Mean values were obtained with serum containing rheumatoid factor or spiked with native CD20 antigen. The assay was reproducible despite variations in reagent concentrations, incubation and washing conditions, blood clotting conditions, and sample storage conditions within the specified range. Up to 3-fold enhancement of anti-lymphocyte activity was seen in samples that had been heat-treated or stored for over a month at 4°C. This might be due to aggregation, since in the absence of the complex anti-idiotypic reagent gave enhanced activity. Alemtuzumab and anti-lymphocytes interact with each other to reduce the signal in either assay if both were present in the same sample. Thus, the

**Patients, materials, and methods**

**Patients**

Clinical studies were carried out with the approval of local and, in the United Kingdom, regional ethical committees. All patients gave written informed consent prior to enrolment.

**Study design: An open-label study**

An open-label phase 2 trial was conducted at 5 centers in the United Kingdom (Aberdeen, Birmingham, Bournemouth, Glasgow, Leeds). Primary objectives included the assessment of safety and efficacy as well as measurement of pharmacokinetics. Patients were eligible if they were at least 18 years old, had confirmed B-CLL requiring treatment, had failed previous treatment with purine analogs, had a World Health Organization (WHO) performance status of 2 or less, and had creatinine and bilirubin concentrations less than twice the upper limit of normal (unless due to disease). Exclusion criteria were active infection, HIV positivity, pregnancy or lactation, history of lymphocytosis or lymphoma, less than 3 weeks since chemotherapy or less than 6 weeks since investigational therapy, central nervous system (CNS) involvement or persisting severe pancytopenia, or severe concurrent diseases, secondary malignancy, or mental disorder.

Patients were premedicated with cefazolin and chlorothalidone 30 minutes before the first infusion. Septins (sulfadiazine/trimethoprim 150 mg/160 mg twice a day, 3 times per week) and acyclovir (200 mg thrice daily) were given prior to therapy and continued until normal blood lymphocytes returned to the normal range. Allopurinol was given during the first 4 weeks of treatment. Alemtuzumab (M&K Partnership, Cambridge, MA) was diluted to 100 mL of 0.9% saline and administered intravenously over approximately 2 hours. A dose of 3 mg was given on day 1 and 5 if tolerated, a 0.5-mg dose was given on day 2 and a 160-mg dose on day 3. If severe reactions occurred, the same dose was repeated daily until it was well tolerated and then the dose was escalated. Subsequent 0.5-mg doses were given thrice weekly for up to 12 weeks, though treatment was occasionally extended if clinically indicated.

Before therapy, a full history, physical examination, and laboratory evaluation were performed, including measurement of lymphocyte, liver, and spleen size, computed tomographic (CT) scan, Rai staging, blood analysis, bone marrow aspirate, and trephine and immunophenotyping by flow cytometry. Disease parameters were reassessed and blood and bone marrow were remeasured by flow cytometry for residual CLL cells every 4 weeks. Therapy was stopped if there was no evidence of CLL or if sequential bone marrow samples showed no fall in the level of CLL. Blood samples were collected weekly to measure alemtuzumab concentrations and anti-lymphocytes. After the last dose, samples were collected daily for 4 days and then weekly for 3 weeks. This was not always possible for logistical or clinical reasons.

During follow-up, patients were assessed monthly for 6 months. Responders were assessed every 6 months thereafter until disease progression. Disease response and toxicity were graded according to the criteria of the National Cancer Institute (NCI).
antiglobulin assay measures only the concentration of free anti-
alemtuzumab antibody, that is, the excess over the levels of alemtuzumab itself. Considering that alemtuzumab concentration was never more than 26 
μg/mL, then it might interfere with measurement of antiglobulin responses 
less than about 26 000 U/ml. However, the antiglobulin levels in a patient 
who made a clear-cut response exceeded 10^6 U/ml. We report data for all 
samples measured, both during and, where available, after treatment. For 
complete assessment of antiglobulin responses, it is always preferable to 
analyze samples over an appropriate period of time after the end of 
treatment.

Measurement of minimal residual disease by flow cytometry

Residual CLL cells were quantified by sensitive 4-color flow cytometry; a 
method more sensitive than consensus primer polymerase chain reaction 
(PCR) and more practicable than sequence-specific quantitative PCR. At 
least 5 × 10^6 bone marrow leukocytes were incubated with a mixture of 
fluorescent-labeled antibodies, washed twice, and analyzed using a FACSort 
(Becton Dickinson, Oxford, United Kingdom) with CELLQuest v3.1 
software. The antibodies used were CD45/CD48 (Chemicon, Chanders 
Ford, United Kingdom)/CD19/CD3, kappa/lambda/CD19/CD3, CD20 
(Beckman Coulter, High Wycombe, United Kingdom)/CD79a (Beckman 
Coulter)/CD19/CD3, and CD20 (Beckman Coulter)/CD3/CD79b (BD bio-
sciences, Oxford, United Kingdom)/CD19/CD3 conjugated to FITC/ 
phycocerythrin (PE)/PE-Cy5/allophycocyanin (APC), respectively. Re-
agents without named manufacturer were produced in-house. Between 
30 000 and 500 000 cells were analyzed. B cells were identified by setting 
a region on CD19 versus side scatter (SSC), followed by a forward scatter 
region, and then ensuring that no CD3^+ events fell within the combined 
gate. CLL cells were discriminated from mature B cells by their stronger 
expression of CD5 and weaker expression of CD20 and CD79b, and from T 
progenitors by their weaker expression of CD38. This assay can detect 1 
CLL cell in approximately 10^6 to 10^7 leukocytes.

Results

Collection and analysis of samples

Serum samples were obtained from all 30 patients in the intrave-
nous study and 20 of the 41 patients in the subsequent study, 
equally almost from a single clinic (Karolinska Hospital). Samples were tested in duplicate and the mean concentration was 
calculated. If the mean was less than 0.5 μg/mL (LLOQ), a level of 
less than 0.5 μg/mL was recorded. If either result was more than 20 
μg/mL or a measurement was technically faulty, then the test was 
repeated, using a higher dilution if appropriate, and the repeat 
results were used.

Optimal time for collection of peak samples following 
intravenous administration

A preliminary experiment was carried out to identify the time 
following intravenous administration when the peak antibody 
concentration might be found. Samples were collected from 3 
patients at 15 minutes, 30 minutes, and 60 minutes after the end of 
one dose each week for 4 to 7 weeks. The peak sample occurred at 
15 minutes, significantly more often (21 times) than at 30 minutes 
(6 times) or 60 minutes (2 times) (P < 0.1); paired Wilcoxon signed 
ranking test. Therefore, for subsequent patients a single sample was 
collected at 15 minutes to determine the peak concentration.

Serum concentrations of alemtuzumab during 
intravenous treatment

e total of 1561 patient samples were tested. Terminal samples 
(after the last dose) were not available for some patients, and in a 
few cases only a small number of terminal samples were available.

Figure 1. Example of alemtuzumab concentrations in patient treated with 
intravenous antibody. After an initial dose escalation, 30 mg of alemtuzumab was 
administered 3 times a week for 8 weeks (O). Serum samples were taken before (X) 
and after (Y) the dose once a week. This patient made a good clinical response to 
the therapy.

All samples were tested in duplicate; the overall mean coefficient of 
variation (CV) was 10%. Many of the early samples and many 
trough samples were below the limit of quantitation (< 0.5 
μg/mL). Five samples gave anomalous results, substantially diverging 
from other results for the same patients. These could be 
explained by accidental mix-ups at the clinical centers and were 
omitted from analysis. An example of the doses and blood 
concentrations throughout the course of treatment for one patient is 
shown in Figure 1.

In contrast to patients who had received transplants, there 
were wide variations in alemtuzumab concentrations between 
different patients with CLL. The highest peak ranged from 2.8 
μg/mL to 26.4 μg/mL (mean 10.7 μg/mL). The highest trough ranged 
from less than 0.5 μg/mL to 18.3 μg/mL (mean 5.4 μg/mL). The 
cumulative dose before the trough concentration reached 1.0 
μg/mL ranged from 13 mg to 316 mg (mean 90 mg; Table 1). In 9 
of 21 evaluable patients, the highest trough concentration was 
measured just before the last dose, indicating that a steady state had 
not been reached. Total cumulative doses varied between patients, 
but did not correlate with the final antibody concentrations 
(Table 1).

Comparison of the starting lymphocyte count with the peak 
concentration following the first 30-mg infusion showed a modest 
negative correlation, that is, the higher the initial lymphocyte 
count, the lower tended to be the peak concentration of alemtu-
zumab (Figure 2).

In Figure 3 the highest trough concentration for each patient is 
pictured against the response measured by NCI criteria for 27 
patients where the clinical response was reported within 4 months 
of the end of treatment. There was a significant increase in trough 

Figure 2. Relationship between initial CLL count and alemtuzumab blood 
concentration: Intravenous study. The numbers of CLL cells in the blood directly 
before intravenous therapy are plotted against the peak concentration of alemtu-
zumab measured directly after the first 30-mg dose (O). In 8 patients the concentra-
tion was below the limit of quantitation, and these have all been plotted at an arbitrary 
level of 0.25 μg/mL (X). Pearson correlation coefficient for log (initial CLL count) 
versus log (alemtuzumab concentration) was -0.44, P < .01.

ND indicates not determined.

Concentrations with increasing clinical response (P <.006, Kruskal-Wallis test). There was an even more striking correlation between trough concentrations and the attainment of minimal residual disease (MRD) negativity in 7 patients (filled symbols) compared with the 17 patients who still had residual CLL cells in the bone marrow at the end of treatment as measured by 4-color flow cytometry (P < .0001, Kruskal-Wallis test).

In Figure 4 the mean trough concentration is plotted throughout the treatment for 2 groups of patients: (1) 8 responders who reached MRD less than 0.4%, and (2) 22 others. The mean trough concentration was significantly higher in the responders throughout the whole course of treatment from week 2 to week 11 (P < .02 at each time point, Kruskal-Wallis test).

Clearance of alemtuzumab following the last dose showed a similar correlation with residual disease. In patients with undetectable CLL cells, there was a single clearance phase characterized by

![Figure 3](image-url)  
**Figure 3.** Relationship between maximum trough concentrations of alemtuzumab and clinical response: Intravenous study. The highest trough concentration of alemtuzumab (which generally occurred following the penultimate or last dose) is plotted against the clinical response at the end of intravenous treatment as determined by WBC count. PD, progressive disease; SD, stable disease; PR, partial remission; CR, complete remission. A better clinical outcome was significantly associated with higher alemtuzumab concentrations (P < .006, Kruskal-Wallis test). There was an even stronger correlation between high trough concentrations (> 5 μg/mL) and good responses measured by less than 0.1% CLL cells in the bone marrow (<0.001). Three patients who died before the end of the planned treatment course are not included in this figure. Of those patients, 2 had low alemtuzumab concentrations (< 1.1 μg/mL) and progressive disease at the time of death. The third had a high anody concentration (183 μg/mL) and low levels of residual disease (0.2%). Each symbol represents a single patient; • indicates a patient with no detectable MRD; ○, a patient with detectable MRD.

![Figure 4](image-url)  
**Figure 4.** Mean trough concentrations of alemtuzumab during Intravenous therapy. The mean trough concentrations during treatment (measured 48 hours after a dose, once a week) are plotted, with standard deviations, for 8 patients who ultimately reached less than 0.4% CLL cells in the bone marrow (□) and compared with 22 patients who still had residual CLL cells at the end of treatment (●).
a relatively long half-life. In patients who still had a substantial tumor burden, most of the antibody was rapidly cleared from the blood. Patients with low levels of residual disease showed an intermediate pattern. An example of each is shown in Figure 5.

Sixteen patients contributed informative terminal samples after the last 30-mg dose. From these data the following mean pharmacokinetic parameters were calculated (ILEX Oncology, unpublished data, September 2001). The apparent steady-state volume of distribution (VSS) was 0.185 L/kg and the apparent volume of distribution during the terminal phase (VZ) was 0.252 L/kg. These are larger than for other monoclonal antibodies in humans but are consistent with the notion that alemtuzumab distributes through the plasma compartment and a substantial extracellular lymphocyte compartment. The mean terminal phase half-life (t1/2) was 6.1 days, which is consistent with previous measurements for alemtuzumab and other chimeric antibodies in humans.

Serum concentrations of alemtuzumab during subcutaneous treatment

This study was started in 1998 using alemtuzumab manufactured at the Therapeutic Antibody Centre. During June 2000, commercially produced material became available and was subsequently used. No obvious differences were observed in the clinical responses. A total of 542 patient samples were received and tested. Two were mislabeled and were not included here. The overall mean CV was 8%. Assessment of pharmacokinetics in 7 patients was inadequate due to the limited number or inappropriate timing of samples.

Patient no. 8036 (who started with alemtuzumab from the Therapeutic Antibody Centre and was switched to commercial alemtuzumab) never achieved concentrations above the LLOQ. This patient had rapidly made a strong anti-IgG1 response to the alemtuzumab, which probably neutralized all of the administered antibody (Antibodies following subcutaneous treatment). The patient never showed any clearance of lymphocytes but showed continued reactions at the injection site. Because of this, the patient was switched to intravenous administration after 6 weeks.

There were some changes from the dose regimen due to clinical reactions. There were 2 patients who received lower doses throughout (10 mg and 20 mg) and 2 (including patient no. 8036, above) who were switched to intravenous dosing. The dose escalation rate was often slower than originally planned, typically taking 1 to 2 weeks to reach 30 mg. After this, the planned dose was usually maintained but only 1 of the 21 patients analyzed received the maximum planned dose of 1573 mg. The mean total dose was 1249 mg and the lowest dose was 712 mg.

The highest concentrations ranged from 0.6 μg/mL to 24.8 μg/mL and the mean (5.4 μg/mL) was the same as in the intravenous study (Table 2). However, the cumulative dose before the concentration reached 1.0 μg/mL ranged from 146 mg to 1106 mg (mean 551 mg), which was substantially more than in the intravenous study. An example of the time course in one patient illustrating this delay is shown in Figure 6.

Inadequate samples were available for analysis of terminal phase pharmacokinetics. No correlation could be demonstrated between alemtuzumab concentrations and clinical responses because nearly all of the patients (18/20) were responders (CR or PR), and levels of MRD were not reported.

Antibodies following intravenous treatment

A total of 519 serum samples from 30 patients treated with intravenous alemtuzumab were tested for antibodies. These included all samples taken more than 24 hours after the last dose and representative pre-dose samples during treatment. All of them were below the limit of detection (488 U/mL). In 12 patients there were no or very few samples available after the end of treatment, and in the other 18 patients samples were only available between 2 and 6 weeks after the last dose. Therefore, we cannot completely exclude the possibility of delayed responses.

Antibodies following subcutaneous treatment

A total of 281 samples were tested from 21 patients (one patient had adequate late samples for antibody measurement, but none suitable for pharmacokinetic analysis). These included all samples taken after the last dose and representative samples taken during treatment. There were 4 patients who had no or few samples after the end of treatment, but 17 who had adequate posttreatment samples. All samples except those described below were below the LOD.

One patient (no. 8027) had a single sample taken at day 238 (114 days after the last dose) that gave a weak signal just above the LOD. All previous and subsequent samples were less than the LOD. The patient made a good clinical response to therapy, achieving a CR, and no relevant adverse effects were noted. It is possible that the patient made a very weak, transient response to the alemtuzumab, but we doubt that it could have been clinically significant.

One patient (no. 8036) showed a very high titer response, reaching a peak of approximately 3.7 × 10^6 U/mL 24 days after the last dose of alemtuzumab (Figure 7). This anti-IgG1 bound strongly to CAMPATH-1G, the parental rat antibody from which alemtuzumab was humanized, but did not bind other human IgG1.
monoclonal antibodies. Therefore, essentially all of the response was directed against the alemtuzumab idotype. No free alemtuzumab could be detected throughout treatment and there was no significant depletion of tumor cells during therapy. This patient developed a pronounced injection site reaction including edema, erythema, and slight local pain but otherwise no marked general symptoms. As a result, the patient did not achieve the 30-mg dose level during 6 weeks of subcutaneous dosing and alemtuzumab was subsequently administered intravenously. Due to nonresponsiveness, the patient was subsequently treated with fludarabine and went into a long-lasting partial remission. He was restaged 18 months after the end of alemtuzumab treatment (continuing in PR) and still had a high-tier antiglobulin (approx. 1.8 × 10^5 U/mL). There was a very low anti-alemtuzumab signal in one of two samples taken before therapy. This patient might have had a natural anti-IgG (rheumatoid factor) prior to therapy and perhaps was predisposed to make an antiglobulin response.

A search was made for samples from other patients who had received subcutaneous alemtuzumab. Samples were collected between 4 to 50 months after the end of treatment from an additional 9 patients of the original subcutaneous study plus 2 others who received subcutaneous alemtuzumab as part of a compassionate program. A substantial response was detected in patient no. 8020 of approximately 4800 U/mL at 32 months after the end of treatment. Like the response in patient no. 8036, this response cross-reacted on the parental rat antibody but not on other human antibodies, showing it to be essentially anti-idotype. The patient had not responded to the therapy, but was reported to have prolonged skin reactions to the infusions. A very weak response was detected in one other patient of 541 U/mL, barely above the LOD. Unlike the other 2 patients, this serum cross-reacted with other human IgG but not with CAMPATH-1G. We consider that it is a nonspecific rheumatoid-like factor and probably had no clinical significance with respect to alemtuzumab.

In total, therefore, of 32 patients treated with subcutaneous alemtuzumab (30 who were previously untreated with any anti-CLL agent), 2 produced a significant antiglobulin response, which persisted at potentially neutralizing concentrations for more than a year. Both of these patients had received alemtuzumab manufactured at the Therapeutic Antibody Centre, as did most of the patients in this study, although patient no. 8036 had been switched to the commercial product after 3 weeks.

**Discussion**

Alemtuzumab is extensively used for patients with B-CLL who have failed treatment with alkylating agents and purine analogues and investigators are exploring its use in other disease settings. To enable safe and effective use it is essential to understand alemtuzumab's pharmacokinetics and biodistribution as well as the potential for anti-idotype responses, which all may differ according to disease, patient status, and route of administration. We have started to address these issues by comparing blood concentrations of

*Some doses for patients no. 8033 and no. 8036 were given intravenously due to infusion site reactions during the subcutaneous administration.
alumtuzumab and antilglobulin responses in 2 different studies for treatment of CLL, namely intravenous treatment of chemotherapy-resistant disease and first-line subcutaneous treatment. The studies were initiated independently and had different objectives; nevertheless the pharmacologic results are instructive.

Alumtuzumab may cause substantial "first dose" reactions as a result of cytokine release when it is given intravenously. 3, 14, 19 Therefore, the standard treatment regimen involves dose escalation and frequent, relatively small doses, though it has not been formally established whether the reactions are strictly dose related. A treatment course for chemotherapy-resistant CLL consists of approximately 1 gram of the antibody. However, a cumulative dose of 40 mg to 100 mg is highly immunosuppressive and clinically effective in patients without bulky tumors, for example those treated for prevention of transplant rejection, 15, 20 multiple sclerosis, 21 and other autoimmune diseases. 22-24 as well as to eradicate detectable minimal residual disease in CLL. 23 The biodistribution of alumtuzumab is likely to depend on the bulk of tumor cells, possibly more so than other monoclonals because CD52 is such a highly expressed antigen. There are approximately 5 x 10^9 binding sites for alumtuzumab on a normal lymphocyte. 26, 27 There are about 10^12 lymphocytes in a healthy adult. 28 At least 125 mg of alumtuzumab is therefore required to saturate all of the CD52 sites. CLL cells express a similar amount of CD52 antigen to normal lymphocytes 29 but their total number may be 10 times greater. Therefore, more than 1 g of alumtuzumab would be required to saturate all the receptors in some patients, especially considering that the antibody has a relatively low affinity and that there will be a significant clearance during a 12-week course of treatment. Hence, it is not surprising that the biodistribution and clearance of antibody during the treatment of patients with CLL is dominated by the tumor burden and cannot be fitted to a simple pharmacokinetic model.

There was a strong correlation between the concentrations of antibody throughout intravenous treatment and the ultimate clinical response, or the achievement of minimal residual disease (MRD) negativity in the bone marrow by flow cytometry. It has recently been reported that survival correlates better with MRD than with the standard NCI criteria for clinical responses. 30 Without a good measure for the initial total tumor burden it is difficult to distinguish cause and effect. One possibility is that patients with high tumor burden were treated with inadequate amounts of antibody to achieve sufficient receptor site saturation and see a clinical effect. In any event, it appears that measurements of alumtuzumab concentrations after 2 to 4 weeks of treatment might provide an indicator of the ultimate outcome and guide the physician whether to continue, stop, or adjust the dose of antibody. Most of the antibody was cleared within a few days of the final dose in the nonresponders. However, the half-life at the end of treatment in the responders was comparable with those previously reported for patients without bulky tumors.

Accumulation of alumtuzumab in the blood was significantly slower in the subcutaneous study and it took on average about 6 weeks longer to reach 1.0 μg/mL (an arbitrary threshold known to be potentially lympholytic). This could be a slight overestimate because samples were not always collected every week. Nevertheless, the eventual maximum trough concentrations were very similar in both studies. We cannot tell whether the slower accumulation of antibody in the blood was due to less favorable biodistribution, more effective binding to tumor cells, or the slower dose escalation used in the subcutaneous study compared with that used with intravenously treated patients. It should be possible to resolve this by studies of alumtuzumab given subcutaneously to patients not suffering from malignancies (ie, without excess CD52 cells).

Because clinical responses were much more frequent (19% CR and 68% PR), 8 we could not detect a significant correlation between blood concentrations and clinical responses in the subcutaneous study. With only 2 nonresponders in the group of patients we analyzed, the sample was too small to discern any relationship.

Clear-cut results were obtained from the measurements of antilglobulin responses (antihuman antibody [HAHA]). There were no detectable responses at all in the intravenous study (heavily pretreated patients) and only one patient in the subcutaneous study (previously untreated patients) made a strong response, reaching a peak of approximately 3.7 x 10^4 U/mL 3 weeks after the final dose. This was equivalent to 3.7 mg/mL of the monoclonal anti-idiotype standard and represented a substantial proportion of the total lg in the patient. Similar titers were previously reported during treatment of rheumatoid arthritis patients with subcutaneous alumtuzumab 31 when all of the patients (10/10) made a positive response. After screening 11 other patients we found one with a significant antilglobulin titer of 4800 U/mL. Considering that this sample was taken 32 months after the last treatment with alumtuzumab, it seems likely that this patient also had made a very strong response.

Previous studies on antilglobulin responses to alumtuzumab have given widely different results. In 12 patients treated for kidney transplant rejection no antilglobulins were detected, in contrast to 15 of 17 patients treated with the parental rat antibody CAMPATH-1G. 31 In 167 patients treated for chemotherapy-resistant lymphoid malignancies there were only 3 weak or borderline responses. However, out of 115 patients treated for rheumatoid arthritis, there were 59 positive responses (ILEX Pharmaceuticals, unpublished data on file, July 2003), some of high titer similar to that reported here for patient no. 8036. 19 Many factors could affect the immunogenicity of alumtuzumab, including the dose and length of treatment, the underlying disease, prior exposure to chemotherapy, concomitant immunosuppressive drugs, and possibly the route of administration or the formulation of the drug. Subcutaneous administration might allow more effective antigens presentation, for example, by Langhans cells and with less "excess" antibody circulating to provide tolerogenic signals, the balance might be tipped toward an immune response. From our present study we cannot say whether subcutaneous administration in CLL is more immunogenic than intravenous administration since there were other differences between the 2 groups, most notably the subcutaneous group had received no prior chemotherapy. Even if the 2 groups had been comparable, the difference in responses (0/30 vs 2/32) did not reach statistical significance. This issue needs to be investigated in larger numbers of patients. Both patients who made an antilglobulin response had been treated with alumtuzumab manufactured at the Therapeutic Antibody Centre. We are aware that the manufacture, formulation, or storage of biologics might affect their immunogenicity, but so far we have no evidence to suggest that there is a major difference between the academic or commercial source since antilglobulin responses have been reported in other patients treated with alumtuzumab from either source. The 2 patients (no. 8020 and no. 8036) who produced anti-alumtuzumab antibody on subcutaneous treatment, unlike the other patients, did not show significant reductions in lymphocyte counts but had marked local skin reactions which did not diminish with continued therapy. An antilglobulin response should be considered when there is no drop in the blood lymphocyte count and/or there are persistent injection site reactions.
Alentuzumab provides a useful therapeutic option for patients with CLL. It has excellent activity as first-line treatment and can give good responses in patients who are unresponsive to conventional chemotherapy. The optimal dose route and regimen are not yet known. However, the subcutaneous route can deliver concentrations of antibody comparable to the original intravenous route. The dominant factor influencing biodistribution and pharmacokinetics appears to be the tumor burden. With intravenous dosing, serum concentrations of alentuzumab can provide an early prediction of the ultimate response and might be useful to guide dose adjustment to improve responses or reduce side effects. Strong anti-idiotypic responses may occur in a small minority of patients. Although not associated with serious adverse effects, such responses neutralize the therapeutic benefit and therefore patients with a known anti-idiotypic response should not be further treated with this monoclonal antibody.

Acknowledgments

We are very grateful to the staff of the Therapeutic Antibody Centre, Oxford, United Kingdom, for the manufacture and supply of some of the alentuzumab used in this study. We thank Peter Bone, Ian Clements, and the team at ILEX Oncology for constructive comments and for sharing unpublished data.

THE CAPE TOWN EXPERIENCE WITH HAEMATOPOIETIC STEM CELL TRANSPLANTATION IN CHILDREN II: A PRIVATE SECTOR PROGRAMME

Peter Jacobs, Lucille Wood, Jo Lund, June Juritz. The Bone Marrow Transplant Unit – Department of Haematology, Constantiaberg Medi-Clinic; The Division of Clinical Haematology – Department of Internal Medicine, Stellenbosch University-Tygerberg Academic Hospital, Cape Town; Department of Mathematical Statistics, University of Cape Town.

Introduction: Following 5 years of development in a rabbit model traditional bone marrow transplantation in adults was started in 1978 and extended to children in 1986. Our initiative at Groote Schuur Hospital has recently been updated reporting outcome in 28 individuals under 18 years of age. A separate program, outside the state hospital, was activated in 1995. Here the prototype ex vivo T-cell depletion, using Campath monoclonal antibodies, was retained with indications extended to treating immunodeficiency, liposomal storage disease and the haemoglobinopathies. Increasingly donor source includes matched unrelated volunteers. Concurrently oral busulphan has been replaced by the intravenous formulation in preparative regimens. Materials and Methods: With appropriate informed consent consecutive individuals, having a median age of 11 (range 1 – 18), were entered on approved protocols. Outcome was reported and audited by the International Bone Marrow Transplant Registry. Mobilised peripheral blood mononuclear cells were harvested using standardised apheresis technology. Autologous (group I: n=20), allogeneic siblings (group II: n=38) or matched unrelated allografts (group III: n=10) were characterised for mononuclear and CD34+ populations in addition by clonogenic assay prior to infusion with recipients conditioned using a uniform regimen of busulphan and cyclophosphamide. Radiotherapy was reserved for those with high bulk lymphoid tumours. Cyclosporin A was given only to group III with titrated dose reduction over 1 year. Stabilised human serum and viral prophylaxis were discontinued after 3 months whereas that for pneumocystis with cotrimoxazole continued for 1 year. Outcome for age, disease category and transplantation technique was subject to Kaplan-Meier analysis in 68 procedures carried out in 64 patients. Results: Current survival for myeloid leukaemia (n=11) is 73%, the lymphoblastic variant (n=14) is 43%, chronic myeloproliferative syndrome (n=7) is 86%, lymphoma (n=5) is 80%, thalassaemia and haemoglobinopathies (n=6) is 100%, acquired bone marrow aplasia (n=6) is 60%, Fanconi anaemia (n=11) is 55% and miscellaneous group including solid tumours (n=6) is 83%. Additional individuals with immunodeficiency and liposomal storage disease are alive and well. Non-engraftment occurred in 1 of group III and he was successfully retransplanted. Late presenting acute graft-versus-host disease occurred in 3 and responded to topical steroids. Transplant related mortality (n=10) was 15%. Four patients (6%) had cytomegalovirus isolated and pre-emptive ganciclovir prevented progression to disease. Survival was shown to be influenced only by age and disease category. Conclusion: Children can clearly be managed both safely and cost-effectively as part of a well-structured adult programme. Conditioning with intravenous busulphan is now standard having replaced the oral equivalent because of greater recipient acceptability and more reliable pharmacokinetics. Post-transplant mucositis has been virtually abolished by the use of oral sulphate. Currently cyclosporin A is being evaluated in matched unrelated allografts to establish whether it significantly influences any aspect of transplant outcome.

Control of GVHD and graft rejection with the monoclonal antibody CAMPATH-1G

Geoff Hale and Herman Waldmann for the CAMPATH users group

T cell depletion of donor bone marrow is the most effective means of preventing GVHD. Unfortunately, it creates an increased risk of graft rejection and, in some cases, of leukaemia relapse. Within the collaborative group of CAMPATH users, we have studied the possible role of CAMPATH-1G (rat IgG2b) for both eliminating the donor T cells and helping to deplete residual T cells from the host. The original method of T cell depletion used CAMPATH-1M (IgM) and human complement to lyse the T cells. In 490 patients transplanted for leukaemia from matched siblings, the incidence of graft failure (or rejection) was 17%. Various studies to reduce graft failure (eg use of post-transplant CyA, total lymphoid irradiation) resulted in only small improvements. Interim results of an ongoing study using CAMPATH-1G to treat the recipient are encouraging. A low incidence of graft failure and GVHD was observed and the disease-free survival of the patients appears to be better than before. In other studies, CAMPATH-1G was used to opsonize the donor bone marrow before infusion. In this case excess antibody may contribute to immunosuppression of the host. So far 20 patients have been treated. Only one suffered severe GVHD but two suffered graft rejection, suggesting there is still some residual host immunity. Current studies focus on the use of CAMPATH-1G both in vivo and ex vivo to control both problems.
CAMPATH-1 Monoclonal Antibodies in Bone Marrow Transplantation

GEOFF HALE and HERMAN WALDMANN for CAMPATH USERS

ABSTRACT

CAMPATH-1 (CDw52) antibodies recognize a very small lipid-anchored glycoprotein that is expressed on the surface of human lymphocytes. They are remarkably lytic with human complement. In addition, CAMPATH-1G (rat IgG2a) and CAMPATH-1H (human IgG1) bind to human Fe receptors and are very effective for cell lysis in vivo. CAMPATH-1M (rat IgM) and CAMPATH-1G have been used to control GVHD and graft rejection in bone marrow transplantation by depletion of the T cells of the donor and recipient. Depletion of donor T cells alone gave excellent control of GVHD but up to 20% of the patients transplanted from HLA-matched siblings, and 51% of those transplanted from nonsibling donors, experienced graft failure caused by immunological rejection. Graft rejection could be partly overcome by additional immunosuppression either with CsA or total lymphoid irradiation (TLI). More effective was the use of CAMPATH-1G in vivo to deplete residual host lymphocytes. Preliminary results from current protocols of antibody depletion give two year actuarial leukemia-free survival as good as or better than similar studies with conventional GVHD prophylaxis, as well as a decreased morbidity from chronic GVHD, although engraftment was delayed by about 5 days. We propose that prophylactic T cell depletion with CAMPATH-1 antibodies is a simple and valid alternative to drug-based immunosuppression that may be particularly applicable to patients with acute leukemia or nonmalignant diseases transplanted from HLA-matched siblings as well as any patients transplanted from unrelated donors. Future developments of antibody-based immunosuppression may allow the extension of marrow transplantation for tolerance induction to organ transplants or in autoimmune diseases.

INTRODUCTION

Bone marrow transplantation can be used in the management of several different kinds of disease. It gives a remarkably powerful effect against some types of leukemia (notably CML) and would often be the treatment of choice for inborn or acquired defects of the hemopoietic system. In theory, it could be used to create tolerance to other organs and as a radical treatment for severe autoimmune diseases. The biggest problem is the two-way immune recognition of donor and recipient that leads to the major complications of graft-versus-host disease (GVHD) or graft rejection. With powerful immunosuppressive drugs, these can be controlled to some extent, yet GVHD still remains a significant cause of morbidity even when the donor and recipient are HLA-matched siblings. When the donor and recipient are less well matched, or unrelated, GVHD and graft rejection are major problems and this currently limits the use of marrow transplantation to only the most severe diseases. The key players in the generation of immune responses are T lymphocytes, and it has been shown that they are the prime mediators of...
GVHD and rejection. If T cell alloreactivity could be more effectively controlled, then the immunological complications could be overcome and marrow transplantation could be more widely applied.

Several years ago it was shown in animal models that removal of mature T cells from the donor bone marrow would prevent GVHD (1–4). However, ablation of recipient T cell function has not been so straightforward. Even after total body irradiation some recipient T cells remain and, in the absence of donor T cells, they can gain the upper hand and reject the marrow (5–7). The methods that were originally developed for depleting the donor T cells (e.g., agglutination with soybean lectin, E-rosette, density gradient centrifugation) were mostly not applicable to depletion of the same cells in vivo, so it was difficult to tackle this side of the problem with any specificity. The one type of agent that could be used both in vitro and in vivo was antilymphocyte globulin, and this was shown to be immunosuppressive and capable of preventing GVHD (8). The problem with antilymphocyte globulin is that it is a heterogeneous mixture of antibodies directed against different cell antigens, only a minority of which are T cell specific. It was therefore difficult to obtain samples that were reproducibly active and nontoxic.

When monoclonal antibodies became available, one of the first clinical applications was for purging marrow of donor T cells. However, most monoclonal antibodies were singly very inefficient at killing target cells because they did not activate human effector mechanisms (complement and/or Fc-receptor-dependent cell-mediated killing). Early efforts were therefore not very successful (9,10) and this led many investigators to search for different ways of using the antibodies for cell depletion. One method was to couple the antibody to a toxin (e.g., ricin) (11); others have used magnetic particles (12) or immunoadsorption (13). However, we continued to look for antibodies that could exploit natural human effector functions, with the prospect that these could eventually be used in vivo as well. Thus finding a lytic antibody for T cell depletion of bone marrow was not just an end in itself, but also a way to test reagents that might later find wider applications for immunosuppression.

THE CAMPATH-1 ANTIGEN

From a fusion of rat spleen cells with a rat myeloma cell line, we selected a set of antibodies that was unusually lytic for human lymphocytes using autologous complement (14–16). It turned out that all of them recognized the same antigen, which we now know to be a glycoprotein that is attached to the cell membrane by a lipid (glycosylphosphatidylinositol, GPI) anchor (17,18). Most of the antibodies were IgM or IgG2a, but just one was a rat IgG2b. This contrasted with antibodies against other cell surface antigens isolated from the same fusion, which were almost exclusively IgG2a or IgG2b. The CAMPATH-1 antibodies recognized virtually all human lymphocytes, both T cells and B cells as well as monocytes and macrophages, although the latter seemed to be less sensitive to complement-mediated lysis. Tests on panels of fresh leukemia and lymphoma cells and cell lines showed that they recognized most cases of lymphoid malignancy, but only a small minority of myeloid leukemias (17,19). In the fourth leukocyte workshop the CAMPATH-1 antibodies were assigned to the cluster CDw52 (20). Little or no reactivity with colony-forming cells could be detected either by complement-mediated lysis, or by cell sorting (14,15). This important result was confirmed in numerous laboratories (21–24), although one group has reported only approx. 40% recovery of colony-forming cells (25). Valentin and co-workers (26), using a different CDw52 antibody, which is known to have a broader reactivity than CAMPATH-1M, also found a significant depletion of CFU-GM. In these cases, we cannot be sure that the colony-forming cells did not require growth factors from the lymphocytes since the appropriate controls were not included. However, a recent comprehensive study of CAMPATH-1H found no evidence for reactivity with the cells that give rise to colony-forming cells during long-term culture (27).

CAMPATH-1 antibodies were found to recognize lymphocytes from old world monkeys, but not other species (15,23). At this time we also found that red cells were recognized in some of the monkeys. Antigen expression on the red cells seems to be under the control of a single autosomal gene, whereas expression on lymphocytes is constitutive (28). It has been reported that some CAMPATH-1 antibodies can recognize an antigen on human red cells (26), but despite extensive studies with large panels of cells using numerous techniques, we have never been able to detect such reactivity (15) (V. Taylor and G. Hale, unpublished observations).

Structure of the antigen

Recent work indicates that the antigen is a remarkably small glycoprotein, having only 12 amino acids, with a single N-linked carbohydrate on Asn-3, which is comparatively large and complex (Fig. 1) (18,29,30). At the C-terminus the peptide is attached to a glycosylphosphatidylinositol anchor that has a conventional structure similar to other mammalian GPI anchors. The N-linked carbohydrate, and indeed the 9 N-terminal amino acid residues, can be removed without destroying the antigenicity or sensitivity to complement lysis. The CAMPATH-1 antibodies therefore seem to recognize an epitope which includes the three or four C-terminal amino acids and possibly part of the GPI anchor. This implies that they bind very close to the cell membrane, which
could be one of the reasons why the antibodies are so good for cell lysis, since one of the critical events in the complement cascade is the covalent attachment of activated C4 and C3 to the cell membrane. These molecules have a very short half-life when activated and so could easily decay before reaching the membrane if activation by antibody bound C1 occurred at a greater distance from the lipid bilayer.

However, there is another plausible explanation why GPI-anchored antigens, in general, could be good targets for complement attack, since we now believe that they are organized into clusters on the cell surface (31,32). The first component of complement, C1, needs to bind to at least two antibody molecules to become activated and so the density and distribution of the antigen is critical (33–35). Even abundant antigens can be poor targets for lysis, but there is a dramatic improvement when two monoclonal antibodies are used that recognize different epitopes (36,37). This results in a high frequency of antibody pairs suitable for binding C1. It is possible that the same thing occurs with single monoclonal antibodies against antigens that naturally occur in clusters.

There are several other examples of antigens that are good targets for complement lysis and that have proved to be good targets for therapy (38–44) [reviewed by Xia (42)]. Most of them are glycolipids or small GPI-anchored glycoproteins, in which case either of the above explanations could be relevant. The importance of these observations for bone marrow purging is that not all target antigens will be appropriate for efficient complement-mediated attack, irrespective of the isotype of the antibody.

Expression of antigen on spermatozoa

There is very little information about the physiological function of the CAMPATH-1 antigen. Like virtually all other GPI-anchored glycoproteins, there is some evidence that cells can be activated by CAMPATH-1 antibodies under suitable conditions (17,26,43). However, an intriguing observation was the discovery of the same antigen on mature human sperm (44–47). It actually seems to be synthesized by the epithelial cells of the epididymis, secreted into the seminal plasma (probably in the form of membrane-bound vesicles) from where it is taken up by the sperm as they pass through. Mature sperm are therefore sensitive to complement attack in the presence of CAMPATH-1 antibodies, but this is not thought to be a major problem in the context of therapy because only minute amounts of antibody would be expected to reach the seminal fluid and there the sperm would be protected by the large excess of vesicular antigen (47).

A homologous epididymal antigen has recently been identified in monkeys (48). It has a mature protein sequence of only 11 amino acids, which is very similar to the human antigen. It is likely that this is the same antigen that we detected on monkey lymphocytes. In mice, a related antigen has also been described that is expressed on lymphocytes and epididymis (49,50). Although the mature peptide (approx. 20 amino acids) does not closely match the human antigen, it contains a similar N-glycosylation site and the untranslated portions of the cDNA are significantly similar. We expect that these homologues will provide good targets for experiments to elucidate the antigen function. Meanwhile, they will also provide models for studying the therapeutic applications of CAMPATH-1 antibodies, which are by now well advanced in humans.

APPLICATIONS OF CAMPATH-1 ANTIBODIES IN BONE MARROW TRANSPLANTATION

CAMPATH-1M for T cell depletion

CAMPATH-1M was selected because it gave the highest titre of cell lysis with no effect on colony-forming cells. Studies in cynomologous monkeys and in patients with end-stage lymphocytic leukemia showed no unexpected toxicity (51) and experiments in monkeys also showed no delay in the engraftment of autologous bone marrow treated with CAMPATH-1M and complement in vitro (52). On the basis of these studies, colleagues at the Hammersmith Hospital, London, the Hadassah University Hospital, Jerusalem, and the University Hospital, Ulm, started to use CAMPATH-1M with complement from donor serum for T cell depletion of donor bone
marrow for allogeneic transplants. A series of 11 patients transplanted for advanced leukemia from HLA-matched siblings demonstrated that this was a very effective method of preventing GVHD, even when no posttransplant immunosuppression was used (21). Nevertheless, even in this small series, three cases of graft failure were observed, which we now know is the almost inevitable corollary of extensive T cell depletion.

Several lines of evidence suggest that the graft failure was mainly due to immunological rejection of the donor bone marrow, rather than, for example, an adverse effect of the antibody treatment on stem cells or their ability to repopulate the recipient (53). First, only one case of graft failure has been seen in more than 60 patients who received autologous bone marrow purged by the same method (to remove residual leukemia cells). Second, the incidence of graft failure was higher when bone marrow from unrelated or mismatched donors was used. Third, there were several cases in which host-derived cytotoxic T cells could be detected immediately preceding graft failure and some of them were shown to be specific for donor cells (54–56).

Since 1983, more than 500 transplants have been performed by 23 transplant centers throughout Europe and the Middle East, using this method of preventing GVHD in HLA-matched siblings (22,57–63) (Protocol 01, Fig. 2). Various modifications to the regime were made in an effort to reduce the risk of graft rejection. Some patients received posttransplant CsA. Others received intensified conditioning regimes, including additional radiotherapy, drugs, or total lymphoid irradiation.

A recent analysis (64) in patients transplanted for malignant diseases showed that the incidence of either severe or chronic GVHD was substantially reduced compared with other types of therapy. Overall, the frequency of acute GVHD > grade 1 in patients at risk was 17% and the frequency of severe acute GVHD (grade 3–4) was only 7%. The frequency of chronic GVHD was 19% and of severe chronic GVHD, 2%. The incidence of graft failure was lower in those patients who received CsA or TLJ (12–13%) compared with those who did not (19–21% graft failure). The use of CsA (though not TLJ) was also associated with a significant reduction in transplant-related mortality. Only a small number of patients (n = 24) received both TLJ and CsA, but they fared particularly well with only 4% graft failure.

**Prevention of rejection with CAMPATH-1G**

The partial success in prevention of graft failure by immunosuppressive reagents led us to believe that better control might be achieved with more selective and potent immunosuppressants. Experiments in animals showed that treatment of the recipient with depleting anti-T cell antibodies could abolish rejection of T cell-depleted bone marrow, even with reduced irradiation or when the donor and recipient differed across major histocompatibility barriers (7,65). We therefore looked for monoclonal antibodies that could produce a similar effect in humans. Antibodies that could deplete lymphocytes in vivo were important in these experimental studies and so again we turned to the CAMPATH-1 antibodies since they were the most effective reagents available at the time (66).

The original IgM antibody CAMPATH-1M, although extremely lytic with complement, gave only transient depletion of lymphocytes in vivo in patients with CLL or lymphoma (51). However, from another CDw52 clone that secreted an IgG2a antibody, we were able to isolate a spontaneous class-switch variant, the rat IgG2a antibody CAMPATH-1G (62). The IgG2a subclass is not only the best rat IgG for activating complement but is also optimal for binding to human Fc receptors and activating cell-mediated killing (67–69). CAMPATH-1G proved to be very efficient at depleting lymphocytes in vivo in several patients with lymphoid malignancies and in patients

| Day | -15 | -10 | -5 | 0 | 5 |

**FIG. 2.** Illustration of the different antibody protocols studied by the CAMPATH users group. The dose of CAMPATH-1M was typically 25 mg for in vitro purging, whereas the dose of CAMPATH-1G was usually 5–10 mg for in vitro purging or 5–10 days at 5–10 mg/day for in vivo treatment.
suffering steroid-resistant kidney graft rejection (70,71). In both studies, the treatment with CAMPATH-1G gave a beneficial clinical response in many of the patients.

The first objective was to see whether treatment with CAMPATH-1G would decrease the risk of graft rejection in the context of "standard" T cell depletion. This was not easy to test because the actual incidence was comparatively low, and so quite a large number of patients was needed to demonstrate an effect. Initially we did not know whether the recipient's effector mechanisms would be compromised by the conditioning regimen, so it was possible that administration of antibody at the time of the transplant might not be effective. Therefore the CAMPATH-1G was given at 5–10 mg/day for 5 days before the start of chemoradiotherapy (Protocol 02). Although this had the slight disadvantage that extra inpatient time was required, the protocol had several advantages: (a) the degree of lymphocytopenia produced by CAMPATH-1G could be measured, uncomplicated by other treatments, (b) adverse effects of the antibody could likewise be assessed, and (c) most of the antibody would be cleared by the time of the transplant and so be unlikely to contribute to extra depletion of the donor T cells. T cell depletion with CAMPATH-1M and other elements of the conditioning regime were kept the same as in historical control groups. No other prophylactic agents to prevent GVHD or graft rejection (e.g., CsA, TLI) were given. The plan is to enroll 100 patients with acute leukemia in first remission, which will provide a homogeneous group where the effect of the antibody protocol on relapse can also be observed.

To date about 75 such patients have been enrolled by three transplant teams (Royal Free, London; University Hospital, Ulm; King Faisal Hospital, Riyadh). The interim results are very satisfactory and a detailed report will be published when the study is complete. Meanwhile we have analyzed these study patients as part of a larger group of patients, including CML and advanced disease, who all received the same antibody protocol (Table 1). Out of 144 patients there has been only 2% severe acute GVHD, no case of severe chronic GVHD, and 9% graft failure. The risk of death at 2 years from all causes other than relapse is 21 ± 8%, which is significantly lower than that seen with the original protocol (38 ± 3%). Furthermore, the leukemia-free survival at 2 years is also significantly better (Fig. 3A). Although graft failure has not been totally eliminated, there is a possibility that in the future, the addition of a short course of CsA might make the risk still lower.

The degree of lymphocyte clearance induced by CAMPATH-1G in vivo has been measured by a sensitive limiting dilution analysis and found to be similar to that achieved with busulphan/cyclophosphamide or total body irradiation (72). Antibody therapy was as effective as the conventional treatments at depletion of cytotoxic T cell precursors (> 99%) but far more effective at eliminating helper T cells that were relatively resistant to chemotherapy or radiotherapy.

The use of CAMPATH-1G for prevention of GVHD

The successful use of CAMPATH-1G to eliminate cells in vivo suggested that it could be used in a similar way to remove the donor T cells in order to prevent GVHD. In principle, this could be done either by addition of the antibody to the donor bone marrow to opsonize the cells for subsequent clearance in vivo (Protocol 03), or by administration to the patient at or around the time of the transplant (protocols 04–06). In both cases, the antibody should also help to remove residual host lymphocytes though its effect on the donor T cells would presumably be greater when it was administered with the bone marrow. The advantage of these procedures is that no additional complement or processing of the bone marrow would be required. Both approaches have been tried by different transplant centers and the results prove that sufficient depletion of donor T cells to avoid GVHD can be achieved by either method (Table 1).

Teams at the Hadassah Hospital, Jerusalem and the University Hospital, Cape Town have used CAMPATH-1G in vivo (Protocol 03) (73–75). Most patients (24/26) received additional total lymphoid irradiation to prevent graft rejection, but no posttransplant immunosuppression. The incidence of either severe GVHD or graft failure was very low, but as the number of patients so far treated is small, this is not yet significantly different from the results with the original protocol. However, the 2 year transplant-related mortality of this group of patients is already significantly better than those treated on the original protocol and so is the leukemia-free survival (Fig. 3B).

These results provide convincing evidence that more opsonization with CAMPATH-1G is sufficient to deplete the donor T cells. We know that CAMPATH-1G can bind to human Fc receptors as well as activating human complement, but we cannot say which mechanism is more important. If the donor bone marrow was not washed free of plasma, significant lysis of T cells was obtained within 30 min of addition of CAMPATH-1G, even though no extra complement was added (W. Fiehe and R. Willemze, University Hospital, Leiden and E. Yousaf and D. Pamphilon, Blood Transfusion Service, Bristol, unpublished observations). However, the procedure seemed to be equally as successful with bone marrow separated on Ficoll and washed free from plasma, so presumably the necessary effector mechanisms are sufficiently intact in the recipient despite the chemoradiotherapy.

An alternative way of using CAMPATH-1G to prevent GVHD has been tested by teams at the University Hospi-

*The fraction who suffered graft failure or GVHD is calculated as a percentage of the patients at risk. Patients were considered not evaluable for engraftment if they died before day 20 without engraftment, and not evaluable for GVHD if they suffered graft failure or died before day 100 without GVHD (day 120 for chronic GVHD). Results in each protocol were compared with the original protocol (01) by the χ² test. Those that are significantly better are in boldface and those that are worse are in italics. Note: Leukemia-free survival means freedom from hematologic disease. Cytogenetic relapse in CML was not included.
CAMPATH-1 IN BONE MARROW TRANSPLANTATION

PATH-1M \textit{in vitro}. However, an observation that may be relevant is that all of the patients who have received CAMPATH-1G \textit{in vivo} had slower engraftment than normal, with a median time to reach 500 neutrophils of about 24 days compared to a median of about 19 days for patients who had only \textit{in vitro} T cell depletion (64). This delay in engraftment was more marked when the CAMPATH-1G was given close to or around the time of the transplant. We do not think there was a direct toxic effect on bone marrow stem cells because no delay was seen with CAMPATH-1G \textit{in vitro}. Possibly, a small number of lymphocytes, either donor or host, play a role in engraftment, perhaps by secreting cytokines that promote the growth of progenitor cells.

**Leukemia relapse**

One of the potential risks of T cell depletion for patients with leukemia is the loss of a beneficial graft-versus-leukaemia effect. In 1979 the Seattle transplant team showed that patients with advanced acute leukaemia who suffered from GVHD were at lower risk of relapse, compared with those who did not develop GVHD (78). Subsequent analysis of large collections of data has confirmed this finding in all the major categories of leukaemia treated by marrow transplantation (79). There has been considerable speculation as to whether the beneficial graft-versus-leukaemia effect can be separated from GVHD, perhaps by selective manipulation of the donor T cells, and there have been several experimental studies in animals which suggest that this may be possible (80–83). However, there are very considerable practical difficulties in applying these principles to human therapy. At present, we can only examine whether the trade-off between decreased transplant-related mortality and increased relapse is favorable or not.

The risk of relapse for all patients with early leukemia who received T cell-depleted transplants is shown in Fig. 4. Results of both \textit{in vitro} and \textit{in vivo} depletion are included, but patients who received any form of T cell addback are excluded. With up to 10 years follow-up, the risk of relapse in ALL and AML shows a plateau at approx. 30%, with most cases occurring in the first year. In CML, the risk of hematologic relapse continues to rise for at least 5 years, reaching an apparent plateau of about 60% by 7 years. It has been clear for some time that T cell depletion results in a significant increase in relapse risk for patients with CML transplanted from matched siblings (59,61,62,84,85), though it was initially surprising to find that the risk of relapse of T-depleted patients is much greater than for conventionally treated patients who do not suffer from GVHD (79). This is perhaps the best evidence yet in humans that the antileukemic effect of the marrow transplant might be distinct from clinical GVHD.
HALE AND WALDMANN

In contrast, the results in acute leukemia do not show such a distinction, since the effect of T cell depletion can be accounted for in terms of the improved control of GVHD. The relapse rates we see are a little greater than reported using conventional therapy with MTX/CsA (86.87) and this results in a slightly lower leukemia-free survival when we consider the CAMPATH-1-treated patients as a whole. However, the overall control of transplant-related complications is so much better with the recent protocols, particularly 02 and 03, that this should compensate for the slightly increased risk of relapse. Currently the leukemia-free survival at 2 years for patients with acute leukemia treated according to protocol 02 or 03 is 56%, which is almost exactly what would be expected using MTX/CsA. However, the improved control of GVHD, particularly chronic GVHD, with antibody therapy is likely to be a significant advantage.

Transplants for nonmalignant diseases

If antibodies could be routinely used to control GVHD and rejection, one of their most useful applications would be in transplants for nonmalignant diseases, such as severe aplastic anemia and eventually thalassemia or sickle cell anemia. These situations are not complicated by the potential graft-versus-leukemia effect of donor T cells. Irradiation is also undesirable and so there would be significant long-term advantages in obtaining a powerful but nontoxic immunosuppressive conditioning regimen.

To date the CAMPATH-1 users group have carried out 116 such transplants from HLA-matched siblings (80 aplastic anemia, 22 thalassemia, 9 Fanconi’s anemia, 5 other inborn errors). A diversity of conditioning regimens and antibody treatment protocols has been tested as in the patients with malignant diseases. However, the numbers of patients treated according to each individual protocol are small. Two main groups of patients can be identified according to the antibody treatment (Table 2). The first group received T cell depletion in vitro, either with CAMPATH-1M (31 patients, protocol 01) or CAMPATH-1G (16 patients, 17 transplants, protocol 03). The second group received CAMPATH-1G in vivo either with

T cell depletion in vitro (11 patients, protocols 02, 07) or without (9 patients, protocol 06). Three of the transplants in the second group were retransplants after graft rejection of patients in the first group (75). In every case the control of GVHD has been excellent. There were only two cases of acute GVHD ≥ grade 1 and only one case of chronic GVHD (not severe). In the group who received only in vitro T cell depletion, the incidence of graft failure was 45%, but in the group who received in vivo T cell depletion it was only 5% (p < 0.01, χ² test). The actuarial survival at 1 year for the in vitro group was 74% and for the in vivo group 100% (p < 0.03, log-rank test). Unlike the situation in transplants for leukemia, the use of CAMPATH-1G in vivo was not associated with any delay in engraftment. The median day to reach 500 neutrophils for the in vitro group was day 19 and for the in vivo group was day 14 (excluding patients who did not engraft). Unlike the patients with leukemia, most of these patients did not receive TBI. Possibly their bone marrow microenvironment was therefore more conducive to rapid regeneration.

Transplants from donors other than HLA-identical siblings

Only a minority of patients who might benefit from a marrow transplant have a suitable HLA-identical sibling. Patients who receive transplants from HLA nonidentical family members or from "HLA-matched" unrelated donors are at significantly higher risk of GVHD and other severe transplant complications. Therefore much attention has been given to the use of T cell depletion in these situations. CAMPATH-1 antibodies have been particularly used in transplants from parents for immune deficiencies and other inborn errors (88-92) and in unrelated donor transplants (93-95).

A summary of the results to date is given in Table 3. T cell depletion in vitro gave good control of GVHD with only 25 cases of severe acute GVHD out of 180 patients evaluable (14%). However, the incidence of graft failure was substantial (51%) in those patients who did not receive additional therapy with CAMPATH-1G in vivo. This is despite the fact that many of them received various other treatments designed to reduce the risk of graft rejection, such as additional irradiation or CsA or other antibodies, including LFA-1 and CD2 (92). Patients who received in vitro T cell depletion combined with in vivo treatment with CAMPATH-1G had a significantly lower incidence of graft failure (24%), though it was still a substantial problem. The use of in vivo antibody alone combined with conventional GVHD prophylaxis using MTX/CsA gave a similar rate of graft failure and GVHD.

Because these results included all categories of patients with early or advanced leukemia or nonmalignant disease, it would be uninformative to compare the survival curves. The largest subset is the patients transplanted for CML in chronic phase from unrelated donors (94). They are of particular interest in view of the high incidence of relapse that was seen following T cell depletion in HLA-matched sibling transplants. The patients are divided into two groups (Table 4). Thirty patients received in vivo CAMPATH-1G combined with in vitro T cell depletion (Protocol 02) and 60 received only in vivo CAMPATH-1G with conventional GVHD prophylaxis (Protocol 05/06). There were no significant differences between the incidences of graft failure and GVHD in the two groups although, as expected, the trend was toward less GVHD but more graft failure with in vitro T cell depletion. However, in both cases the incidence of relapse seemed to be much lower than in comparable transplants from HLA-matched siblings (Fig. 5). Two-year survival was significantly better in the group who received only in vivo antibody, and the

Table 4: Results in Transplants for CML in First Chronic Phase
CAMPATH-1 IN BONE MARROW TRANSPLANTATION

FIG. 5. Relapse after T cell-depleted transplants for CML. Comparison of unrelated and matched sibling donors. The results are pooled from all antibody protocols, excluding patients who received T cell addback.

leukemia-free survival in this group (53 ± 15%) was as good as that obtained in matched sibling transplants and superior to published results for unrelated donor transplants using conventional GVHD prophylaxis (96).

Lymphoproliferative disease, immune reconstitution, and infections posttransplant

Unlike some other trials of T cell depletion (97–100) lymphoproliferative disease was rare. Out of 1529 transplants, 10 cases of lymphoproliferative syndrome or secondary lymphoma have been reported (101). This represents an actuarial risk at 5 years of 1% in transplants from siblings (5/1067) and 2.3% from mismatched or unrelated donors (n = 5/462). CAMPATH-1 antibodies recognize B cells as well as T cells and it is possible that bone marrow purging with CAMPATH-1M or CAMPATH-1G helps to reduce the potential target for EBV-driven oligoclonal proliferation of B cells in the early posttransplant period, which can lead to fatal malignant lymphomas if uncontrolled.

The CAMPATH users group have not centrally collected data on the recovery of lymphocyte subsets or the incidence of nonfatal infections because of the huge amount of complex reporting and analysis this would have entailed. The number of fatal infections late after transplant did not seem to be more than seen with conventional GVHD prophylaxis, since transplant-related mortality did not increase much after the first 9 months. However, individual centers have observed relatively slow T cell regeneration following lymphocyte depletion with CAMPATH-1M (102,103) and some have found a high incidence of CMV viremia (A Bacigalupo, Genoa, and D. Bunjes, Ulm, unpublished observations). Since the normalizations of T cell numbers may not occur for a year or more after a bone marrow transplant even with conventional GVHD prophylaxis, it is not easy to assess the impact of T cell depletion on this parameter. Furthermore, we do not know how well the T cell phenotype really reflects the immune status of an individual. Probably functional assays of T cells are more relevant although they are more laborious to carry out.

CONCLUSION

T cell depletion is certainly the most effective method of preventing graft-versus-host disease. We have developed simple procedures to accomplish this using the patient's own immune effector mechanisms. CAMPATH-1 monoclonal antibodies are particularly effective, possibly because of the unique properties of their target antigen. Furthermore, there is the possibility that in vivo antibody treatment may contribute to elimination of residual leukaemia in some cases (70).

Better control of GVHD is a prerequisite before bone marrow transplantation can be fully used in the treatment of a wide range of diseases. Unfortunately, T cell depletion is associated with increases in the risks of graft rejection and leukemia relapse. Substantial progress has been made toward overcoming the problem of graft rejection by giving increased immunosuppression to the recipient, either with CsA or TLI, or most successfully by in vivo treatment with CAMPATH-1G. Eventually we believe that a combined strategy should permit successful engraftment in virtually all HLA-matched sibling transplants and the great majority of others. This should mean that bone marrow transplants can be used for nonmalignant hematological diseases with less fear of procedure-related mortality and it might open the way to the use of marrow transplantation for tolerance induction in organ transplantation and autoimmune disease.

The risks of leukemia relapse associated with extensive T cell depletion have now been well defined, at least in patients with early disease. In acute leukemia the increase in risk is modest compared with current results using drug-based GVHD prophylaxis. The extra mortality from relapse is likely to be offset by a reduction in transplant-related complications. In CML, T cell depletion has a significant adverse effect, at least in patients transplanted from HLA-matched siblings. We do not know why a similar increase in relapse was not seen in patients transplanted from unrelated donors. It may be relevant that most of the latter group receive higher doses of radiotherapy (95), but it is also possible that there is a stronger allogeneic effect that is not completely abrogated by the antibody depletion.

Some groups have tried to add back small numbers of lymphocytes to the depleted bone marrow or after the transplant in order to preserve a graft-versus-leukemia effect (74,104,105). The effect has been to increase the risk of GVHD and decrease the risk of leukemia relapse.
(64) and, overall, the results are similar to those obtained without T cell depletion. In other cases donor T cell infusions have been used to effectively treat outright relapse (106, 107), but this procedure is not always effective and carries a high risk of fatal GVHD. Ideally, T cell addback could be administered 2–4 months after the transplant when the patient had recovered from the effects of the conditioning regime but before hematological relapse is likely to have occurred. If a sensitive assay were available to indicate the amount of residual disease at that stage (108), this immunotherapy could then be reserved for only those patients who were likely to relapse and had not suffered any GVHD. However, whatever refinements are made in the timing, dose, or cellular content of lymphocyte therapy, it is unlikely that its potential for producing severe GVHD will be eliminated. The biological effect will largely be dictated by the immune repertoire of the lymphocytes and the genetic disparity between donor and recipient. The alternative strategy is to seek for new drug treatments for residual leukemia, or more effective combinations of existing ones. For example, the drug thiota pera is reported to be myelosuppressive and may be useful for treatment of CML in the context of T cell depletion (109, 110). So far the clinical results are very early, and longer follow-up is needed to be sure whether this treatment will give improved results.

Bone marrow transplantation will continue to be an important arena for the testing of new types of biological therapy. As the clinical results gradually improve and the range of potential new treatments become wider, it will be more and more difficult to design prospective trials that have a good chance of showing significant improvements. We believe that the best use can be made of these limited opportunities if we test therapies that, like CAMPATH-1, potentially have a very broad application. Although we have not described here the wider range of clinical applications where CAMPATH-1 antibodies are being used, such as for treatment of leukemia, control of organ transplant rejection, and treatment of autoimmune diseases (70, 71, 111–114), nevertheless, the results obtained from the studies in bone marrow transplantation have helped to make those possible.

number of patients suffered from EBV-B lymphoproliferative disease after receiving an IR-depleted graft (6 out of 12 patients), whereas the control group had limited EBV-SLPOD (3 out of 20 patients). This might be caused by the effect of SBE in the control group, resulting in an additional B cell depletion. So, a new study is currently being performed in which B cells are also depleted, using CD19 and CD22 tetrameric complexes, in order to avoid this complication.

750 IMMUNOMAGNETIC SELECTION OF PERIPHERAL BLOOD STEM CELLS (PBSC) IN HAEMATOLOGICAL MALIGNANCIES

Hospital Universitario de Canarias, Tenerife, Spain

Apheresis harvests from patients with haematological malignancies can be purged with immunomagnetic methods, yielding an important enrichment in CD34+ cells and simultaneously a substantial depletion of contaminating neoplastic cells. Methods: We describe the results of twenty-four immunomagnetic selection procedures performed with the Isolox 300i magnetic cell separator system (Baxter, U.S.A.): 9 multiple myelomas, 12 non-Hodgkin's lymphomas, 2 chronic lymphocytic leukaemias, and 1 Waldenström's disease. Double selections using anti-CD19 and anti-CD20 monoclonal antibodies were done in all cases. To assess the double purging efficacy, CD19+ cells in the final (IP) and final product (FP) were analyzed by flow cytometry. Results: The average total CD34+ cells x 10^6 and CD34+ cells/kg x 10^6 were 559.61 ±224.50 and 8.33 ±22.32 in the IP and 283.36 ±110.74 and 4.05 ±1.48 in the FP respectively. Average purity was 99.65% (70.30-98.70) and the CD34+ yield was 49.45% (38.51-59.28). The medium reduction of CD 19+ cells was 4.06 logs±1.59. Thirteen patients were transplanted and the time of engraftment was similar to historical patients transplanted with unmanipulated products. Conclusions: Isolox 300i immunomagnetic device offers a more purging method for PBSC harvests in haematologic malignancies. Autologous transplantation with these products is safe and ensures a normal haematopoietic reconstitution.

751 FURTHER EXPERIENCE WITH CAMPATH-1H IN MONOCLONAL ANTIBODY FOR T-CELL DEPLETION OF PERIPHERAL MONONUCLEAR CELLS IN THE-BAG

J Watkins D#, Wood L*, Hale G*, Waldmann H#

*Bone Marrow Transplant Unit, Constantiaberg Medi- Clinic, Cape Town, South Africa and ^St. William Dunn School of Pathology, Oxford, United Kingdom

Unmanipulated allogeneic transplantation of haematopoietic stem cells derived from bone marrow or peripheral blood has a significant rejection rate, acute and chronic graft-versus-host disease (GVHD) and cytomegalovirus (CMV) infection (CMV). We have previously reported that T-cell depletion by exposure of bone marrow mononuclear cells to either yttrium or saponin forms of the antibody abolishes these three major complications and has a low relapse rate in acute myeloblastic leukaemia. A subsequent switch to peripheral blood improved outcome by shortening time to engraftment by about 7 days. We now update this experience using the humanised immunoglobulin (n~80) and confirm uniform engraftment with median time to 0.5x10^9/L neutrophils at 12 days and 50x10^9/L of platelets at 14 days. CMV was isolated in 6 patients (17.5%) and of these 4 (66%) died. A notable new feature is erythrodema considered to be late presenting acute GVHD without involvement of bilary endothelium or gut. These patients generally responded to topical steroids. In our first 5 unrelated donors, because of uncertainty about the efficiency of ex vivo T-cell depletion across antigen disparity, cyclosporin was given for 3 months without side effects. Furthermore, of the initial 4 related but mismatched grafts CMV occurred in 2 and mild GVHD in 2. In these nine engraftment was uniform and the time to haematopoietic reconstitution was the same as matched pairs. It concluded that this ex vivo manipulation is both practical and reliable in histocompatible sibling grafts. Additionally it is applicable to matched unrelated and minimally mismatched families donors but here it is not yet established whether cyclosporin post transplantation can be avoided.

752 ASSOCIATION OF DONOR IL-10 POLYMORPHISM GENOTYPE WITH ACUTE GVHD IN SIB-IDENTICAL ALLOT-MENT

Colman H

University of Newcastle upon Tyne, Newcastle upon Tyne, UK

IL-1 receptor antagonist (IL-1ra) is the naturally occurring antagonist to both IL-1α and B. A VNTR polymorphism in intron 6 of the IL-1ra gene has been associated (allele 2) with increased IL-1ra production. We determined the genotype of this polymorphism in both donors and patients receiving HLA identical allogeneic bone marrow transplants. The association of allele 2 in the patients genotype showed no association with the occurrence of acute GVHD (aGVHD) for patients receiving either combination immunosuppressive therapy or cyclosporin monotherapy. However, for all immunosuppressive therapies possession of allele 2 in the donor genotype was shown to be significantly associated with less severe GVHD grade 0-1 (27/57), rather than with the more severe grades III-IV (21/22) p<0.0146 (Fishers exact test). In those transplants given cyclosporin monotherapy presence of allele 2 in the donor genotype was also significant; 20/44 with grade 0-II and 2/19 with grades III-IV (p=0.0065). We also tested for association between the less common allele of the IL-1α-3953 TaqI polymorphism in patient and donor genotypes with aGVHD occurrence. Allele 2 of this polymorphism has been associated with increased production of IL-1. No significant association was found between this polymorphism and severity of GVHD. These results show that donor genotype for the IL-10 polymorphism may have a protective role with respect to severity of GVHD following transplantation. This significant finding may be an additional factor for individual patient risk assessment for complications, including GVHD after bone marrow transplantation.

753 RECIPIENT INTERFERON-GAMMA & INTERLEUKIN-6 GENE POLYMORPHISMS ASSOCIATE WITH GVHD IN HLA-MATCHED SIBLING BMT. A GENOTYPIC GVHD RISK INDEX

Cavez J, Norden J, Taylor RRA, Dickinson AM, Middleton PG

University Department of Haematology, Medical School, University of New castle upon Tyne, Newcastle upon Tyne, UK

Pre-inflammatory cytokines including IFNy, IL-6 & TNFα are implicated in the "cytokine storm" mediating acute GVHD & other inflammatory BMT complications. The anti-inflammatory cytokine IL-10 has been linked to reduced GVHD. Polymorphism within cytokine genes is associated with functional differences in cytokine regulation & affected clinical performance in a variety of diseases. Polymorphism in the IFNy intron 1 (CAG) microsatellite repeat has been shown to correlate with in vitro IFNgamma production and acute renal transplant rejection. The IL-6-174(G/C) single nucleotide polymorphism allele C has been previously linked to lower in vitro and in vivo IL-6 production and with juvenile chronic arthritis. We examined potential association of GVHD with IFNy & IL-6 polymorphisms in a cohort of 87 cyclosporin A-treated HLA-matched sibling BMT donor/recipient pairs. Recipients homozygous for the IFNy intron 1 allele 3 had significantly more severe (grade III-IV) acute GVHD (p=0.013). Recipients homozygous for the IL-6-174 allele C had significantly less severe acute GVHD (p=0.012). We have previously demonstrated association of recipient TNFα and IL-10 gene polymorphisms with GVHD severity (Blood 52:394). Having found recipient IFNy & IL-6 genotype association with GVHD severity we have combined these findings with the previously identified TNF & IL-10 gene polymorphisms to examine the cumulative impact of these genotypes on GVHD severity. Recipient possession of more than one high-risk-associated genotype (TNF3383: IL-10 -1064 [1-2-16]) was associated recipient IFNy intron 1.33 correlates strongly with severe acute GVHD, even in the presence of the low-risk-associated genotype IL-6-174 CC (p<0.0003). Absence of the three recipient high-risk-associated genotypes is associated with no or mild (grade I) GVHD only (p=0.0143). We propose that a combined cytokine genotypic risk factor index may facilitate acute GVHD prediction, enabling accurate pre-BMT assessment and appropriate individual adjustment of GVHD prophylaxis.
CHAPTER 6

PERIPHERAL BLOOD STEM CELL GRAFTING

- TRANSFER OF EVOLVING TECHNOLOGY -

THE THIRD LOCAL INNOVATION
Four sets of experimental and laboratory data have combined to advance this technology. Here aspirated bone marrow rich blood becomes the source of the stem cell graft from which is recovered the matching population that is normally and predominantly resident in immunohaematopoietic niches in the medullary cavities.

Firstly the long established demonstration of the nomadic nature exhibited by these progenitor cells as having the equivalent capacity to not only repopulate empty bone marrow space in a lethal irradiation animal model but, concurrently, producing matching all lineage haematopoiesis in the spleen.\textsuperscript{177-179}

Secondly in long-term bone marrow culture to show that in blood and marrow colonies and clusters were comparable from both populations. This confirmed that a circulating pool existed and theoretically could be tapped into.\textsuperscript{180-182}

Thirdly preliminary reports translated the early experimental haematology observations into clinical reality by use of continuous flow blood fraction separators. Here a population could be identified, recovered and then shown to replicate all the essential characteristics required for successful reconstitution by engraftment of haematopoietic and immunologic lineages.\textsuperscript{168,183-185}

Fourthly was the observation, relevant in clinical context, that in a variety of animals, including non-human primates, the acquired donor material could be quantitatively and qualitatively enhanced in a range of circumstances. These manipulations are described as mobilisation and release, by altering states of adhesion via a range of different molecules pluripotential cells into blood for harvesting by mechanical means.\textsuperscript{186-188} In parallel by interacting with transfusion, immunology and transplantation communities worldwide each of these steps was established and standardised. Crucially to operate with rigorous quality control according to international standards, exemplified by the Joint Accreditation Committee of the International Society for Cellular Therapy (JACIE)\textsuperscript{189,190} and US Based Foundation for Accreditation of Cellular Therapy (FACT), to match locally approved bone marrow transplantation programs to these plans for harmonisation across countries.\textsuperscript{189}
Over the last 10 years the necessary quality control has been embodied in standard operating procedures. Accordingly after introduction and ongoing evaluation with upgrading, this somewhat rigid approach, guaranteed the consistent recovery of quantitatively and qualitatively adequate stem and progenitor cells for the clinical program\textsuperscript{4}. This mandated control, which is documented and monitored is currently, as elsewhere in the world, regarded as standard of practice\textsuperscript{10,13,52,191,192} and included a number of diseases.

Some variations exist when the specified limits for recovery of mononuclear cell numbers and CD34 expressing numbers appear inadequate\textsuperscript{4,193}. Additionally, particularly with matched-unrelated programs flexibility is crucial. For example with international collaboration through the local and corresponding registries' worldwide there persist the specified prescription that bone marrow as opposed to peripheral blood is required in some geographical areas\textsuperscript{194,195}. In this bi-directional collaboration handling of the two different graft sources needed to be accommodated and separate sets of criteria maintained\textsuperscript{196-198}.

In an extension of this ever evolving upgrading of peripheral blood stem cell grafts is the use of umbilical blood or cord donations\textsuperscript{193,199-201} including our association with Eurocord and Netcord\textsuperscript{202-204}. Additionally new studies are turning to the use of amniotic fluid\textsuperscript{205-207} and occasionally foetal liver although this is a less well-established clinical practice\textsuperscript{208,209}. Endorsement for this now firmly introduced technology underlies confirmed accreditation as a transplantation, harvest and donor centre specifically by the European Group for Blood and Marrow Transplantation\textsuperscript{10,210} and the American National Donor Program\textsuperscript{211,212}.

Distribution of marrow repopulating cells between bone marrow and spleen early after transplantation

P. Artur Platt, Stacy M. Frankovitz, and Christie M. Orschell

Whether hematopoietic stem cells (HSCs) home selectively to bone marrow (BM) early after transplantation remains an issue of debate. Better understanding of homing mechanisms may benefit BM transplantation protocols in cases of limited graft cell number or nonmyeloablative conditioning regimens. Using flow cytometry and serial transplantation to stringently identify HSCs, trafficking patterns of long-term engrafting cells were mapped between BM and spleen early after transplantation. Low-density BM cells were tracked in irradiated or nonirradiated mice 1, 3, 6, and 20 hours after transplantation, at which time recipient BM and spleen were analyzed for recovery of primitive donor cells by phenotype and adhesion molecule expression. In addition, phenotypically defined HSC-enriched or HSC-depleted grafts were tracked 20 hours after transplantation in recipient BM and spleen and analyzed for recovery and long-term repopulating potential in mice undergoing serial transplantation. Regardless of irradiation status, recovery of donor Sca-1+ Lin- cells was higher at most time points in recipient BM than in spleen, while recovery of total Sca-1+ cells was variable. A significantly higher percentage of BM-homed donor Sca-1+ cells expressed CD43, CD49e, and CD49d 20 hours after transplantation than spleen-homed cells, which contained significantly more non-HSC phenotypes. Furthermore, BM-homed cells were significantly enriched for cells capable of secondary multilineage hematopoiesis in mice undergoing serial transplantation compared with spleen-homed cells. These results support the notion of specific homing of HSCs to BM by 20 hours after transplantation and provide a basis for the enhanced engraftment potential afforded some Sca-1+ Lin- cells subfractionated on the basis of adhesion molecule expression. Introduction

Engraftment and reconstitution of normal hematopoiesis following transplantation of hematopoietic stem cells (HSCs) rely on the ability of these cells to lodge within specialized bone marrow niches where the process of proliferation and self-renewal of stem cell functions commence for lifelong hematopoiesis. The ability to manipulate this process may hold clinical benefits in cases of limited graft cell number or compromised homing ability of ex vivo-manipulated cells. However, whether transplanted cells home to bone marrow (BM) by a coordinated series of events based on their potential or whether homing represents a nonspecific process whereby these cells are retained in BM based on the relative size of this organ remains undefined. Evidence exists to support both specific and nonspecific lodging of transplanted HSCs in BM, and data are beginning to suggest that homing mechanisms may be more functional in nonirradiated hosts. Knowledge of the specificity and kinetics of homing is an essential first step in the design of methods aimed at increasing the efficiency of transplantation.

Results from homing studies that tracked unfractonated cells or progenitors in recipient BM or spleen may not signify the trafficking of target stem cell populations. More direct homing assays have focused on tracking phenotypically defined populations of transplanted cells in host tissues by flow cytometry, or transplanting prospectively isolated purified stem cell grafts. To directly examine HSC trafficking, investigators have more recently focused on isolation and retransplantation of tracked BM- or spleen-homed cells in long-term reconstitution assays, given that hematopoietic reconstitution is regarded as the only true test of HSC function. These studies have documented the presence of repopulating cells in both BM and spleen hours after transplantation but exclusive absence in BM 48 hours later. In these studies, repopulating cells present in spleen 3 hours after transplantation provided more rapid reconstitution than BM-homed cells, suggesting the possibility of hierarchic differences in the hematopoietic potential of BM-homed versus spleen-homed cells. Functional studies of BM- versus spleen-homed cells in serial transplantation studies may more precisely define kinetics of BM homing and trafficking patterns of HSCs.

In the current investigation, trafficking patterns of transplanted stem cell grafts were determined in recipient BM and spleen using several different approaches. In the first, grafts of low-density BM (LDBM) were tracked 1 to 20 hours after transplantation by phenotypic characterization of BM- and spleen-homed donor Sca-1+ cells possessing a complex phenotype of adhesion molecules and other markers associated with repopulating cells. In the second approach, HSC-enriched and HSC-depleted grafts were tracked in vivo. Non-HSC grafts were significantly enriched in spleen tissue, while BM recovery of either group of cells was similar. However, serial transplantation studies revealed the exclusive

presence of long-term repopulating cells in BM rather than spleen by 20 hours after transplantation. Collectively, these studies support the notion of selective homing or survival of HSCs in BM 20 hours after transplantation.

Materials and methods

**Mice**

C57BL/6 mice (CD45.2 allele) were purchased from Jackson Laboratories (Bar Harbor, ME) at 8 to 10 weeks of age and allowed to acclimate for 1 to 2 weeks prior to use in their studies. B6.5L/Per.CpFe/5Boyl (B6.Boyl) congenic mice (CD45.1 allele) were either purchased from Jackson Laboratories or maintained in our breeding colony and used between 9 and 12 weeks of age. All studies were approved by the Indiana University School of Medicine Institutional Animal Care and Use Committee.

**Primary short-term (1ST) cell tracking**

BM grafts consisted of LDMB cells or purified Sca-1- lin- cells subfractionated on the basis of CD49e or CD262 expression into fractions enriched for long-term engraftment potential (ENG: Sca-1- lin- CD49e+ or Sca-1- lin- CD262L+ or those devoid of such potential (non-ENG: Sca-1- lin- CD49e- or Sca-1- lin- CD262L-)) as previously documented. Adhesion molecules CD49e and CD262L were chosen in these studies so that grafts would consist of phenotypes where both positive expression and negative expression enriches for long-term repopulating cells (CD49e+ and CD262L+) and nonrepopulating cells (CD49e- and CD262L-), as previously shown. Donor LDMB, ENG, and non-ENG cells were isolated from C57BL/6 or B6.Boyl mice and tracked in vivo with PKH26 or PKH2 (Sigma, Immunocytometry Systems, San Jose, CA) and 1 x 10⁴ to 5 x 10⁴ events were acquired per sample. BM, spleen, and PB from 1ST recipients of ENG and non-ENG transplants were analyzed for presence of donor cells by flow cytometric analysis of data files containing 2 x 10⁴ to 1 x 10⁵ events. No further phenotyping was performed in ENK/non-ENG experiments. In all experiments, donor cells were distinguished from recipient by PKH26, PKH26, CFSE, or appropriate CD45.1 or CD45.2 staining as described in "Primary short-term (1ST) cell tracking."

**Calculation of recovery of primitive donor cells**

The frequency of donor cells falling within a light scatter gate including lymphocytes and large granular cells was determined for each harvested tissue based on the background fluorescence of cells from control mice, as previously described. Control mice were subjected to the same treatment at experimental groups, including radiation and injection of vehicle. Frequency of Sca-1+ cells among donor cells and frequency of lin- cells among donor Sca-1+ cells were likewise determined and used in conjunction with tissue cellularity to calculate recovery of primitive phenotypes after LDMB transplants. Frequencies were multiplied by the total number of cells in each tissue and then divided by the number of cells in the original graft to calculate the recovery of transplanted cells. The number of BM cells harvested from both thymi and femurs was considered to represent 18.7% of total marrow volume. The total volume of PB was assumed to be 2 mL per mouse. A sample calculation of recovery of Sca-1+ cells in nonirradiated BM is as follows: No. BM cells in whole mouse (210 x 10⁶) x Frequency of donor cells in BM (2%) = No. BM-bred donor cells (4.2 x 10⁷) x Frequency of Sca-1+ cells among donor cells (20%) = No. BM-bred Sca-1+ donor cells (0.84 x 10⁷)/No. Sca-1+ cells injected (6.4 x 10⁶) = 0.13 x 10⁴ = 1.6% Recovery of Sca-1+ donor cells in BM (13%).

Similar calculations were then used to obtain the recovery of lin- Sca-1+ donor cells in BM. Due to the low frequency of detectable donor cells when ENK or non-ENG cells were injected, the frequency of donor cells was calculated manually using event count of saved fluorescence-activated cell sorted (FACS) files.

**Serial transplantation studies**

BM- and spleen-bred donor cells from irradiated or nonirradiated 1ST recipients of ENG cells were isolated 20 hours after transplantation by flow cytometric cell sorting using CD45.1,41-P and CD45.2-fluorescein isothiocyanate (CD45.2-FITC). Identical numbers of sorted donor cells (range, 50-500 cells per mouse), along with 1 x 10⁴ competitor LDMB cells of recipient origin, were transplanted into primary long-term (1LT) congenic recipients within 3 hours of receiving lethal irradiation in a split dose of 700 cGy plus 350 cGy 4 hours apart. Recipient mice were bled from the tail vein monthly until 6 months for analysis of donor-derived hematopoiesis. In 3 experiments (1 irradiated 1ST and 2 nonirradiated 1ST), 1LT recipients were killed 6 months after transplantation, and 1 x 10⁴ to 5 x 10⁵ LDBM cells were transplanted into lethally irradiated (700 cGy plus 350 cGy) secondary L1 (2LT) recipients without competition. 2LT recipients were bled from the tail vein monthly until 6 months for analysis of donor-derived hematopoiesis. Donor-derived cells from some 1LT and 2LT L cells were analyzed 6 months after transplantation for the percentage of lineage cells using PE-conjugated antibodies specific for CD3+, B220+, Gr-1, and Mac-1 cells.

**Statistical analysis**

Data are expressed as the mean ± SEM where applicable. Differences between groups were analyzed using an unpaired 2-sided t test. Differences in chimerism were analyzed by repeated measures analysis of variance using an arcsine transformation. A probability value of less than .05 was considered significant for all tests.
Results

Primitive phenotype of BM- and spleen-homed donor cells

To investigate trafficking patterns of primitive hematopoietic progenitor cells (HPCs), irradiated or nonirradiated mice underwent transplantation with LDBM and were killed 1, 3, 6, or 20 hours later. Donor cells harvested from BM or spleen or circulating in PB were phenotyped for expression of primitive markers. In irradiated mice, the frequency of Sca-1+ donor cells in BM and spleen was similar and 3 hours after transplantation but increased significantly in spleen by 20 hours (Figure 1A). The frequency of Sca-1+ donor cells in nonirradiated mice was significantly higher in spleen than BM at 3, 6, and 20 hours after transplantation (Figure 1C). Cellularity of BM, spleen, and PB from irradiated mice ranged from 24 × 10^6 to 55 × 10^6, 33 × 10^6 to 88 × 10^6, and 1 × 10^9 to 4 × 10^9, respectively, depending on the time after irradiation that mice were killed. Mean cellularity of BM, spleen, and PB from nonirradiated mice was 212 × 10^6, 72 × 10^6, and 14 × 10^6, respectively. Data on cellularity are reproduced from Peltt and colleagues. Due to the higher cellularity of BM compared with spleen, recoveries of Sca-1+ cells did not differ significantly between BM and spleen in either transplantation group (Figure 1B, D).

In contrast to total Sca-1+ cells, frequencies and recoveries of the more primitive Sca-1+ lin-1 donor cells in irradiated and nonirradiated recipients tended to be higher in BM than spleen, although these data were not significant at all time points (Figure 2).

Adhesion molecule phenotype of BM- versus spleen-homed donor cells

We previously examined the expression of adhesion molecules on BM-homed Sca-1+ donor cells 1 to 20 hours after transplantation in irradiated or nonirradiated recipients. In the present study, we compared concurrently the adhesion molecule expression of BM- and spleen-homed cells in irradiated recipients. Expression of CD43, CD49e, and CD49d significantly decreased on spleen-homed Sca-1+ cells between 1 and 20 hours after transplantation, while remaining relatively constant on BM-homed Sca-1+ cells (Figure 3A-C). By 20 hours after transplantation, expression of these 3 adhesion molecules, previously shown to be present on primitive HPCs from both murine and human sources, was significantly greater on BM-homed Sca-1+ cells than on similar spleen-homed cells (Figure 3A-C). Because the cellularity of BM was higher than that of spleen, not only was the frequency of CD49e+, CD43-, and CD49d- Sca-1+ cells higher in BM than in spleen, but absolute numbers were also higher in BM (4.3, 2.8, and 1.7-fold higher at 20 hours after transplantation, respectively). Similar results were observed in nonirradiated mice (data not shown).

The frequency of CD62L- cells increased among BM- and spleen-homed Sca-1+ cells until approximately 70% of these cells expressed CD62L by 20 hours (Figure 3D). Expression of CD41 and CD44 was not different between BM- or spleen-homed Sca-1+ cells at any time point and ranged from 95% to 100% on donor Sca-1+ cells in all tissues examined (n = 4, data not shown).

Differential trafficking of ENG versus non-ENG cells in irradiated mice

We next examined the in vivo movement of BM cells highly enriched for long-term engraftment potential in comparison to BM cells known to be devoid of such activity. Such a strategy would identify whether long-term engrafting cells possess specific trafficking mechanisms and whether nonengrafting cells lack such mechanisms, which may in turn contribute to their lack of stem cell function. Based on our previously published work identifying cells with long-term engrafting potential, purified populations of engrafting cells (ENG) consisting of Sca-1+ lin- CD49e+ or Sca-1+ lin- CD49d- cells of nonengrafting cells (non-ENG) containing Sca-1+ lin- CD49e- or Sca-1+ lin- CD49d+ cells were...
isolated prior to transplantation and tracked in vivo. Irradiated 
1ST mice received $4 \times 10^4$ to $3 \times 10^5$ sorted ENG or non-ENG 
cells, and then BM, spleen, and PB were analyzed 20 hours later for 
the presence of donor cells by flow cytometric analysis. Frequency 
and recovery of donor cells did not differ between non-ENG and 
ENG grafts in recipient BM (recovery = 4.3% ± 1.4% and 
4.2% ± 1.4%, respectively; n = 10-11). However, frequency of 
non-ENG cells was consistently higher in spleen than that of ENG.

Figure 3. Frequency of CD43+ , CD44+ , CD49d+, and CD92L+ 
cells among donor Sca-1+ cells in BM, spleen, and PB at 1, 3, 6, and 26 
hours following transplantation of low-density BM cells. Mice were 
irradiated with 900 cGy, underwent transplantation an average of 18.5 
hours later with $1 \times 10^5$ to $1 \times 10^6$ LDBM cells, were killed at the indicated 
time points, and donor Sca-1+ cells in BM and spleen were analyzed for 
expression of CD43 (A), CD44d (B), CD49d (C), and CD92L (D) by flow 
cytometry as described in "Materials and methods." All 4 time points were 
assayed in every experiment. Data are expressed as the mean ± SEM 
percent of donor Sca-1+ cells with light scatter properties characteristic of 
primitive hematopoietic cells and that express each adhesion molecule. 
n = 4. *P < 0.05 when compared with spleen at the same time points, 
**P < 0.05 when compared with earlier time points of same tissue. Data for 
BM cells are partially reproduced, with permission, from Piwek et al.

Figure 2. Frequency and recovery of lineage-negative cells among 
Sca-1+ donor cells in BM, spleen, and PB for times up to 26 hours following 
transplantation of low-density BM cells in irradiated and nonirradiated 
recipients. Mice underwent transplantation with $1 \times 10^7$ 
to $1 \times 10^6$ LDBM cells, were killed at the indicated time 
points, and were analyzed for frequency and recovery of donor 
Sca-1+ lin- cells in BM, spleen, and PB as described in "Materials and methods." Data in panels A and 
C are expressed as the mean ± SEM percent of 
donor Sca-1+ cells falling within a light scatter gate 
including lymphocytes and large granular cells and that 
lack lineage expression. Horizontal lines in panels A and 
C represent the mean percentage of lineage-negative 
donor Sca-1+ cells in the original graft. Using a similar 
light scatter gate, recoveries of Sca-1+ lin- donor cells 
were calculated and are shown in panels B and D. Bars in 
panels B and D represent mean ± SEM recovery of 
Sca-1+ lin- donor cells (sum of recoveries in BM plus 
spleen plus PB), and lines represent mean ± SEM 
recoveries in BM, spleen, or PB. Numbers above each 
bar represent mean recoveries. n = 6-12 in panel A, 
n = 4-11 in panel B; n = 4-5 in panel C; n = 5-6 in panel D. 
*P < 0.05 when compared with spleen of the same time 
point. To provide an SEM value for total recovery at each 
time point, total recoveries were not calculated by adding 
the means of the recoveries from each tissue but rather 
by averaging the total recoveries from each individual 
experiment.
undergoing serial transplantation. To this end, 50 to 200 BM- or spleen-homed donor cells were isolated from irradiated or nonirradiated 1ST recipients 20 hours after transplantation and equal numbers transplanted competitively into 1LT irradiated recipients. In 8 experiments using a total of 41 mice, no differences were noted in the degree of donor-derived chimerism in 1LT mice up to 6 months after transplantation of BM-homed or spleen-homed cells, regardless of irradiation status of 1ST recipients (Figure 5A, pooled data from irradiated and nonirradiated 1ST mice). Six months later, 1 x 10^6 to 5 x 10^6 LDBM cells from 1LT mice in 3 experiments were transplanted into 2LT irradiated mice without competition. Interestingly, chimerism was significantly higher in mice that received cells initially homed to BM rather than spleen in 1ST recipients (Figure 5B, pooled data from 1 experiment with an irradiated 1ST recipient and 2 experiments with nonirradiated 1ST recipients). In one particular experiment where spleen-homed cells provided 88% donor-derived hematopoiesis in 1ST recipient BM, 70% of 2LT recipients undergoing transplantation with this marrow failed to survive beyond 1 month of transplantation, illustrating the inability of spleen-homed cells to support hematopoiesis in secondary recipients.

No differences in chimerism in 1LT or 2LT mice were noted when Sca-1+/lin- CD49e+ or Sca-1+ lin- CD42L+ cells were used.
in the initial homing step in 1ST mice. In addition, BM-homed and spleen-homed cells from 1ST mice did not apparently differ in their relative contribution to either myeloid or lymphoid lineages (data not shown).

Discussion

In this report, evidence is presented that supports the notion of selective distribution or homing of transplanted HSCs to BM during the first 20 hours after transplantation. Phenotypic evidence documenting increased frequency and recovery of donor Sca-1+ lin- cells in BM relative to spleen, as well as increased frequency and recovery in BM of adhesion molecule phenotypes known to be enriched for HSCs, further support this notion. Significant enrichment of purified non-ENG grafts in spleen 20 hours after transplantation suggests trapping of nonengrafting cells in secondary hematopoietic tissues. Finally, selective homing of HSCs to BM is further supported by serial transplantation studies that revealed the exclusive presence of cells capable of secondary long-term multilineage hematopoiesis in BM by 20 hours after transplantation, while donor cells in spleen at this time failed to provide secondary donor-derived hematopoiesis and, in some cases, failed to provide radioprotective support in 2LT recipients.

Previous reports have documented the presence of rapid reconstituting ability in spleen-homed donor cells collected 3 hours after transplantation but exclusive presence of repopulating cells among BM-homed cells by 48 hours.1 In the present studies, both BM- and spleen-homed donor cells isolated 20 hours after transplantation from both irradiated and nonirradiated 1ST recipients were capable of supporting hematopoiesis in 1LT recipients to a similar degree, but BM-homed cells provided a significantly higher degree of chimerism in 2LT recipients than spleen-homed cells. Of interest was the apparent lack of radioprotective cells in the marrow of some 1LT recipients of spleen-homed cells, despite high levels (up to 85%) of donor-derived chimerism. These results suggest that 20-hour spleen-homed cells, while capable of sustaining long-term hematopoiesis for one generation, do not contain the most primitive HPCs capable of providing hematopoiesis in secondary recipients and illustrate a hierarchic process that results in efficient homing of the most primitive HPCs to BM rather than to spleen during the first 20 hours following transplantation. These results corroborate those of Szilvassy et al,5 in which this group reported more rapid reconstitution by 3-hour spleen-homed cells than BM-homed, emphasizing the degree of heterogeneity in the stem cell pool and possible presence of more "mature" HSCs in spleen at this time point. The relatively higher recovery in spleen of total Sca-1+ cells (Figure 1) compared with the more primitive lin- fraction that was relatively enriched in BM, especially in nonirradiated mice (Figure 2), further supports the notion that more mature cells home to spleen. Alternatively, it is also possible that transplanted HSCs survive better in BM than spleen during the first 20 hours after transplantation as previously suggested,10 contributing to their engraftment potential.

To eliminate variables influencing stem cell phenotype after transplantation, and to test the possibility that certain classes of cells fail to engraft due to an inability to efficiently home to the BM, we examined the homing of populations of cells highly enriched for HSCs (ENG) and those lacking this potential (non-ENG). Notably, although ENG cells were highly enriched for HSCs,10 this phenotype was still heterogeneous in stem cell potential and in vivo trafficking ability, as revealed in selective homing of long-term repopulating cells to BM while cells of lesser potential segregated to spleen. Homing experiments performed in nonobese diabetic/severe combined immunodeficiency (NOD/SCID) mice suggest little selectivity in BM-versus spleen-homing of transplanted primitive HPCs.11-12 Whether differences in results obtained in NOD/SCID mice and the present studies are secondary to xenogeneic homing models or differences in stringency of HSC assays requires further investigation.

Interestingly, trafficking of ENG and non-ENG cells to BM was similar, suggesting that defects in homing are not the cause of the reported engraftment failure of non-ENG cells but, rather, limited intrinsic hematopoietic potential. Whether differences in adhesion molecule expression between ENG and non-ENG cells translates to differences in the ability of these 2 groups of cells to communicate effectively with the BM microenvironment for determination of their fate remains an interesting possibility that may explain lack of engraftment potential of non-ENG cells. While several adhesion molecules have been implicated at various steps of homing and egress from the BM,13-15 a direct role for any adhesion molecule in homing of HSCs has not been documented. Because interactions between CD49d and fibronectin are known to stimulate proliferation and differentiation of primitive HPCs (reviewed by Chun and Watt),16 it is likely that cells lacking CD49d expression are unable to effectively contribute to BM hematopoiesis. A role for CD62L in hematopoiesis is less well defined, but data are beginning to suggest that this molecule may be more important for progenitor cell function than stem cell function,9,26,31,32 providing a possible reason for the rapid up-regulation of CD62L on BM-homed Sca-1+ cells in the present studies. We and others have previously documented the presence of CD49d+ and absence of CD49d- on murine long-term engrafting cells. We now show that lack of expression of CD49d and expression of CD62L predisposes Sca-1+ lin- cells to sequestration in the spleen, suggesting the direct involvement of these or other, yet unknown, adhesion molecules in directing the trafficking of hematopoietic cells. The percentage of non-ENG cells recovered in spleen was nearly twice that of ENG cells and similar to that previously reported for grafts of LDBM (1.5% ± 0.2%), another source of cells composed largely of nonengrafting cells. Our present studies provide a mechanistic link between phenotypically defined engrafting cells identified previously by our group based on expression of adhesion molecules and the potential of these molecules to direct the homing of engrafting cells to the BM.

Increased frequency and recovery of CD43+, CD49e+, and CD49d+ Sca-1+ donor cells in BM compared with spleen was greatest 20 hours after transplantation. These results can potentially be explained by either trafficking of these phenotypes from spleen to BM between 1 and 20 hours, as previously suggested,5,9 or modulation of the expression of these markers on Sca-1+ cells that had already homed to BM or spleen in the first 20 hours (possibly to facilitate anchorage of these cells). Because recovery of total Sca-1+ cells remained fairly constant in spleen while the percentage of CD43+, CD49e+, and CD49d+ Sca-1+ cells declined, and because recovery of ENG cells in BM was similar between 3 and 20 hours (4.0% ± 1.3% and 4.2% ± 1.4%, respectively), it is plausible that phenotypic down-modulation of adhesion markers on spleen-homed cells is responsible for the observed changes. However, trafficking of donor cells between BM and spleen during this time frame cannot be ruled out. It is also possible that BM and spleen act cooperatively to ensure efficient homing of transplanted HSCs to BM; in this case spleen would be a necessary component of the homing process. Manipulation of the trafficking of transplanted HSCs by blocking pathways involved in spleen homing, or via splenectomy, may provide more precise answers to the role of spleen in homing of primitive HPCs to BM.
We have previously documented an enrichment of long-term repopulating cells in BM of nonirradiated recipients compared with irradiated ones. This observation may signify a more hospitable environment and more efficient trafficking of cells to nonirradiated BM compared with ablated BM, where endothelial damage may hinder efficient movement of cells to BM and/or increase nonspecific binding of cells to other sites. Our present studies add to these results by showing that even within an irradiated host, despite endothelial damage and relatively inefficient trafficking, a certain degree of selective trafficking to BM remains. It is possible that host influences elaborated by irradiated tissues promote proliferation and survival of transplanted cells in BM. Whether the differing or timing of host conditioning prior to transplantation can be manipulated to better preserve a microenvironment that is more conducive for homing warrants further investigation. Nevertheless, these results begin to define a basis for the enhanced engraftment potential afforded some groups of Sca-1+ LSA cells fractionated on adhesion molecule expression and begin to outline distinct in vivo trafficking patterns of transplanted long-term engrafting cells within the first 20 hours of transplantation.

In vivo trafficking, cell cycle activity, and engraftment potential of phenotypically defined primitive hematopoietic cells after transplantation into irradiated or nonirradiated recipients

P. Artur Plett, Stacy M. Frankovitz, and Chrisle M. Orschell-Traycoff

Recent interest in bone marrow (BM) transplantation in nonconditioned or minimally conditioned recipients warrants investigation of homing patterns of transplanted hematopoietic progenitor cells (HPCs) in irradiated and nonirradiated recipients. To this end, phenotypically defined populations of BM cells were tracked in lethally irradiated or nonirradiated mice at 1, 3, 6, and 24 hours after transplantation. Recovery of transplanted cells at all time points was higher in BM of nonirradiated mice, similar to earlier suggestions. The percentage of lineage-negative Sca-1+ cells and Sca-1+ cells expressing CD43, CD49e, and CD49d steadily increased in BM of nonirradiated mice up to 24 hours, while fluctuating in irradiated mice. Cell cycle status and BrdU incorporation revealed that less than 20% of Sca-1+ cells and fewer Sca-1+Lin+ cells had cycled by 24 hours after transplantation. To more directly examine trafficking of primitive HPCs, purified grafts of CD62L+ or CD49e+ subfractions of Sca-1+Lin- cells, previously shown to be enriched for long-term repopulating cells, were also tracked in vivo. Recovery of purified cells was similarly increased in BM of nonirradiated mice. When 50 to 100 of these BM-homed cells were examined in serial transplantation studies, BM-homed cells from initially nonirradiated mice were enriched 5- to 30-fold for cells capable of long-term hematopoiesis in secondary recipients. Collectively, these data suggest that homing or survival of transplanted cells in irradiated recipients is less efficient than that in nonirradiated recipients, implicating an active role of radiation-sensitive microenvironmental cues in the homing process. These results may have important clinical implications in the design of BM transplantation protocols. (BLOOD. 2002;100:3545-3552)

Homing, engraftment, and fate of transplanted hematopoietic stem cells (HSCs) remain poorly understood phenomena. While some studies support the specificity of certain components of the homing process, such as chemotaxis, extravasation, anchorage, survival, and proliferation of transplanted HSCs, other studies show no differences in the seeding efficiencies of mature and primitive bone marrow (BM) stem cell subsets or in the distribution of BM-homed cells in secondary recipients, suggesting that homing is not specific.

The majority of in vivo tracking studies have focused on examining the trafficking and cycling activity of phenotypically undefined populations of BM cells, with little regard for phenotypic characterization of donor cells homing to specific organs. It is possible that HSCs, which constitute less than 1% of graft cells, may proficiently home to BM, but that their specific homing is concealed by the massive movement of the large cohort of other, more mature BM cells. Studies examining homing of colony-forming cells may not accurately reflect the homing of long-term repopulating cells. Examinations of populations of cells defined on the basis of stem cell phenotype are beginning to show a different, possibly more specific, picture of homing. Identification of the adhesion molecule repertoire of primitive hematopoietic progenitor cells (HPCs) homing to the BM shortly after transplantation may provide evidence of adhesion molecules potentially involved in trafficking, homing, and lodging of transplanted HSCs in the BM and may outline a sequential requirement of different adhesion molecules at different stages of homing.

Investigations into the homing of HSCs following transplantation have most commonly been performed in myeloablative recipients. Increased vascular permeability resulting from radiation damage of endothelial and stromal cells may lead to nonspecific seeding of transplanted cells in various organs based largely on tissue mass and vascularity. Studies showing broader tissue distribution of donor cells in irradiated recipients and greater recovery of donor cells in BM of nonmyeloablative murine recipients suggest more efficient homing or better survival of primitive HPCs in nonmyeloablative marrow. Homing patterns of primitive HPCs in nonmyeloablative recipients may be even less informative, as nonmyeloablative recipients may lack the radiation-induced tissue damage and inflammation that can influence the homing patterns of transplanted HPCs. Studies using conditional models of nonmyeloablative or minimally myeloablative recipients, in the present work, trafficking patterns of primitive HPCs were mapped in the first 24 hours after transplantation of grafts.
consisting of either unfractionated low-density BM cells or purified Sca-1+ lineage (Lin-) fractions. We examined the in vivo distribution, recovery, cell cycle status, adhesion molecule expression patterns, and secondary long-term engraftment potential of cells homing to the BM of irradiated or nonirradiated mice. The results presented herein demonstrate that transplanted HSCs capable of long-term secondary hematopoiesis home more efficiently or survive better in nonirradiated recipients, which may have important clinical implications for BM transplantation in nonablated or minimally ablated patients.

Materials and methods

Mice

C57BL/6 female mice (CD45.2 allele) were purchased from Jackson Laboratories (Bar Harbor, ME) at 8 to 10 weeks of age and allowed to acclimate for 1 to 3 weeks prior to their use in these studies. B6.SJL-Pgk-1<sup>−/−</sup>B6.129.S2-Pkk2<sup>−/−</sup> (86.Boyl) congenic mice (CD45.1 allele) were either purchased from Jackson Laboratories or maintained in our breeding colony and used between 8 to 12 weeks of age. All studies were approved by the Indiana University School of Medicine Institutional Animal Care and Use Committee.

Donor cells

Bone marrow grafts consisted of low-density BM (LDBM) cells or purified Sca-1<sup>−</sup> lineage (Lin<sup>−</sup>) cells subfractionated on the basis of CD49e or CD26L expression into fractions enriched for long-term engraftment potential ([ENG]), Sca-1<sup>−</sup> lineage (Lin<sup>−</sup>CD26L<sup>−</sup>) as previously described. Adhesion molecules CD49e and CD26L were chosen in these studies so that grafts would consist of phenotypes where both positive expression (CD49e<sup>+</sup>) and negative expression (CD26L<sup>−</sup>) are enriched for long-term repopulating cells, as previously described. Donor LDBM or ENG cells were isolated from C57BL/6 or 86.Boyl mice and stained with either PKH26 or PKH6 (Sigma ImmunoChemicals, St. Louis, MO) as previously described, or with 0.5-1.0 μM CFSE<sup>−</sup> (Molecular Probes, Eugene, OR) according to manufacturer's instructions. After staining, cells were washed extensively and resuspended in complete medium (CM) (RPMI modified Dulbecco medium [RPMI] supplemented with 10% fetal calf serum [FCS]; Hyclone, Logan, UT), 2 mM t-glutamine, 100 U/ml penicillin, and 100 μg/ml streptomycin). All of the CM ingredients (except for FCS) were obtained from BioWhittaker (Walkersville, MD). When available, congenic donor cells were not labeled with any dye and were identified by appropriate CD45.1 or CD45.2 expression by flow cytometry. The choice of the green fluorescent dye CFSE and PKH26 or the red fluorescent dye PKH6 was based on the nature of the analyte to be performed on the cells after staining. The different tracking methods used in different experiments were evenly distributed along the time course of analyses after transplantation and were equally effective in detecting donor cells. Since CFSE<sup>−</sup>-stained cells exhibit aberrant cell surface staining of some antigens for 1 to 2 hours following CFSE<sup>−</sup>-staining (C.F.O.-T., unpublished data, 2000), cells were not tracked with CFSE<sup>−</sup> at the 1- and 3-hour time points.

Primary short-term (1<sup>st</sup>ST) cell tracking

Female recipient C57BL/6 or 86.Boyl mice between 10 and 12 weeks of age were lethally irradiated with 950 cGy administered in a single dose from a 137 Cs gamma irradiated (GammaCell 40; Nordion International, Kanata, ON, Canada) 17.5 to 20 hours prior to transplantation (mean ± 18.5 hours). Irradiated or nonirradiated mice received transplants via tail vein injections of 1 × 10<sup>5</sup> to 1 × 10<sup>6</sup> LDBM donor cells or 4 × 10<sup>5</sup> to 4 × 10<sup>6</sup> purified ENG cells. In experiments where BM-homed ENG cells were isolated and assayed for long-term engraftment potential, (<sup>1</sup>ST)-irradiated recipients were injected with at least 1 × 10<sup>5</sup> graft cells, while nonirradiated mice received at least 2 × 10<sup>5</sup> purified cells to facilitate donor cell isolation. Mice were killed 1, 3, 6, and 20 to 24 hours later, and BM, spleen, peripheral blood (PB), lung, and liver were collected and single-cell suspensions prepared and lysed. Lysed cells from LDBM transplant were analyzed for donor cell recovery, primitive phenotype, adhesion molecule expression, cell cycle status, and proliferation history, while lysed cells from ENG transplant were analyzed for donor cell recovery and engraftment potential in serial transplantations.

Calculation of recovery of donor cells

The frequency of donor cells falling within a light scatter gate including lymphocytes and large granular cells, was determined for each harvested tissue, based on the background fluorescence of cells from unmanipulated mice. This frequency was multiplied by the total number of cells in each tissue, then divided by the number of cells in the original graft to calculate the recovery of total transplanted cells. The number of BM cells harvested from both tibiae and femurs was considered to represent 18.7% of total marrow, or 40% if humerus and pelvic bones were also included. The total number of PB cells was calculated assuming the total PB volume to be 2 ml per mouse. Because of the low frequency of detectable donor cells when ENG cells were injected, flow cytometric files containing 2 × 10<sup>6</sup> to 1 × 10<sup>7</sup> events were saved and the frequency of donor cells calculated manually using event count.

Adhesion molecule and lineage analysis of harvested donor cells

Harvested BM cells from recipient of LDBM grafts were stained with Sca-1 and biotinylated antibodies to either CD11b (clone 2D10), CD43 (clone 5R), CD44 (clone 1H10), CD49e (clone 5H10.32; MFR5), CD31 (clone MEC 13.3), CD63 (clone MEL-14), or CD3 and CD45RB/B20. Biotinylated antibodies were developed with streptavidin-allophycocyanin (APC; Molecular Probes). Donor cells were distinguished from recipient by PKH2, PKH6, CFSE, or appropriate CD45.1 or CD45.2 staining as described above. All antibodies were from BD PharMingen (San Diego, CA). Donor cells exhibiting small light scatter properties characteristic of primitive cells were gated and examined for Sca-1 expression and primitive phenotype (CD3<sup>−</sup>CD45RB<sup>−</sup>) or adhesion molecule expression using a FACScan or FACSCalibur (Becton Dickinson Immunocytometry Systems [BDIS], San Jose, CA). Between 1 × 10<sup>5</sup> and 5 × 10<sup>5</sup> events were acquired per sample. To avoid seeing very large files, in some cases only donor-positive events were saved during flow cytometric acquisition.

Serial transplantation studies

BM-homed donor cells from 1<sup>ST</sup> recipients of ENG cells were isolated by flow cytometry, and 50 to 200 of these cells, along with 1 × 10<sup>4</sup> competitor LDBM cells of recipient origin, were transplanted into primary long-term (<sup>1</sup>ST)engraftment recipients within 3 hours of receiving lethal irradiation in a split dose of 700 cGy plus 350 cGy 4 hours apart. 1<sup>ST</sup> recipients were bled from the tail vein monthly for 6 to 7 months for analysis of donor-derived hematopoiesis by determining the percentage of CD45<sup>+</sup> or CD45<sup>−</sup> PB leukocytes. In some experiments, 1<sup>ST</sup> recipients were killed 6 to 7 months after transplantation, and 2 × 10<sup>6</sup> to 1 × 10<sup>7</sup> BM cells were transplanted into lethally irradiated (700 cGy + 350 cGy) secondary LT (<sup>2</sup>ST) recipients without competitor cells. 2<sup>ST</sup> recipients were bled from the tail vein monthly for 6 to 7 months for analysis of donor-derived hematopoiesis. In some experiments, donor-derived cells from 1<sup>ST</sup> and 2<sup>ST</sup> recipients were analyzed 6 to 7 months after transplantation for the percentage of lineage cells using phycoerythrin (PE)-conjugated antibodies specific for CD<sup>3</sup>, CD<sup>45RB</sup>, Gr-<sup>1</sup>, and Mac-1 cells.

Cell cycle status

Fresh or donor-derived Sca-1<sup>−</sup> cells from harvested BM and spleen of transplant recipients were isolated by cell sorting using a FACStar<sup>+</sup> or FACSVantage S flow cytometer (BDIS) and analyzed for cell cycle position using propidium iodide (PI) as previously described. The low
number of donor Sca-1+ cells attainable from PB precluded cell cycle analysis of these cells.

BrDU administration
Mice received 4 intraperitoneal injections of 100 µg BrDU in 200 µL H2O at 26, 24, 12, and 1 hour before receiving transplants of LDBM cells. Mice destined for 24-hour homing studies received an additional injection of BrDU 12 hours after BM transplantation.

BrDU staining
Donor-derived cells from mice administered BrDU were assayed for BrDU uptake by 2 different methods. In the first, donor Sca-1+ cells from BM or spleen at 1, 3, 6, or 24 hours after transplantation were isolated by flow cytometric cell sorting and then stained for BrDU as previously described. Briefly, sorted Sca-1+ cells were fixed with 1% formaldehyde (Tobininski, Rockville, MD) and 0.2% Tween 20 (Sigma) in phosphate-buffered saline (PBS) for at least 10 minutes but no longer than 24 hours. Cells were then treated with 4 M HCl in 0.5% Tween 20/PBS for 30 minutes at 37°C, washed with 0.1 M sodium borate (Sigma), and then washed with 0.2% Tween 20/PBS. Cells were then stained with fluorescein isothiocyanate (FITC)-conjugated anti-BrDU antibody (BD Pharmingen). Prior to acquisition, PI was added to a final concentration of 10 µg/mL for 60 minutes.

In the second method, bulk unsorted BM or spleen cells were analyzed for flow cytometrically using 4-color analysis for donor origin, surface phenotype, and BrDU incorporation simultaneously as previously described with slight modifications. Briefly, cells were stained with the appropriate anti-CD45.1-PE or anti-CD45.2-PE to identify donor cells, biotinylated Sca-1, anti-CD3 eychocyte, and anti-B220 eychocyte, followed by streptavidin-APC, then fixed with 1% formaldehyde overnight. In some experiments, Sca-1 eychocyte was used with biotinylated lineage markers developed with streptavidin-APC. All antibodies were from BD Pharmingen. Cells were permeabilized with 0.1% saponin PBS (Perm Buffer) plus 2% formaldehyde for 10 minutes at room temperature, pelleted, then permeabilized with 0.2% Tween 20/PBS for 10 minutes at room temperature, washed with Perm Buffer, and incubated with 100 to 500 Kunitz units of DNase (Sigma) in Hanks balanced salt solution for 60 minutes at 37°C. Cells were washed in Perm Buffer and then stained with anti-BrDU-FITC (BD Pharmingen).

Statistical analysis
Data are expressed as the mean ± SEM where applicable. Differences between groups were analyzed using an unpaired 2-sided t-test. Differences in chimerism were analyzed by repeated measures analysis of variance using an arcsine transformation. A probability value of less than 0.05 was considered significant for all tests.

Results
Identification of graft sizes allowing for adequate detection of homed cells
As a first step in examining the distribution of donor cells in vivo following transplantation, the number of donor cells homing to BM, spleen, or remaining in PB after transplantation was determined. Log increasing doses of donor LDBM cells from 1 × 10^6 to 1 × 10^10 cells were injected into single irradiated mice and allowed to home for 3 hours. The frequency of donor cells detected at 3 hours in all 3 tissues examined positively correlated with the number of graft cells injected (Table 1). Based on these results, subsequent experiments were designed to deliver between 17 and 90 × 10^6 cells per graft.

Recovery of donor cells in LDBM transplants
Total recovery (BM + spleen + PB) of graft cells was calculated based on the frequency of donor cells detected in BM, spleen, and PB, and the total number of nucleated cells within each tissue, as described in "Materials and methods." The frequency of donor cells ranged from 0.3% in nonirradiated spleen at 24 hours to 39% of total cells in 1-hour irradiated PB. The cellularity of irradiated BM, spleen, and PB in recipient mice ranged between 24.55 × 10^6, 3.8 × 10^6, and 1.4 × 10^7, respectively, depending on the time of analysis after transplantation (range, 19.5 hours for 1-hour time points to 42.5 hours for 20- to 24-hour time points). Cellularity of nonirradiated BM, spleen, and PB averaged 2.12 × 10^7, 7.2 × 10^6, and 1.4 × 10^7, respectively.

Total recovery of donor cells did not vary significantly between 1 and 24 hours in either transplant setting but was, however, slightly higher in nonirradiated recipients at each time point compared with irradiated mice (bars in Figure 1A-B), in agreement with previous suggestions. Total recovery in nonirradiated mice was significantly higher than that in irradiated mice when data from all 4 time points were pooled together (7.6 ± 0.6, n = 18; and 5.6 ± 0.3, n = 38, respectively, P < .05). When individual tissues were examined in both transplant settings, recovery of donor cells was highest in BM from 3 to 24 hours after transplantation (Figure 1A-B), reflecting either the specificity of BM homing of graft cells or the relatively larger mass of this tissue, or both. Distribution of donor cells differed with time in the 2 transplant settings. While recovery of donor cells in BM increased rapidly and reached a plateau by 3 hours in irradiated mice, recovery in nonirradiated marrow remained fairly constant. Recovery in nonirradiated BM was significantly greater than that in irradiated BM when data from all 4 time points were pooled together (5.7 ± 0.5%, n = 18; and 3.70% ± 0.2%, n = 38; respectively, P < .05). Interestingly, while recovery in irradiated spleen did not change significantly over time, donor cells accumulated initially in nonirradiated spleen and then declined at later time points (Figure 1A-B). As expected, cell recovery was highest in PB at 1 hour but declined thereafter. In initial experiments, lung and liver were also examined for the recovery of donor cells, but since total recovery in the 2 tissues combined was typically less than 0.1%, these tissues were omitted from subsequent analyses.

Table 1. Frequency of donor cells detected in BM, spleen, and PB of irradiated mice 3 hours after transplantation is positively correlated with the number of graft cells injected

PB indicates bone marrow; PB, peripheral blood.

*Numbers of PHK298* syngeneic low-density BM cells injected into single irradiated recipient mice.

*Numbers represent the percent of donor graft cells detected by flow cytometry in BM, spleen, and PB at 3 hours after transplantation. The lower limit of detection was <0.01%: n = 1 for each value.

*Correlation coefficient of linear regression analysis of cell dose and percent of donor cells detected in BM, spleen, and PB.
performed on donor Sca-1+ cells exhibiting light scatter properties characteristic of primitive HPCs (low side and forward scatter). Frequency of lineage-negative, CD43+, CD49e+, CD49d+, and CD62L+ BM-homed donor Sca-1+ cells increased in irradiated mice from 1 to 24 hours after transplantation, while these frequencies mostly fluctuated in irradiated mice (Figure 3A-E). CD11a and CD44 were present on 95% to 100% of donor Sca-1+ cells in the graft and all tissues examined and did not differ in irradiated and nonirradiated mice (n = 3-11, data not shown). At 20 to 24 hours, a slightly higher frequency of Sca-1+ cells in nonirradiated mice expressed CD43, CD49e, and CD49d and were CD3-CD45R/B220- (Figure 3), matching a phenotype enriched for long-term engrafting cells. Interestingly, while approximately 45% to 55% of donor Sca-1+ graft cells and those remaining in PB at 1 hour expressed CD62L, the majority of Sca-1+ cells recovered from BM at 1 hour lacked CD62L expression (Figure 3E).

Recovery and serial transplantation of donor cells in ENG cell transplants

To examine the trafficking of primitive HPCs more directly, grafts composed of $4 \times 10^4$ to $3 \times 10^5$ sorted cells enriched for stem cell phenotype (Sca-1- lin CD49c+ or Sca-1- lin CD62L+) were tracked at 20 hours in irradiated and nonirradiated 1ST mice. Figure 4 shows representative dot plots of typical analyses of donor cells found in BM and spleen tissues and the range of frequencies of donor cells detected in all experiments in BM, spleen, and PB. Similar to increased recovery of graft cells in BM of nonirradiated recipients when LDBM grafts were transplanted, recovery of purified ENG phenotypes was higher in nonirradiated mice, while recovery in spleen and PB was similar in the 2 settings (Figure 5).

We next defined the in vivo trafficking patterns of HSCs in irradiated or nonirradiated mice by examining the long-term repopulating potential of BM-homed donor cells 20 hours after injection of ENG cells. To this end, BM-homed donor cells were isolated from irradiated or nonirradiated 1ST recipients, and 50 to 200 of these cells transplanted competitively into 1ST-irradiated recipients. No significant differences in chimera were detected in 1ST recipients of BM-homed donor cells from irradiated or nonirradiated 1ST mice (Figure 6A) up to 6 months after transplantation. However, when $2.5 \times 10^6$ LDBM cells from 1ST recipients were transplanted into 2LD mice, donor-derived chimera was significantly greater in recipients of BM-homed cells from nonirradiated 1ST recipients (Figure 6B), suggesting more efficient homing or better survival of primitive HPCs in nonmyeloablative marrow. BM-homed cells from both irradiated and nonirradiated 1ST mice were equally effective in providing multilineage engraftment in both 1ST and 2LD recipients and did not apparently differ in their relative contribution to either myeloid or lymphoid lineages (data not shown).
Figure 3. Frequency of lineage-negative, CD43+CD49e+CD49d−, and CD62L+ cells among donor Sca-1+ cells in BM and PB at 1, 3, 6, and 20 to 24 hours following transplantation in irradiated or nonirradiated recipients. Irradiated or nonirradiated mice received 10^7 to 10^8 LD50 cells, killed at the indicated time points, and donor Sca-1+ cells in BM and PB analyzed for lineage expression (A), expression of CD43 (B), CD49e (C), CD49d (D), and CD62L (E) by flow cytometry as described in "Materials and Methods." PB samples were only analyzed at 1 hour because of infrequency of donor cells at later time points. Data are expressed as the mean ± SEM percent of donor Sca-1+ cells that have light scatter properties characteristic of primitive hematopoietic cells and that express each adhesion molecule. Horizontal bars on each graph represent the mean percent of Sca-1+ cells in the original graft that express each adhesion molecule. For each time point, n = 6-11 for irradiated BM, n = 3-6 for nonirradiated BM, n = 3-7 for PB, and n = 4-7 for graft cells. *P < 0.05 when compared with earlier time points of same transplant group. **P < 0.05 when compared with 1-hour BM values.

Cell cycle status

To examine the activation of primitive HPCs following transplantation, donor Sca-1+ cells from BM and spleen were analyzed for cell cycle status by PI staining of sorted cells or by BrdU incorporation. Figure 7 shows representative BrdU and cell cycle analysis of BM-homed Sca-1+ and Sca-1+lin+ cells from irradiated and nonirradiated recipients 6 hours after injection of LDBM. More than 95% of donor Sca-1+ cells isolated from BM or spleen were in G0/G1 regardless of time of analysis or irradiation status, a frequency similar to that of Sca-1+ cells in the original graft (Figure 8A-B). No significant differences in G0/G1 status were noted between irradiated and nonirradiated mice at different times of analysis.

Less than 22% of BM- and spleen-homed Sca-1+ cells from irradiated or nonirradiated mice were found to contain BrdU when analyzed between 1 and 24 hours, although this frequency declined by 24 hours in irradiated mice (Figure 8C-D). The more primitive Sca-1+lin− cells were also analyzed for BrdU incorporation and found to contain less than 10% BrdU+ cells regardless of irradiation status (data not shown). Of interest is that in 6 of 9 experiments, donor Sca-1+ cells homing to BM of nonirradiated recipients contained between 2- and 10-fold more BrdU+ cells than BM-homed Sca-1+ cells in irradiated marrow (Figure 8D-C). A similar trend of increased cycling in nonirradiated marrow was noted for the more primitive Sca-1+lin− cells and the more mature Sca-1-negative cells (3 of 5 and 7 of 7 experiments, respectively; data not shown).

Figure 4. Flow cytometric analysis of donor cells in BM and spleen 24 hours after transplantation of purified Sca-1+lin− CD45+ cells into irradiated or nonirradiated C57BL/6 mice (CD45.2+) received 1-5 × 10^7 sorted Sca-1+lin− CD45+ cells of B6/Rij origin (CD45.1+). irradiated 20 hours later, and donor cells in harvested BM and spleen detected by flow cytometry as described in "Materials and Methods." The frequency of donor cells is given in the upper left quadrant of each dot plot and was calculated manually using event count from listmode files containing between 5 × 10^4 and 1 × 10^5 events. The range of frequencies of detected donor cells in all experiments is given in the table.

Figure 5. Percent recovery of donor cells in BM, spleen, and PB 20 hours after transplantation of purified Sca-1+lin− CD45+ cells into irradiated or nonirradiated C57BL/6 mice. Irradiated or nonirradiated mice received 4 × 10^7 to 5 × 10^8 sorted Sca-1+lin− CD45+ cells of B6/Rij origin (CD45.1+), killed 20 hours later, and percent recovery of donor cells in harvested BM, spleen, and PB was calculated as described in "Materials and Methods." Bars represent mean ± SEM recovery of cells in each tissue; n = 11 for irradiated, n = 4 for nonirradiated.

Discussion

In this report, we define the trafficking patterns and adhesion molecule repertoire of classes of phenotypically defined primitive BM cells early after their transplantation into lethally irradiated or nonirradiated recipient mice. Higher recovery of transplanted cells and increased incidence of CD43+, CD49e+, CD49d+, and Lin− BM-homed Sca-1+ cells in nonirradiated mice relative to irradiated mice suggests more efficient homing or better survival of primitive HPCs in a nonirradiated environment. The primitive nature of these cells was further substantiated in serial transplantation experiments, where BM-homed cells in nonirradiated mice were found to be relatively enriched for long-term engrafting cells capable of sustaining long-term hematopoiesis for 2 generations. Our results are in agreement with those recently reported by Bubnic and Keating, who documented the homing of long-term repopulating cells to BM of nonirradiated mice by 24 hours after transplantation in a similar transplant model.

The increase in CD43, CD49e, and CD49d expression on BM-homed Sca-1+ cells in nonirradiated mice correlates with the enhanced engraftment potential of BM-homed cells in nonirradiated mice and supports the earlier studies and those of others, suggesting an importance of these molecules in homing or engraftment of primitive HPCs. Whether these molecules are involved in homing and/or anchorage of primitive HPCs to BM or in modulating a yet-to-be-identified parameter important in engraftment remains to be determined. Nevertheless, these data suggest that while homing in myeloblastoid recipients may represent a random process due to radiation damage of stromal and endothelial cells, homing in nonmyeloblastoid recipients may not only be more specific, but may also better portray natural trafficking patterns of HSCs in vivo. Recent studies in parabiotic mice support the notion that a small number of HSC naturally traverse between blood and marrow in normal mice, further suggesting the existence of established migratory pathways for HSC between blood and BM in nonablated hosts. Our data suggest that these pathways are at least partially disrupted after lethal irradiation, such that fewer HSC home to, or survive within, an irradiated BM microenvironment. The reported generalized up-regulation of adhesion molecule counterreceptors, such as VCAM, ICAM, and PECAM, after irradiation may contribute to nonspecific seeding of transplanted HSC to sites other than BM.

Preliminary studies in our laboratory suggest that shorted time intervals between radiation dosing and transplantation may have favorable outcomes for homing and possibly engraftment, supporting the notion that radiation-sensitive microenvironmental cues may be involved in the homing process and fate of transplanted cells. Whether

**Figure 2. Flow cytometric analysis of BrdU incorporation in donor Sca-1+ and Sca-1+ cells in irradiated and nonirradiated recipient BM, and cell cycle analysis of donor Sca-1+ cells in irradiated recipient BM 6 hours after transplantation.** S5 × 10^6 BM cells of B6.BrdU origin were transplanted into irradiated or nonirradiated C57Bl6 mice. Mice were killed 6 hours later, and BM cells were lysed and stained with anti-BrdU-PE, Sca-1-biotin, CD3-cyocrome, and N-APC, followed by streptavidin-PE. Cells were permeabilized and stained with anti-BrdU-PE as described in Materials and Methods. A) and B) represent typical analyses, where donor cells (5.5%) are gated from all nucleated cells and analyzed for Sca-1 and lineage expression (B). Donor Sca-1+ cells (77% of donor cells; solid region in B) were then analyzed for their BrdU incorporation in irradiated (D) or nonirradiated (F) mice, or cell cycle status by PI staining (typical cell cycle histograms shown in G). Donor Sca-1+ cells (21% of donor Sca-1+ cells; dotted region in B) were likewise analyzed for BrdU incorporation (E). Sca-1+ cell histograms contain between 75 and 85 events, whereas Sca-1+ cell histograms contain between 250 and 701 events. Frequencies of BrdU+ cells and cells in S/G2 are given on each histogram.
radiation-induced bystander effects (reviewed in Mothersill and Seymour) negatively impact the function of transplanted primitive HPC and account for some of our observed differences in homing and engraftment in irradiated and nonirradiated mice is unknown. Nevertheless, our finding that graft cells home more efficiently to nonirradiated BM may partially explain the recent successes of BM transplantation in this scenario. A Better understanding of homing mechanisms may open these areas to manipulation and the possible design of protocols aimed at enhancing trafficking of transplanted HSCs to BM, which may be especially beneficial to those patients undergoing minimally ablative BM transplantation.

This report examined the adhesion molecule repertoire of phenotypically defined Sca-1+ cells early after transplantation. Although analysis of adhesion molecule expression on Sca-1+ cells would have yielded more complete knowledge of the homing patterns of primitive HPCs, analysis of such rare donor cell populations in recipient mice is technically difficult. However, the finding that CD62L−Sca-1+ cells, known to be enriched for long-term engraftment potential, rapidly homed to BM within 1 hour while the more mature CD62L+ cells remained in PB suggests the rapid trafficking of primitive HPCs in both irradiated and nonirradiated hosts. The dynamic changes in adhesion molecule expression observed on BM-homed donor Sca-1+ cells between 1 and 24 hours after transplantation suggest some of the differences in homing and engraftment seen in long-term bone marrow transplantation.

Hematopoietic Reconstitution of Irradiated, Stem Cell-Injected Mice:
Early Dynamics of Restoration of the Cell Lineages
of the Spleen and Bone Marrow

SANDRA C. MILLER

ABSTRACT

Hematopoietic stem cells, numbering approximately 1/100,000 cells in mammalian bone marrow, are capable of complete hematopoietic and immune reconstitution upon injection into a myeloablated host. The present studies aimed to analyze the earliest events in reconstitution of lethally irradiated host murine bone marrow and spleen, after injecting purified Thy 1"Lin-Sea-1" stem cells. Thy-1"Lin-Sea-1" cells were isolated by fluorescence-activated cell sorting (FACS) from the bone marrow of 4-week-old C57BL/6J-Thy 1.1, 1.1,5.1 mice and injected into preirradiated, syngeneic hosts. These stem cells were also injected into congenic hosts, i.e., C57BL/6-1.1, 1.5.2), and confirmed the donor origin of hematopoietic cells in the reconstituted host mice. Hematologically stained smears of the spleen and bone marrow of stem cell-injected recipients were prepared at 11, 14, 17, 21, 24, and 28 days after stem cell injection, and nucleated erythroid cells, mature granulocytes, and their myeloid precursors, monocytoids, and large and small lymphocytes were recorded as a proportion of all nucleated cells in each organ at each time interval. The results indicated that in the earliest post-stem cell injection intervals, both organs were predominantly erythroid and myeloid. Only at the later intervals did both organs show high proportions of large lymphoid cells and their progeny, small lymphocytes. Thus, early (<1 month) dynamics of hematopoietic reconstitution after transplantation of purified hematopoietic stem cells, is cell lineage specific.

INTRODUCTION

The concept and definition of the pluripotent stem cell stands without controversy as a cell that (1) reconstitutes lethally irradiated hosts into which it is injected, (2) is capable of self-renewal, and (3) enables full reconstitution of all hematopoietic and immune cell lineages in the recipient. Such pluripotent stem cells in the bone marrow occur with a frequency of 0.5-1/106 bone marrow cells (<1-3). Successful separation of primitive stem cells by means of the phenotype Thy-1"Lin-Sea-1" has been achieved (<1). The aim of the present work was to follow the relative reappearance of several categories of hematopoietic and immune cell lineages in both the bone marrow and the spleen at selected, frequent intervals throughout the first month after lethal irradiation and injection of irradiated syngeneic mice with only 500 Thy-1"Lin-Sea-1" stem cells. This early, post-transplant time period represents an important, critical phase in which survival or death of the transplant animal is often determined. The additional advantage of studying the dynamics of return of the various hematopoietic and immune cell lineages in this model system derives from the fact that the transplant, consisting of only purified stem cells, is uncomplicated by overwhelming numbers of committed precursors and mature forms for the various hematopoietic lineages, all of which are mixed with very few stem cells in normal bone marrow grafts.

Department of Anatomy & Cell Biology, McGill University, Montreal, Quebec, Canada H3A 2B2.
Long-term bone marrow culture data are the most powerful predictor of peripheral blood progenitor cell mobilization in healthy donors

Background and Objectives. There is wide interindividual variation in progenitor cell mobilization. The present study was aimed to analyze steady state hematopoiesis in healthy donors and its influence on hematopoietic progenitor cell (HPC) mobilization.

Design and Methods. Bone marrow (BM) was aspirated from 72 healthy donors prior to administration of recombinant human granulocyte colony-stimulating factor (G-CSF). Analyses of CD34+ cells and semisolid cultures as well as long-term cultures were performed from BM or leukapheresis products.

Results. Male donors showed a higher number of BFU-E (p=0.007) and committed progenitors (p=0.05), a better stromal layer (p=0.02), and higher long-term bone marrow culture (LT-BMC) counts (p=0.05) when compared to those in female donors. When correlating the culture pattern of the BM with the data from the leukapheresis products, we observed that the number of the immature progenitors in BM correlated significantly with both the number of CD34+ cells and CFU-GM in the first leukapheresis. Univariate analysis revealed that the following variables had a beneficial impact on the number of CD34+ cells: male sex, body weight >73 Kg, G-CSF schedule and results of LT-BMC; although in the multivariate analysis only the number of CFU-GM obtained after LT-BMC showed a significant influence (p<0.001).

Interpretation and Conclusions. These results confirm the interindividual variation in HPC mobilization among healthy subjects, with LT-BMC counts being the most reliable predictor, expressing the behavior of the immature progenitors and their relationship with the microenvironment.

Key words: healthy donors, long-term bone marrow cultures, CD34+ cells, hematopoietic progenitor cells, mobilization.

Haematologica 2005; 90:353-359

Peripheral blood progenitor stem cells (PBSC) obtained after granulocyte-colony stimulating factor (G-CSF) administration are being increasingly used for autologous and allogeneic transplantation. Allogeneic transplantation using peripheral blood instead of bone marrow stem cells is associated with faster neutrophil and platelet recovery, without a higher incidence of acute graft-versus-host disease (GvHD). These events are probably due to a higher number of hematopoietic progenitor cells (HPC). Glimm et al. have also reported that PBSC contain a higher number of short-term repopulating hematopoietic cells (STRC) that engraft sequentially in NOD/SCID-β2 microglobulin-null mice. However, several studies indicate substantial interindividual variation in HPC mobilization among healthy donors. Some donor characteristics such as age, sex and weight, as well as apheresis volume or G-CSF schedule have been identified as variables influencing CD34+ cell collection, but there are several studies showing that there are poor mobilizers even among young, healthy donors. As far as we know, the in vitro behavior of immature progenitor cells in healthy individuals has not been extensively analyzed by long-term bone marrow cultures (LT-BMC). Although cell cultures (especially LT-BMC) are not routinely performed in transplantation centers, the results of such assays are important for understanding the behavior of different types of progenitors and the mobilization pattern, which is more important from theoretical and intellectual points of view than it is of practical use.

The aim of the present study was to analyze healthy donors in order to ascertain whether there are individual characteristics influencing steady state hematopoiesis behavior. We also wanted to analyze whether hematopoietic parameters
could influence the final yield of leukapheresis products. For these reasons, the percentages of CD34+ cells, committed HPC and immature HPC (assessed by LT-BMC) were evaluated in bone marrow cells prior to mobilization and their influence on leukapheresis yields was assessed.

Design and Methods

Donors
Bone marrow cells and leukapheresis products from 72 healthy donors, considered for allogeneic hematopoietic stem cell transplantation were analyzed. The donors' characteristics are shown in Table 1. Their median age was 41 years (range 11 to 72) with a male/female ratio of 44/28. After informed consent had been obtained, a bone marrow aspiration was performed in all donors before starting recombinant human G-CSF. Donors received G-CSF at a dose of 5 μg/kg/day (19% of cases) or 5 μg/kg/12h (81% of cases) over at least four days, until the apheresis procedures had been completed according to the policy of our center; both protocols were used sequentially and each donor received the dose active at that moment. The collection of peripheral blood stem cells was started on the fifth day of G-CSF administration. The blood volume processed was two to three times the donor's total blood volume. Donors underwent 1 to 3 leukaphereses (median 1). Procedures were performed using a continuous flow cell separator (CS-3000 plus, Baxter Healthcare corp., Deerfield, USA or COBE Spectra, COBE Inc., Colorado, USA). All patients were included in this study protocol after signed consent had been obtained according to the ethics committee of our institution. Flow-cytometry studies and cell cultures were performed in all healthy donors.

Flow cytometry studies
Whole bone marrow or leukapheresis product samples were stained using a stain-and-then-lyse direct immunofluorescence technique for analysis of the proportion of CD34+ cells, as previously described. Data were acquired in two consecutive steps on a FACScalibur (Becton Dickinson Biosciences, San Jose, USA) flow cytometer using the CellQuest software (BDB). In the first step, a total of 20,000 events/tube were acquired, and in the second step, acquisition throughout an electronic live-gate drawn on CD34+ cells was performed. In this latter step, 3x10⁶ events were measured with information only obtained from those events fulfilling the live-gate criteria. The Paint-A-Gate PRO software program (BDB) was used for data analysis.

Cell cultures
Mononuclear cells from bone marrow and leukapheresis products were used for semisolid and long-term cultures using methods previously reported. For clonogenic assays, mononuclear cells (MNC) were separated by centrifugation on a Ficoll Hypaque gradient (Lymphoprep™, Norgaard Co., Oslo) (d=1.077 g/mL). Interface cells were washed and resuspended on IMDM supplemented with FCS. The cells for long-term cultures were obtained by gravity sedimentation using a solution of 0.1% methylcellulose. The cells remaining in suspension were washed with IMDM-FCS.

Clonogenic assays
These assays were carried out, according to previously described methodology, in order to evaluate the committed HPC (CFU-GM, BFU-E and CFU-Mix) from bone marrow. In the leukapheresis products only CFU-GM were analyzed. We considered as CFU-GM colonies those colonies with a translucent appearance that contained granulocytes or macrophages or both. In our laboratory, colonies are considered to be more than 40 cells in an aggregate, whereas smaller numbers (5<40 cells) are considered to be clusters. The BFU-E colonies displayed a burst configuration of three to eight closely arranged erythroid clusters (mature BFU-E) or of more than eight clusters (primitive BFU-E), both dependent on erythropoietin being added to the culture. CFU-Mix colonies usually contained an erythroid component as well as cells from two of the other myeloid lineages. CFU-Mix showed a focus of hemoglobinized red cells and, at the same time, areas of dispersed translucent cells similar to parts of the granulocyte-macrophage colonies.

All the tests were performed in all patients (n=72).

Cultures were performed as previously described. Plating efficiency was defined as the number of colonies produced by 10^6 plated cells.

Long-term bone marrow cultures

LTBMSC were established in order to analyze the immature HPC in bone marrow and were carried out according to the method of Gartner and Kaplan with slight modifications. Briefly, 2x10^6 cells/ml were inoculated in tissue culture flasks in LTBMSC medium IMDM supplemented with 10% pre-selected fetal calf serum (PCS, Biowhittaker, Belgium), 10% horse serum (HS, PAA Laboratories, GmbH, Austria) and 5x10^-6 M hydrocortisone sodium succinate. The cultures were incubated in a humidified atmosphere with 5% CO2 in air at 33°C for eight weeks. At weekly intervals before re-feeding, the stromal layer formation was studied under an inverted microscope. The degree of confluence and the presence of adipocytes and cobblestone areas of hematopoiesis were assessed and four stromal layer subtypes were established: (i) with all cellular components; (ii) without adipocytes; (iii) without adipocytes or cobblestone areas; and (iv) without stromal layer formation. For re-feeding, half of the supernatant was removed and replaced with fresh LTBMSC medium. The non-adherent cells harvested were quantified and assayed for their CFU-GM content. After 8 weeks of culture the whole supernatant was removed and the adherent layer was detached by exposure to trypsin. Cells were recovered, washed, counted and assayed for their CFU-GM content.

Long-term cultures from leukapheresis products

These assays were performed in a two-step procedure: stromal layers were established with bone marrow from a volunteer donor. When at least 70% of the flask’s surface was covered by the layer, the flask was irradiated with 15 Gy in a Cobalt bomb (Theratron 780). A second inoculum to obtain hematopoiesis was constituted by leukapheresis mononuclear cells. CFU-GM progenitors were evaluated during 8 weeks, as for the one stage long-term culture.

Statistical analysis

Statistical computations were carried out with the SPSS 10.0 program. The following tests were used: Student’s T-test for unpaired data, Pearson’s or Spearman’s test for quantitative correlation and multivariate stepwise analyses.

Results

PBSC collection results

As shown in Table 1, only one apheresis procedure was necessary for the majority of donors (72%) and three aphereses were necessary in only four cases. The mean number of mononuclear cells and CD34+ cells obtained in the first leukapheresis was 5.3±1.9x10^6/kg and 4.5±2.3x10^6/kg, respectively.

Results from bone marrow samples

Results of semisolid and long-term cultures obtained from steady state donor bone marrow samples are shown in Table 2. The sum of all committed progenitors (CFU-GM+BFU-E+CFU-Mix) obtained from 10^6 plated cells was 285±265, with CFU-GM being the most frequent progenitors and CFU-Mix the least frequent. In LT-BMC the production of CFU-GM was extremely heterogeneous, as reflected by the wide range of the number of colonies (374 to 31601 colonies/10^6 plated cells).

The mean percentage of CD34+ cells obtained in bone marrow was 0.93±0.05. No significant correlation between these values and the number of bone marrow progenitors (either committed, analyzed by semisolid cultures, or immature, analyzed by LTBMSC) was obtained. By contrast, when the steady-state hematopoiesis was analyzed, there was a clear, positive correlation between the numbers of committed stem cells and the number of immature ones analyzed by LT-BMC (Table 3).

Certain donor characteristics were associated with differences found in the number of colonies obtained both in the semisolid cultures and the LT-BMC (Table 3).

All the tests were performed in all patients (n=72). Results are expressed as mean±SD per 10^6 cells plated for CFU-GM, CFU-E, CFU-Mix and total progenitors, and per 10^6 cells plated for %SL. *p<0.05; **p<0.01. % SL: percentage of surface covered by the stromal layer. Components of SL: 1= all components present in the stromal layer (normality).

4). For example, when a fixed number of cells was plated, compared to female donors, male donors had a higher number of BFU-E (p=0.007), higher number of total progenitors in semisolid cultures (p=0.05) and a better stromal layer formation (p=0.02) with more cellular components. Moreover, donors with a body weight above 73 kg produced more progenitors in culture, although differences only reached statistical significance for CFU-Mix (p=0.04). When the age of donors and percentage of CD34+ cells in bone marrow were analyzed, no statistical differences were found for any of the cut-off points used.

In the LTBMCS studies, we observed that male donors showed higher cell counts (both CFU-GM and mononuclear cells) for values analyzed each week, and they also showed greater stroma formation with more cellular components, which reflects a better microenvironment. These differences between LTBMCS from male and female donors were statistically significant (p<0.05).

Results from leukapherases

Table 5 shows the plating efficiency and absolute numbers of CFU-GM generated both in the first and in all subsequent leukapherases performed. A wide range of inter-individual variation was observed. The median number of CFU-GM in the first leukapheresis was 211 colonies /10^6 cells plated (range 9-1800). (Table 5)

Number of CD34+ cells (n=56; p<0.0001) (Figure 1), and, to a lesser extent, CFU-GM present in the first leukapheresis product (r=0.45; p=0.001) and in the final apheresis (r=0.40; p=0.006). By contrast, neither the committed bone marrow progenitor cells nor the percentage of CD34+ cells in bone marrow showed a significant relationship with the quality of the apheresis.

Factors influencing the PBPCSC collection

In order to ascertain their predictive value, we analyzed a series of clinical and culture assay variables. Univariate analysis revealed that the following variables had a beneficial impact on the yield of CD34+ cells or mononuclear cells (Table 6): male sex, body weight above 73 Kg, dose of 5 µg/kg/12h of G-CSF and a higher number of CFU-GM in LTBMCS. Furthermore, male sex was associated with a lower number of leukaphereses, with differences close to statistical significance (p=0.06). In order to ensure that the donor's body weight did not condition the differences in results, the parameter was independently analyzed and produced similar results with only one new variable, sex, showing an impact on
CFU-GM yields ($p=0.017$). When a multivariate analysis was performed in order to assess which variables could have an independent impact on CD34+ cell mobilization, only the total number of CFU-GM generated after LTBM showed a significant influence ($p<0.001$). This significance was maintained when the body donor’s weight was considered.

### Discussion

Long-term cultures are used to analyze primitive hematopoietic stem cells and their relationship with the bone marrow microenvironment, while clonogenic assays are used to analyze committed hematopoietic progenitor cells. Taken together, both types of assay offer a comprehensive measurement of marrow function.

Peripheral blood hematopoietic progenitor cells have been successfully employed in autologous and allogeneic transplantation and their use has been associated with a significantly faster hematologic recovery than that afforded by bone marrow progenitor cells. This effect is probably related to the fact that the leukapheresis product contains several fold more progenitor cells than does bone marrow but also because higher numbers of STRC are present in mobilized peripheral blood. However, it has frequently been reported that a wide interindividual variation exists in the characteristics of peripheral blood progenitor mobilizations among healthy donors. This is why continuous studies are carried out on steady-state hematopoiesis in healthy donors. In the present work we analyzed how different parameters of steady-state hematopoiesis, as well as other individual characteristics (such age or weight) or the G-CSF schedule, may influence final leukapheresis yields. Regarding the behavior of bone marrow progenitors, a great degree of variability in the

plating efficiency and number of immature progenitors in bone marrow samples from healthy donors was observed, showing that there is considerably interindividual variability in hematopoiesis. Interestingly, differences were particularly striking between sexes with males showing a higher production of all types of progenitors and, moreover, a better stroma confluence, and hence a better microenvironment. As far as we know, this feature (the influence of donor sex on the number of all hematopoietic progenitors and stroma formation) has not been previously reported. However, a higher proportion of erythropoietic precursors in men has been related to the stimulatory effect of androgens.#

The second goal of the present study was to analyze whether steady-state hematopoiesis could influence the yields of leukapheresis. We found that the only parameter which correlated with the final number of progenitor cells obtained in leukaphereses was the number of CFU-GM during LTC-MBC. It is well known that these progenitors reflect the number of immature hematopoietic progenitors in bone marrow, which, theoretically, will be mobilized into the peripheral blood after G-CSF administration. Our results confirm, using a multivariate approach, those published recently by Carlo-Stella et al. who showed that steady state marrow LTC-IC had a clear relationship with the CD34+ and CFU-GM cell yields in leukapheresis after G-CSF mobilization.

In previous studies it was observed that some donor characteristics influenced peripheral blood progenitor cell mobilization. From Data from the Spanish Registry showed that age (above vs below 38 years) and G-CSF schedule (once vs twice a day) are the most powerful predictors of CD34+ cell mobilization. However, poor mobilizers have been observed in all age groups. In the present analysis the clinical factors that influenced the peripheral blood mobilization were: age, male sex, G-CSF schedule, higher body weight and a higher percentage of CD34+ cells in the bone marrow. However, these influences on mobilization were only observed using univariate analysis. The influence of age has been observed by other authors, in fact, older donors show a poorer apheresis yield. It should be noted that among our group only 5 donors were older than 60 years. When a multivariate analysis was performed, the only variable that retained independent predictive value was the number of immature progenitors, as detected by LT-BMC cultures. Previous analyses in the autologous transplantation setting have shown the relevance of immature progenitors on peripheral blood cell recovery. In the present study these results were not confirmed in the allogeneic setting. This could be due to the fact that a second apheresis was performed when not enough cells were obtained with the first apheresis and this could have disguised the real impact of the immature progenitor cells.

Taken together, our results confirm the interindividual variation in progenitor cell mobilization among healthy subjects. Some individual donor characteristics (sex, G-CSF schedule) can influence cell yields after mobilization. However, the only independent parameter that influences mobilization is the production of CFU-GM in LTMC which reflects the behavior of the immature progenitors and their relationship with the microenvironment. Although this kind of analysis is of no clinical value because of the long period that is required for their results, our analysis shows that there are poor mobilizers, even among young donors, because of an inefficiency in mobilizing hematopoiesis. These endogenous differences in hematopoiesis and their possible causes are of great interest for further analysis and point to new ways to overcome such problems in healthy donors.

NLH, CP and MCC were responsible for the conception of the study and interpretation of results. NLH and CP performed the statistical analysis and wrote the manuscript. All authors critically revised the paper and give the final approval for its submission. The order in which the names of the authors appear is based on their contribution to the study. JPSM and MCC, as heads of department and laboratory, are cited last. The authors declare that they have no potential conflict of interest.

CD34\(^+\) cell subsets and long-term culture colony-forming cells evaluated on both autologous and normal bone marrow stroma predict long-term hematopoietic engraftment in patients undergoing autologous peripheral blood stem cell transplantation

(Received 3 February 2001; revised 9 July 2001; accepted 10 July 2001)

Objective. The aim of this study was to evaluate which CD34\(^+\) cell subset contained in leukapheresis products could be regarded as the most predictive of long-term hematopoietic recovery after autologous peripheral blood stem cell transplantation (auto-PBSCT).

Materials and Methods. Based on data from 34 patients with hematologic malignancies, doses of CD34\(^+\) cells and CD34\(^+\) cell subsets, defined by the expression of HLA-DR, CD38, CD117 (c-kit), CD123 (a subunit of IL-3/IL-3R), CD133 (AC133), and CD90 (Thy-1) antigens, were correlated with the number of short-term (i.e., colony-forming cells [CFC]) and long-term culture CFC (LTC-CFC) generated at week 5 of culture and with the kinetics of hematopoietic engraftment following auto-PBSCT. The capacity of autologous stroma (AS), normal human bone marrow stroma, and M2-10B4 marine cell line to sustain CD34\(^+\) cell growth was comparatively evaluated in the LTC assay.

Results. Our data demonstrated that some of the most primitive progenitor subsets (CD34\(^+\)CD117\(^-\)HLA-DR\(^-\), and CD34\(^+\)CD38\(^-\)HLA-DR\(^-\)) showed the strongest correlation with LTC-CFC numbers generated within the AS, whereas no significant correlation was noted using normal bone marrow stroma. Multivariate analysis showed that the only CD34 cell subset independently associated with long-term (3 to 6 months) platelet engraftment after auto-bone marrow transplantation was the CD34\(^+\)CD117\(^-\)HLA-DR\(^-\) phenotype; long-term erythroid engraftment was correlated with CD34\(^+\)CD38\(^-\)HLA-DR\(^-\) cell content. The latter further influenced platelet engraftment in the first 3 months after auto-PBSCT. The most predictive parameters for neutrophil engraftment were CD34\(^+\)CD38\(^-\)HLA-DR\(^-\) cell subtype and the total LTC-CFC quantity infused.

Conclusions. These data further support the hypothesis that the type of stromal feeders influences the frequency of LTC-CFC, possibly because they differ in their ability to interact with distinct subsets of hematopoietic stem cells. Furthermore, as the use of AS in LTC assay can mimic in vitro the human bone marrow microenvironment, it can be speculated that this culture system could be a useful means to study the kinetics of recovery of bone marrow stroma following chemotherapy and PBSCT. From these results, it can be concluded that some CD34\(^+\) cell subsets appear to be more reliable predictors of long-term hematopoietic recovery rates than total CD34\(^+\) cell quantity. © 2001 International Society for Experimental Hematology.
Long-term culture (LTC) of bone marrow (BM) cells have been used as an in vitro model of hematopoiesis to study the interactions among early progenitors, stroma, and regulating factors [1–4]. Different stromal layers have been used in LTC assays, and recent data have shown that the type of stromal feeder used affects the frequency and maintenance of long-term culture colony-forming cells (LTC-CFC) [5]. Transformed murine and human engineered feeder cell lines, such as M2-10B4 [6], MS5 [7], S17 [8], and FBMD-1 [9] secreting supplementary growth factors, are widely used in the LTC assay, even if their ability to support the growth of hematopoietic stem cells (HSC) was found to differ from cell line to cell line [8–10]. Some authors showed that human primary BM cultures [11,12] are able to generate stromal layers that are more efficient in supporting HSC growth than the mouse-derived feeders, even if a regular and reliable provision of normal BM may present practical difficulties to many laboratories. Alternative methods are represented by the use of either cryopreserved normal BM [13] or preformed stroma and autologous stroma (AS) [14]. The use of stromal-dependent LTC has demonstrated the importance of the adherent layer as a reservoir of the most primitive stem cells and that a direct contact between stromal and hematopoietic cells is critical for stem cell growth and differentiation [15–17].

Although CD34+ cells expressing little or no CD38 and lacking HLA-DR antigen define a primitive subpopulation of progenitors in fetal liver, leukapheresis products (LP) [18,19], cord blood, and BM [20,21], at the present time it is not known which progenitor cell subsets are optimally predictive of short- and long-term engraftment after autologous peripheral blood stem cell transplantation (autoPBSC) [22–28]. Most published reports have focused on the analysis of early post-transplant multilineage recovery [29–31], while the influence of CD34+ subsets and LTC-CFC cells on long-term engraftment has not yet been clearly defined [32]. Interestingly, absent stromal layer development was found to be associated with poor hematologic recovery after bone marrow transplantation (BMT) [33].

The aim of this study was to evaluate which CD34+ cell subsets contained in LP could be regarded as the most predictive of long-term hematopoietic recovery after auto-PBSC. To reach this goal, we correlated CD34+ cell subsets with the numbers of both CFC and LTC-CFC generated within allogeneic normal BM stroma (NBMS), M2-10B4 cell line, and AS layers after 5-week culture of selected CD34+ cells obtained from LP of 34 patients with hematologic malignancies undergoing auto-PBSC. In addition, the different CD34+ cell subsets defined by highly sensitive flow cytometry were tentatively correlated with the number of LTC-CFC obtained from the adherent and nonadherent (i.e., supernatant) fractions collected after 5 weeks of culture. Finally, the total CD34+ cell quantity and doses of CD34+ cell subsets and LTC-CFC infused were correlated with the kinetics of hematopoietic recovery over a 6-month follow-up period after auto-PBSC.

Materials and methods

Patients and PBSC collection

PBSC were obtained from 34 patients (19 men and 15 women; median age 44 years, range 25 to 58) in remission: 24 with non-Hodgkin's lymphoma (NHL), 5 Hodgkin disease (HD), and 5 multiple myelomas (MM).

Patients were treated according to the following chemotherapy regimen: MACOP-B followed by sequential high-dose chemotherapy (Milan protocol) for NHL, ABVD schedule for HD, and VAD regimen for MM.

CD34+ cells were mobilized with chemotherapy as follows: 26 patients with high-dose cyclophosphamide (7 g/m²) plus granulocyte colony-stimulating factor (G-CSF, lenograstim or filgrastim, 5 μg/kg body weight/day), and 8 patients with intermediate-dose cyclophosphamide (4 g/m²) plus G-CSF (5 μg/kg body weight/day). Mean percentage of harvested CD34+ cells in LP was 3.23 ± 2.28 (range 1.1–12.6). The conditioning regimens adopted in this study for PBSC were mitoxantrone 60 mg/m² plus melphalan 180 mg/m² for NHL and MM, and BEAM regimen for HD. G-CSF administration started 5 days after PBSC and continued until absolute neutrophil count was >1,000/μL for 3 consecutive days. Mean interval between the end of preconditioning therapy and the mobilization regimen was 36 days (range 30–65). BM samples were collected at least 4 weeks after the last chemotherapy regimen to minimize the effect of cytotoxic drugs to the patient's BM microenvironment.

Mean number of CD34+ cells infused was 6.54 × 10⁹/kg body weight (range 2.65–11.0 × 10⁹/kg body weight). Three patients were transfused with a CD34+ cell dose <5 × 10⁹/kg.

Short-term engraftment was evaluated according to standard criteria (neutrophil count >500 μL and platelet count >20,000/μL on at least three consecutive analyses). Long-term recovery after auto-PBSC was assessed by evaluating the hemoglobin (Hb) level, white blood cell count, neutrophil count, and platelet count at different time intervals (1, 3, and 6 months after PBSC). Secondary graft failure was considered to have occurred if, on 3 consecutive days after full engraftment was documented, granulocytes decreased to <50/μL, and/or platelets to <20,000/μL. Incomplete recovery was considered for platelet count <50,000/μL and/or neutrophil count <1,000/μL.

PBSC were collected on a Baxter CS3000 cell separator (Baxter, Milan, Italy) using a continuous collection procedure until 2.5× the patient's blood volume had been processed [34]. The target value was 4 × 10⁸ CD34+ cells/kg. LP were cryopreserved with 10% dimethylsulfoxide and autologous plasma and stored in liquid nitrogen.

Controls. Normal BM was obtained from proximal epiphysis of eight subjects (mean age 49 years; male/female ratio 1:1) who underwent major orthopedic surgical intervention.

Purification of CD34+ cells from LP

Enriched CD34+ cell fractions were obtained by immunomagnetic separation (Mini-MACS CD34 isolation kit, Miltenyi, Bergisch Gladbach, Germany), as previously described. A mean of 7 × 10⁸ PBSC were separated on LymphoFlow-H 1.077 g/cm³ gradient (Cedarside Laboratories Limited, Hornby, Ontario, Canada), then incubated with an hapten-conjugated CD34 monoclonal antibodies (mAbs) (QBEND-10), followed by incubation with magnetic microbeads conjugated to an anti-hapten antibody. The positive frac-
tion and unseparated cells were stained with CD34 epitope class III-reactive mAb (HPCA2-FITC). CD34+ cell purity was measured by flow cytometry. Recovery, purity, and enrichment factor were calculated according to standard protocols [35].

Flow cytometric analysis of CD34+ cell subsets from LP
Immunomagnetically selected CD34+ cells were analyzed with a Facsscan flow cytometer (Becton-Dickinson, San Jose, CA, USA). The instrument was calibrated with fluorescein isothiocyanate (FITC), phycoerythrin (PE), and peridinin chlorophyll protein (Per-CP) beads provided by Becton-Dickinson. Data were analyzed with appropriate negative (isotypic) controls using CellQuest and Paint-a-Gate research software [36,37]. At least 20,000 cells were analyzed for each sample.

The CD34+ cell population was identified using a combined approach based on multicolor analysis and evaluation of light-scattering properties of the cells [38]. Flow cytometric data were expressed as percentage of positivity (using standard marker approach). Expression of the various antigens by CD34+ cells was evaluated by direct immunofluorescence using a multiparametric approach based on the use of the following combination of mAbs: CD34 (HPCA-2)-FITC/CD38 (HB-7)-PE/HLA-DR (clone L243)/Per-CP; CD34-FITC/IL-3/Receptor (clone 7G3)-PE/HLA-DR/Per-CP; CD34 (HPCA-2)-FITC/AC133-PE; CD34-FITC/CD117 (c-Kit)/R clone: 95C3)-PE/HLA-DR/Per-CP; CD34-FITC/CD90-PE (Thy-1, SE10)/HLA-DR/Per-CP. CD34, CD38, and HLA-DR mAbs were provided by Becton-Dickinson, CD90 and CD123 mAbs were purchased from PharMingen (San Diego, CA, USA), and AC133 was purchased from Miltenyi.

Determination of doses for the various CD34+ cell subsets were calculated by calculating the percentage of total CD34+ cells that expressed the appropriate marker of interest and multiplying that percentage by the CD34/kg values that had been previously determined.

Short-term colony assays from BM and LP samples
BM mononuclear cells (MNC) were isolated by centrifugation on Lymphoprep-H gradient, washed in phosphate-buffered saline, and plated in triplicate at a density of 1 x 10^6 cells in 35-mm Petri dishes (Bn, Milan, Italy) in 1.1 mL of a methylcellulose semisolid medium (Megacult H4343; Stem Cell Technologies Inc., Vancouver, Canada). Petri dishes were incubated at 37°C in a fully humidified atmosphere with 5% CO2 and scored at day 14 under inverted microscope (Wilovet-Wil, Wetzlar, Germany) for the presence of CFU (colony-forming unit granulocyte-macrophage [CFU-GM], burst-forming unit erythroid [BFU-E], multilineage colony-forming unit [CFU-GEMM]). Short-term colony assays also were performed seeding 0.5 x 10^5 cells/mL obtained from LP, as previously described.

BM stromal feeders
Patient microenvironment from 41 patients (including the 34 cases investigated by multivariate analysis in this study) affected by NHL (n = 28), HL (n = 7), and MM (n = 6) were investigated by CFU-fibroblast (CFU-F) assay [39]. Briefly, 1 x 10^9/mL BM-MNCs were resuspended in LTC medium containing Iscove modified Dulbecco’s medium (IMDM; Euroclone Ltd., Paington, UK) with presel ected 12.5% fetal bovine serum, 12.5% horse serum (both sera from Stem Cell Technologies, Vancouver, Canada), 1% L-glutamine (Euroclone), and 1% penicillin-streptomycin (Euroclone), and plated on 35-mm collagenated bio coated Petri dishes (Becton-Dickinson). The medium was changed every week, and cultures were incubated at 37°C in a humified atmosphere supplemented with 5% CO2. Fibroblast aggregates with >30 cells were scored as CFU-F. All determinations were performed in duplicate and expressed as mean values. The same method was used for detecting and scoring spontaneous endothelial colonies (CFU-Endo), according to a previously described technique [40].

Human primary feeder layers were obtained according to a modified version of the Gartner and Kaplan method [1]. BM-MNC cells were seeded at a density of 1 x 10^7 in T12.5-cm^2 plastic tissue culture flasks (Falcon) in LTC medium supplemented with fresh 5 x 10^-6 mol/L hydrocortisone sodium succinate (Sigma, St. Louis, MO, USA). After 20 to 30 days of culture, the confluence of the stromal layers was checked under inverted microscope and assessed by a semi-quantitative scoring system. The degree of confluence from the various culture systems was expressed as percentage of adherent cells covering the bottom of the flask (range 0-100%). Established autologous and normal stromal feeders, at least confluent for 70%, were irradiated at 16 Gy at the first passage of the culture. The stromal layers from 7 of 41 patients examined did not achieve the minimum level (70%) of confluence and, therefore, were not used for estimation of LTC-CFC. Thus, LTC-CFC was evaluated only in 34 patients.

The murine stromal nontransfected cell line M2-10B4 was maintained in RPMI 1640 medium (Euroclone) supplemented with 10% fetal bovine serum (Euroclone). At confluence, M2-10B4 cells were irradiated at 60 Gy. LTC-CFC assay on the M2-10B4 cell line was investigated in a smaller group of 12 patients (8 NHL, 2 HD, 2 MM). For this reason, statistical analysis between LTC-CFC numbers generated on M2-10B4 cells and CD34+ cell subsets and hematopoietic engraftment after PBSCT was performed in this study.

When a confluent stromal layer was achieved, selected CD34+ cells were seeded in T12.5 cm^2 plastic tissue culture flasks (Falcon) on the different irradiated stromal layers at a density of 3 x 10^6 cells in LTC-medium at 37°C and a humidified atmosphere with 5% CO2. Stromal-contact cultures were fed weekly by changing half of the medium. Nonadherent cells recovered from the supernatant were assayed in short-term methylcellulose assay for the presence of committed progenitors. At week 5 of culture, both nonadherent and adherent cells, after treatment with trypsin and after stromal cell depletion, were likewise washed and separately assayed for LTC-CFC content, as described earlier.

The immuno phenotypic characteristics of stromal cells were assessed using immunohistochemical technique with a wide range of mAbs [41].

Statistical analysis
Using the Pearson test, we first compared the percentage of positivity for the various phenotypic markers expressed by mobilized CD34+ cells with the number of week 5 LTC-CFC generated within the different stromal layers. In a further analysis, the Pearson test was used to examine the relationship among the incidence of LTC-CFC generated on AS, doses of total CD34+ cells and CD34+ cell subsets infused, and hematologic parameters (HB value, platelet count, white blood cell count) used to predict long-term engraftment after auto-PBSCT. The incidence of CFC present in PBSCT preparations was correlated with doses of CD34+ cells, CD34+ cell subsets, and clinical parameters at different time intervals after PBSCT. In all cases, the confidence interval was deter-
minded to identify which parameters showed the strongest and most constant correlations. A confidence range with \( p < 0.05 \) was considered significant. To assess whether a certain cell dose could predict for long-term hematopoietic recovery, we calculated the mean doses of the various CD34+ cell subsets transplanted in patients with normal and delayed long-term hematopoietic engraftment. Multiple regression analysis was used to determine which of the CD34+ subsets or LTC-CFC numbers are the best independent predictors for the long-term engraftment.

The number of CFC, CFU-F, CFU-En, and percentage of stromal layer confluence in controls and patients groups were compared using nonparametric statistics (Wilcoxon test).

**Results**

**Immunophenotypic profile of selected CD34+ cells**

Flow cytometric analysis of the selected CD34+ cell population showed a mean purity of 81.3% (range 60–99.7%) and a mean recovery of 60% (range 33–81%). Multicolor analysis of purified CD34+ progenitor cells obtained from PBSC is given in Table 1. In brief, the lowest mean percentage of CD34-expressing cells was found in the CD34+CD38- HLA-DR+ cell fraction (0.12%), as well as in the CD34+CD38+ HLA-DR+ (0.18%), CD34+CD123+ HLA-DR+ (0.32%), CD34+CD90+ HLA-DR+ (0.49%), and CD34+CD38+ HLA-DR+ (1.1%) cell subsets. The highest values were found among the following CD34+ cell subsets: CD34+CD38- HLA-DR+ (98.5%), CD34+CD123+ HLA-DR+ (92.2%), CD34+CD117+ HLA-DR+ (77.3%), and CD34+AC133+ (75.9%).

**Short-term colony assays of BM and LP samples**

No significant difference was found between the clonogenic potential of BM cells from patients in remission and controls. Cell morphology and colony size were comparable in the two groups. Mean values of the clonogenic potential of hematopoietic progenitors obtained from LP are given in Table 2.

**Clonogenic mesenchymal progenitors and stromal confluence assays**

With regard to the microenvironment, patients showed a significantly lower CFU-F number than controls (\( p = 0.003 \)) (Table 2). The incidence of CFU-En found to grow spontaneously in LTC assay was higher in BM samples obtained from NHL and MM patients compared with controls (1.5 vs 0.45; \( p = 0.01 \)) and other patient categories, as previously described by our group [41]. We also evaluated the capacity of the autologous and normal BM stromal cells to form a confluent monolayer usable as primary feeder layer in the LTC assay (Table 2). Healthy control stromal layers always reached the confluence (100%), whereas BM specimens from the patient group displayed a variable confluence degree (range 70–100%). However, in 7 (17%) of 41 samples analyzed (4 NHL, 2 HD, 1 MM), the stromal layer confluence capacity was particularly impaired (mean 35%, range 10% to 55%). Cells from these cases were not used as feeder layers in the LTC-CFC assay and, therefore, were excluded from this study.

**LTC-CFC assay**

The number of committed progenitors generated from week 1 to week 5 of culture was assessed, and the results were subdivided according to the type of stromal layer used in the LTC assay. As shown in Figure 1A, the mean numbers of CFU-GM/10^5 CD34+ cells derived from AS (1416.2 at week 1 of culture to 251.5 at week 5) were found to be higher than those on NBMS (906.8 at week 1 of culture to 165 at week 5) and M2-10B4 cell line (732.2 at week 1 to 61.9 at week 5); however, these differences were found to be not significant, except at week 1 comparing CFU-GM on AS vs those on M2-10B4 (\( p = 0.01 \)). The frequency of BFU-E (Fig. 1B) from the M2-10B4 cell line was lower (42 at week 1 to 0 at week 5) than that on AS (179.2 at week 1 [\( p = 0.01 \)] to 3.2 at week 5) and NBMS (121.8 at week 1 to 0.64 at week 5). No significant differences in the incidence of CFU-GEMM among AS (21 at week 1 to 0 at week 5),

CFU-GM = colony-forming unit granulocyte-macrophage per 10^5 LP derived cells; BFU-E = burst-forming unit erythroid per 10^5 LP derived cells; CFU-GEMM = colony-forming unit granulocyte, erythroid, monocyte, and megakaryocyte per 10^5 LP derived cells; CFU-F = colony-forming unit fibroblast per 10^5 BMMNC; CFU-En = colony-forming unit endothelial colony per 10^5 BMMNC.

NBMS (16 at week 1 to 0.4 at week 5), and M2-10B4 (5 at week 1 to 0 at week 5) were found (Fig. 1C). Figure 1D shows the variation of total CFC number during the 5 weeks of culture of the LTC assay.

With regard to the total number of LTC-CFC after 5 weeks of culture, the highest value was seen on AS compared with both NBMS and M2-10B4, but these differences were not significantly different.

At week 5 of culture, we considered separately the number of LTC-CFC generated from nonadherent and adherent fractions. The mean values obtained from the adherent fraction were significantly lower than the values from the nonadherent fraction. The highest number of LTC-CFC from the adherent fraction was seen on AS, whereas lower values were documented in LTC-CFC on NBMS and, above all, on the M2-10B4 cell line (p values are given in Table 3).

Data collected from a smaller series of 12 patients showed a good reproducibility of our LTC-IC culture system. In fact, if the same CD34 sample was seeded onto three identically derived stromal support layers, the 5-week CFC activity on the three identically derived stromal layers was similar (p = NS).

Furthermore, purified CD34+ cell preparations obtained from different positive selection procedures were grown in triplicate on several AS preformed layers. Results were found to be comparable in all culture systems (CV < 7%; p = NS).

In three experiments, purified CD34+ cells from healthy subjects were grown onto AS and data were compared with

![Diagram](image_url)
allogeneic NBMS and M2-10 B4 cell line. LTC-CFC number was found to be higher on AS than on allogeneic NBMS and cell line (data not shown).

Correlation between CD34+ cell subsets, CFC from LP, and LTC-CFC from different stromal feeders
A strong correlation between the total number of CD34+ cells and of CFU-GM contained in the LP (p = 0.0001) was found. The incidence of CFU-GM from LP was correlated with the CD34+AC133+ cell subset (p = 0.03) and inversely with CD38+DR- (p = 0.048) (Table 4). No strict associations between CFC and other CD34 cell subsets were noted in our study.

With regard to LTC-CFC in vitro assay, the strongest and most constant correlations were observed between CD34+CD117+HLA-DR- (p = 0.016) and CD34+CD38+ HLA-DR+ (p = 0.02) progenitor cell subsets and LTC-CFC number, generated within the AS cell culture. No significant correlations were found between CD34+ cell subsets and LTC-CFC evaluated on NBMS.

With regard to the correlations between the clonogenic potential of CD34+ progenitors obtained from the adherent and nonadherent (i.e., supernatant) fractions collected after week 5 of culture of the LTC assays and the different CD34+ cell subsets, we found that the CD34+CD38+DR- (p = 0.006) and the CD34+CD117+HLA-DR- (p = 0.016) cell subtypes showed a strong correlation with the adherent fraction generated within AS. No correlation were found with the non adherent fraction (Table 4).

Correlation between doses of CD34+ cells, CD34+ cell subsets, CFU-GM colonies, LTC-CFC infused, and kinetics of engraftment after auto-PBSCT
We correlated doses of CD34+ cells and CD34+ cell subsets infused with the incidence of LP-derived CFU-GM and LTC-CFC, and the kinetics of engraftment in the late posttransplant period (3 to 6 months after PBSCT). These data were compared with the following hematologic parameters: Hb level, and neutrophil, leukocyte, and platelet counts at 1, 3, and 6 months after auto-PBSCT.

With regard to clinical data, short-term engraftment occurred in all patients examined in this study (range 9–12 days after PBSCT). For long-term engraftment after PBSCT, 30 of the 34 patients achieved a neutrophil count >1,000/μL, and 29 achieved a platelet count >50,000/μL over a 6-month follow-up period. Within this patient group, two patients with NHL occasionally required platelet and red blood cell transfusions 2 to 6 months after PBSCT. Loss of platelet engraftment occurred in the same 4 patients who experienced a transitory loss of neutrophil engraftment. All five patients who presented a late loss of neutrophil and/or platelet engraftment received a number of CD34+ cells (6.21 × 10^6/kg) comparable to that infused into patients who achieved good long-term hematopoietic engraftment (6.87 × 10^6/kg CD34+ cells) (Table 5).

No significant correlation was found between the total CD34+ cell quantity and clinical parameters.

A positive correlation between the number of transplanted LTC-CFC tested on AS and platelet count 1 month after auto-PBSCT was noted (p = 0.048) (data not shown). Higher correlations were found between LTC-CFC tested on AS and platelet values at 3 to 6 months post-transplantation (p = 0.004). No significant correlation was found between doses of LTC-CFC on NBMS and hematologic parameters (Table 4).

With regard to CD34+ cell subset analysis, complete and durable platelet engraftment was correlated with CD34+CD117+DR- (p = 0.04) and CD34+AC133- (p = 0.027) cell subsets (Table 5). CD34+CD38+DR- cells also showed a direct correlation with both leukocyte (p = 0.025) and neutrophil count (p = 0.023) 3 to 6 months after PBSCT; CD34+AC133- cell doses were correlated with long-term (3 to 6 months) leukocyte (p = 0.03) and neutrophil (p = 0.02) engraftment; and CD34+CD123+DR- correlated only with neutrophil count (p = 0.038).

Table 5 shows that the numbers of CD34+CD117+DR-, CD34+CD38+DR-, and CD34+CD123+DR- cells/kg infused were significantly lower in the group of patients (n = 5) who had delayed or long-lasting loss of engraftment from month 3 to 6 after PBSCT. In contrast, all patients who had received higher doses of these cell subtypes experienced complete and durable platelet and neutrophil engraftment after PBSCT.

Multivariate analysis showed that the only CD34 cell subset independently associated with long-term (3 to 6 month) platelet engraftment after auto-BMT was the CD34+CD117+HLA-DR+ phenotype (b = 0.63, p = 0.039). A significant association between the CD34+CD38+HLA-DR+ cell content and platelet engraftment also was found, but this relation reached a significant level only within 3 months after auto-PBSCT (b = 0.49, p = 0.011). In contrast, the only parameter predictive for long-term erythrocyte engraftment was the CD34+CD38+HLA-DR+ cell content (b = 0.45, p = 0.023). In the first 3 months after auto-PBSCT, both CD34+CD38+HLA-DR- cell number (b = 0.77, p < 0.001) and the total LTC-CFC quantity infused (b = 0.51, p = 0.011) were associated with neutrophil engraftment. In contrast, no correlation was found between CD34+ cell quantity and long-term hematopoietic engraftment.

Discussion

In this article, we assessed the predictive value of the total quantity of CD34+ cells and of the various CD34+ cell subsets obtained from LP for the long-term hematopoietic recovery after auto-PBSCCT in patients with hematologic malignancies in remission phase. To obtain this goal, we also tested the ability of selected CD34+ progenitors obtained from LP to produce progeny over long time spans by LTC assay on different stromal cell feeder layers. Because it has been postulated that BM microenvironment could play a role in HSC engraftment and considering that our LTC system was based on the use of both human primary autologous and normal BM stroma, we also examined the clonogenic potential of BM mesenchymal cells in the pretransplant period. Our data showed that cells from patients with hematologic malignancies could have a lower CFU-F incidence than that of normal BM, and occasionally a slower and reduced stromal layer formation capacity, compared with that of the control group, thus confirming previous reports [42]. However, these alterations do not necessarily lead to altered architecture of BM microenvironment or defective functional support for in vitro hematopoiesis, as further supported by our data from LTC assay on AS that exhibited a normal supportive capacity for stem cells. Previous studies documented that either chemotherapy or autologous and allogeneic stem cell transplantation could damage the BM microenvironment [43–46], and these alterations were found to be correlated with a very poor hematopoietic recovery after BMT [33]. However, based on our results, to obtain an efficient stromal layer from these patients, we would recommend collecting BM aspirates as far as possible from the time of administration of the cytotoxic drugs. This could

Data are subdivided according to whether or not patients achieved good hematologic recovery 3–6 months after autologous transplant.
The two groups of patients with normal or delayed long-term engraftment were compared using Wilcoxon’s test.

AS = autologous stroma; NBMS = normal bone marrow stroma.
minimize the short-lasting negative effect of chemotherapy on the BM microenvironment.

With regard to the capacity of different stromal cell layers (AS, NBMS, and M2-10B4) to sustain the proliferation of selected CD34+ progenitors in the LTC-CFC assay, we observed a higher number of CFC generated within the AS and NBMS than those on M2-10B4 line, thus suggesting a specific release of BM human stroma-derived cytokines capable of inducing the differentiation and proliferation of progenitor cells. These data confirm previous findings indicating that the type of stromal feeder influences the frequency and maintenance of LTC-IC in different pathologies [5] and may suggest that certain cell types do not provide an ideal environment for stem cell growth [5,8,47].

Comparison between the expression of the various immunophenotypic markers (HLA-DR, CD38, CD117 [c-kit/R], CD123 (α subunit of IL-3/R), AC133, and CD90) on CD34+ cells and the in vitro incidence of LTC-CFC from LP showed that some of the more primitive CD34+ cell subtypes, such as CD34+CD117-DR- and CD34+738 HLA-DR-phenotypes) positively correlated with week 5 LTC-CFC numbers generated within the AS. No correlation was found between CD34+ cell subsets and week 5 LTC-CFC numbers from NBMS. These results further support the hypothesis that distinct stromal cell subtypes could in vitro interact selectively with different subsets of stem/progenitor cells, and that the various stromal cell feeders used in this study have a different ability to support in vitro stem cell growth, thus confirming previous results [48,49].

In this study, we also studied the differences in the clonogenic potential of selected CD34+ progenitor cells obtained from the adherent and nonadherent (i.e., supernatant) fractions collected after week 5 of culture of the various LTC assays. Our data confirm that some CD34+ subpopulations, such as CD34+CD38-HLA-DR- and CD34+CD117-HLA-DR- cells, have a preference to proliferate in close contact to human stroma layers and particularly to AS.

Based on our data and the fact that the homing process by HSC is rather specific, the use of AS in the LTC assay can be proposed in some selected cases to better investigate the in vivo interactions between HPC and BM stroma in patients undergoing BMT or PB SCT and for assessment of the kinetics of recovery of patient BM microenvironment after chemotherapy and/or PB SCT [50]. In contrast, NBMS had a prevalent capacity to select in vitro more committed CD34+ progenitor cells cultured in LTC assay. Our culture system also stressed the importance of assessing the progenitor content of the adherent layer, in line with two recent studies [51,52] that investigated the interaction between BM stroma and HSC by an expanding family of proteins, referred to as connexins. Our results could be explained by the occurrence of allogeneic mismatch between the selected CD34+ cells and the type of stromal cells used in LTC assay. Sugiru et al. [53] recently provided further evidence that formation of cobblestone colonies under major histocompatibility complex (MHC)-mismatched stromal cells significantly decreased compared with MHC-matched stromal cells. This was related to MHC class I molecule mismatch [53].

With regard to clinical data, until now no clear correlations between the incidence of transplanted LTC-IC, doses of CD34+ cell subsets infused, and long-term hematopoietic recovery after PB SCT were found [20,22,28,29], even if it is expected that LTC-IC would contribute more to later than early reconstitution following transplant [54]. Several authors found a positive correlation between the presence of certain CD34+ cell subpopulations and the incidence of LTC-IC in apheresis products [55], which is in accordance with our own data showing that complete and durable platelet engraftment after auto-PB SCT was found to be influenced by CD34+CD117-DR- cell content, whereas the only CD34+ cell subset independently associated with long-term neutrophil and erythrocyte recovery was the CD34+CD38- HLA-DR- phenotype. These results suggest that stem cell subpopulations defined by negativity for CD117 and HLA-DR and positivity for CD38 antigen appeared to be more reliable predictors of long-term hematopoietic recovery rates than total CD34+ cell dose infused, thus supporting the validity of our approach in this context. These CD34+ cell subsets were able to identify patients who experienced delayed engraftment 3 to 6 months after PB SCT. Interestingly, the same two CD34+ cell subsets showed the strongest correlation with LTC-CFC grown on AS, thus confirming the biologic role played by these progenitor cell subsets. Multivariate analysis also showed that in the first 3 months after auto-PB SCT, better neutrophil recovery was correlated with the number of transplanted LTC-CFC generated on AS. These in vitro data make a testable prediction that using NBMS or AS cells in LTC assay would improve the in vivo analyses of stem cell recovery after PB SCT. However, the patients examined in this study were mobilized with chemotherapy plus G-CSF. As a result, these conclusions may not apply to PB SCT mobilized with G-CSF alone.

At this point, it should be said that our functional and phenotypic analyses were performed on selected CD34+ cells. From a theoretical point of view, this could represent a bias of the study; however, some considerations must be made. First, it should be kept in mind that using both Ficoll and Percoll density gradients to establish culture assays causes a considerable loss of CD34+ cells [56,57]. Second, multicolor flow cytometric analysis of LP-derived CD34+ cell subsets is far from standardized, especially for samples having low percentages of CD34+ cells. Based on these data, we thought it noteworthy to estimate the presence of the various CD34+ cell subsets on purified CD34+ cells, to minimize these methodologic problems. Selective loss of progenitor subsets following CD34+ cell enrichment procedures has been documented in a few reports [58–60], raising the possibility that our analysis cannot predict the composition of the various progenitor cell subpopulations present in the whole LP.
In conclusion, these data further support the hypothesis that the type of stromal feeders influences the frequency of LTC-CFC, and that the use of human stromal layers could be more suitable for an in vitro study that more strictly analyzes the in vivo engraftment process following autologous PBSC. Furthermore, the CD34+ cell subsets defined by CD117, CD38, and HLA-DR appear to be more reliable predictors of long-term hematopoietic recovery rates than total CD34+ cell quantity. These data may help to predict the repopulation capacity of PBSC, especially when relatively low numbers of CD34+ cells/kg (<3 x 10^6/kg) are reinjected.

The Elusive Peripheral Blood Hemopoietic Stem Cell

Donna E. Hogge, Heather J. Sutherland, Peter M. Lansdorp, Gordon L. Phillips, and Connie J. Eaves

Long-term culture initiating cells (LTC-IC) are primitive hematopoietic progenitors that give rise to clonogenic cells when provided with a supportive feeder layer of mesenchymal cells. These LTC-IC possess many of the characteristics expected of marrow-repopulating "stem cells" including high proliferative and multilineage-differentiative capacity and resistance to 4-hydroperoxycyclophosphamide (4-HC) killing. In addition, stem cells are known to persist and may proliferate in murine LTC, and human marrow grown in LTC has been successfully used as hematopoietic support for myeloablative therapy. LTC-IC, as well as clonogenic precursors, circulate in normal peripheral blood, and the concentration of both progenitor types can be increased by cytotoxic chemotherapy and/or growth factors. When mobilized peripheral blood cells are used as hematopoietic support for high-dose chemotherapy, engraftment has often been more rapid than that achieved with autologous marrow. Thus, primitive hematopoietic cells circulate in human blood, which can enable hematopoietic reconstitution following aggressive therapy for malignant disease.

CHARACTERIZATION OF PRIMITIVE HUMAN HEMATOPOIETIC CELLS IN LONG-TERM CULTURE

The ongoing production of mature blood cells is the end result of the activity of primitive precursor cells termed hematopoietic stem cells. Stem cells are characterized both by their ability to generate more mature, differentiated progeny and by their capacity to self-replicate or self-renew. They are a population distinct from the progenitors that give rise to colonies of mature blood cells when placed in semisolid media with a source of hematopoietic growth factors. These latter cells are committed to differentiate down one or more lineages, and have limited proliferative capacity and little or no ability for self-renewal. In animals the "stem cell" function of a particular cell or population is assessed by its ability to reconstitute multilineage hemopoiesis in lethally irradiated recipients. Since in vivo assays are impractical in man, in vitro systems have been developed to allow the characterization and quantitation of primitive hematopoietic precursors. One such system termed the long-term culture (LTC) assay has been used by our group to study early events in human hemopoiesis.

When unseparated bone marrow cells are placed in culture at high concentration with appropriate medium but in the absence of added growth factors, an adherent layer of mesenchymal stromal cells (largely fibroblasts, endothelial cells, and fat cells) forms with which primitive hematopoietic progenitors become associated. These progenitors proliferate and differentiate over several months in culture, releasing their clonogenic (or colony-forming) and mature cell progeny (largely granulocytes and macrophages) into the culture medium. The ongoing production of these colony-forming units (CFU) and mature cells is the result of the differentiation and proliferation of primitive hematopoietic cells termed long-term culture initiating cells (LTC-IC). The presence of these LTC-IC can be detected and their number counted by assaying for the presence of CFU in cultures where hematopoietic cells are maintained on a feeder layer of bone marrow stromal cells for a minimum of 5 weeks. Beyond this time point, any colony-forming cells initially present in the culture should have disappeared through differentiation or death, and those detected will be the result of differentiation by LTC-IC.

In the absence of added growth factors, the maintenance of hematopoietic activity in LTC is dependent on the presence of the stromal feeder layer. When the hematopoietic population to be assayed is depleted of endogenous stromal cells (as is the case for fluorescence-activated cell sorter (FACS)-purified bone marrow cells) or does not normally contain such stromal cells (which is true for peripheral blood cells), a preestablished feeder must be provided. The total clonogenic content of the cultures after 5 weeks has a linear relationship with the number of hematopoietic cells from a given sample initially plated onto the

Seminars in Hematology, Vol 30, No 4, Suppl 4 (October), 1993: pp 82-91
feeder. The number of these CFU thus provides an indirect quantitation of LTC-IC.

Direct quantitation of LTC-IC and an assessment of their individual proliferative and differentiative potential can be obtained by placing limiting numbers of hemopoietic cells on feeders in microtiter wells. After 5 weeks of culture, the contents of each well are assayed for CFU. From such limiting dilution assays the frequency of LTC-IC in normal marrow has been determined to be one in 20,000 nucleated cells. The frequency in normal peripheral blood is approximately three LTC-IC/mL, or about 100-fold lower than the frequency in marrow as compared with other nucleated cells. In marrow the ratio of CFU to LTC-IC is normally about 8:1, whereas in the blood it is approximately 80:1 (Table 1). Individual LTC-IC produce an average of four clonogenic cells each regardless of whether they are isolated from marrow or blood. (Table 1). However, some LTC-IC from either source produce as many as 30 CFU. Although the majority of such CFU produced are granulocyte-macrophage progenitors (CFU-GM), many LTC-IC from marrow or blood produce CFU of more than one lineage, usually CFU-GM in combination with erythroid (burst-forming units) or mixed-lineage progenitors (CFU-GEMM).

The cell surface phenotype of LTC-IC has been used to partially FACS purify them from human marrow and blood. LTC-IC show low forward and side light scatter properties, and like clonogenic cells, are strongly CD34+. However, they differ from most CFU from bone marrow in that they are largely negative for HLA-DR or CD71 (transferrin receptor), and show weak retention of Rh-123. These characteristics are very similar in LTC-IC isolated from peripheral blood or marrow. However, CFU from blood differ from marrow CFU and are more similar to LTC-IC

from both sources in being HLA-DR and Rh-123-positive (Fig 1).

Bone marrow treated with 4-hydroperoxycyclophosphamide (4-HC) to remove malignant cells before autologous transplantation is depleted of CFU, but retains its marrow-repopulating (stem cell) capability. LTC-IC from marrow or blood are also 4-HC resistant. Although marrow CFU are 4-HC sensitive, their counterparts in peripheral blood survive treatment with the drug in a fashion similar to LTC-IC (Fig 2).

Thus, LTC-IC are primitive hemopoietic cells from which clonogenic cells are derived. They can be detected in both normal marrow and peripheral blood, although at much lower concentrations from the latter source. Many of the characteristics of LTC-IC suggest that they may be, if not identical to repopulating stem cells, at least closely related. These features include their immunophenotype, 4-HC resistance, multilineage potentiality, and the high proliferative capacity that some of them exhibit. In addition, repopulating stem cells are maintained in LTC initiated with mouse bone marrow, and human marrow

maintained in LTC has been used to support high-dose chemo/radiotherapy for patients with leukemia.\textsuperscript{14} The existence of LTC-IC in the peripheral circulation as well as marrow suggests that blood might also be used to support myeloablative therapy in man.

HEMOPHOIETIC RECONSTITUTION WITH PERIPHERAL BLOOD PROGENITOR CELLS

It has been known for many years that clonogenic hematopoietic progenitors are present in the peripheral blood of animals and human beings.\textsuperscript{15-17} Thus, even before LTC-IC had been demonstrated, a number of investigators had suggested that blood cells may have hematopoietic repopulating ability. Successful marrow reconstitution with peripheral blood progenitor cells (PBPC) in mice, monkeys, and dogs preceded the first studies in man.\textsuperscript{15,16,18}

In chronic myelogenous leukemia (CML), the concentration of CFU in the blood is enormously enriched over that in normal blood. McCarthy and Goldman\textsuperscript{19} used cells harvested from the blood of patients with CML in chronic phase to support high-dose chemo/radiotherapy for the same patients when their disease had advanced to the accelerated stage. Chronic-phase hematopoiesis was reestablished readily in most such patients. Although the short duration of the remissions achieved from the accelerated phase has led to this approach being largely abandoned for treatment of CML, these studies did demonstrate the successful use of PBPC for autologous transplantation.

Unfortunately, several initial attempts to use normal peripheral blood for transplantation were less successful, with two patients experiencing graft failure following PBPC transplants for aplastic anemia.\textsuperscript{20,21} Nevertheless, there was strong rationale for pursuing attempts to optimize peripheral blood harvests for hematopoietic reconstitution. First, a significant number of patients with advanced malignancy who would otherwise be candidates for myeloablative therapy cannot undergo marrow harvests, due to marrow involvement with their malignancy or previous irradiation to marrow harvest sites. Second, the ability to avoid general anesthesia and the trauma of the surgical procedure associated with marrow harvests is important in some patients. In addition, apheresis technology has improved sufficiently in the last decade to allow efficient processing of the large volumes of blood required to obtain adequate numbers of PBPC for transplantation. Finally, even in the early series some patients transplanted with autologous blood showed extremely rapid and sustained count recovery. The possibility that PBPC transplants would allow more rapid engraftment than marrow cells has been and continues to be one of the strongest motivations for the use of such cells to support high-dose chemo/radiotherapy for patients with malignant disease.

However, there were concerns about the use of peripheral blood that retarded the widespread adoption of PBPC transplants initially. The development of graft failure in some of the early patients treated with PBPC harvested during steady-state hematopoiesis was almost certainly due to the infusion of inadequate cell numbers. How-
ever, although it was clear that larger numbers of cells were needed to ensure engraftment when blood rather than marrow was used as a source of hemopoietic support, the optimum dose of cells or even the type of cells needed was unknown. In response to this uncertainty, investigators were forced to collect large numbers of cells requiring multiple apheresis procedures per patient. The collection and cryopreservation of these products were cumbersome and time consuming as compared with that for a single marrow harvest. Nevertheless, for certain groups of patients the rationale for PBPC transplants was compelling, and experience with the use of this modality has gradually accrued over the last decade. For example, in 1988 Kessinger et al. reported on a series of patients receiving PBPC transplants to support therapy for advanced, refractory Hodgkin's disease. In their group of 10 patients, median count recoveries on days 22, 27, and 23 for neutrophils numbering more than $0.5 \times 10^9/L$, hemoglobin levels greater than 10 g/dL, and platelets numbering more than $20 \times 10^9/L$, respectively, were comparable to what was typically reported for autologous marrow transplants. Although several patients showed delayed platelet recovery, the overall recovery times were very encouraging in this group of heavily pretreated patients.

**Mobilization of PBPC for Autologous Transplantation**

It had been known for some time that CFU numbers increase in the peripheral blood as the white blood cell (WBC) count increases following the nadir induced by cytotoxic chemotherapy. Juttner et al. were among the first to report a series of patients who received autotransplants of PBPC collected during the rebound that occurs following chemotherapy. In a series of eight patients with acute nonlymphoblastic leukemia who had PBPC collected during their recovery from remission-induction chemotherapy and subsequently used to support a high-dose conditioning regimen, count recoveries occurred at a median of 11, 12, and 14 days for neutrophils numbering more than $0.5 \times 10^9/L$, platelets numbering more than $50 \times 10^9/L$, and lymphocytes numbering more than $0.5 \times 10^9/L$. These times were significantly shorter than the investigators' previous experience with autologous or allogeneic marrow grafts for the same disease. This and the experience of others suggested the potential usefulness of PBPC in decreasing the morbidity and mortality associated with myeloablative therapy.

Clonogenic cells can also be mobilized into the blood of animals and man with the use of hemopoietic growth factors. Socinski et al. showed that patients receiving granulocyte-macrophage colony-stimulating factor (GM-CSF) had a greater than 10-fold increase in the concentration of CFU-GM and a fourfold increase in BFU-E concentrations in the blood. In the same study, they demonstrated the synergistic effect on CFU concentrations of combining GM-CSF with chemotherapy. One hundred-fold increases in CFU-GM concentrations were achieved in patients receiving both modalities.

Gianni et al. harvested PBPC from patients receiving GM-CSF following high-dose cyclophosphamide therapy. These cells were used to supplement autologous bone marrow for support of high-dose therapy in patients with advanced-stage but previously untreated Hodgkin's disease. Count recovery was very rapid in patients receiving PBPC as compared with that in patients receiving marrow alone, with medians of 9 and 11 days for recoveries of neutrophils numbering more than $0.5 \times 10^9/L$ and platelets numbering more than $50 \times 10^9/L$, respectively. These results were very encouraging, but it was not clear whether they could be repeated in different patient groups, particularly in those who had been heavily treated with previous courses of chemotherapy. It was also uncertain whether autologous marrow was necessary for long-term engraftment or whether PBPC alone could provide both short- and long-term hemopoietic support.

Over the last several years, we have treated 18 patients with PBPC alone to support high-dose therapy for advanced, malignant disease. PBPC were harvested in six patients during steady-state hemopoiesis, in six patients during count recovery following 7-g/m² cyclophosphamide therapy, and in six patients following cyclophosphamide plus GM-CSF therapy by continuous intravenous infusion. All of these patients had received one or more courses of chemotherapy with or without radiotherapy before PBPC harvests, and some had marrow involvement with their malignancy. We evaluated the kinetics of mobilization of both CFU and LTC-IC following cyclophosphamide
treatment. Rebound of CFU concentration to a mean of sevenfold above the normal range began 15 to 25 days after cyclophosphamide. The speed of rebound was several days faster in patients receiving GM-CSF in addition to cyclophosphamide (Fig 2). LTC-IC rebound followed kinetics similar to those of CFU, although it tended to occur several days earlier and peaked at a mean of fourfold above normal levels (Figs 3 and 4).

Leukapheresis was performed using a CS 3000 (Baxter Fenwal Division, Deerfield, IL) or Spectra (Cobe Laboratories, Lakewood, CO) blood cell separator. Nine liters of blood were processed over 2 to 3 hours, allowing collections of 5 to 10 \( \times 10^9 \) mononuclear cells. Following cyclophosphamide treatment, collections were begun when the total WBC count had increased after the nadir to more than \( 1.0 \times 10^9 /L \). A mean of seven collections were performed for patients harvested during steady-state hemopoiesis or for those receiving cyclophosphamide with or without GM-CSF (Table 3). Although the total number of mononuclear cells harvested was greater in patients harvested during steady-state hemopoiesis, the number of CFU was significantly increased in patients receiving cyclophosphamide mobilization. The mean number of CFU per kilogram was increased more than 13-fold in patients receiving GM-CSF plus cyclophosphamide. LTC-IC numbers harvested were also increased in patients receiving cyclophosphamide with or without GM-CSF, but the magnitude was less than that seen for CFU.

The PBPC collected from all 18 patients were used to support high-dose chemotherapy for the same patients. The speed of count recovery for neutrophils and platelets was compared with the dose of CFU and LTC-IC infused with the autograft. As shown in Table 4, most patients achieved recovery of both cell types, but in some cases recovery of neutrophils and/or platelets was delayed. In patients receiving cyclophosphamide, the speed of total WBC rebound during mobilization (days to WBC > \( 1.0 \times 10^9 /L \)) predicted the speed of engraftment following reinfusion of PBPC. In general, patients with the lowest CFU and LTC-IC doses had the longest recovery times. In six patients achieving count recovery by day 15, the dose of CFU infused (18 to 360 \( \times 10^9 /L \))
kg) was higher than in the four patients where WBC and/or platelet recovery was delayed past 25 days (1.0 to 12 \times 10^5/kg). Although the mean LTC-IC number infused was highest for patients with rapid engraftment, the range of LTC-IC dose overlapped with that seen for patients with delayed recovery. Thus, LTC-IC numbers do not appear to improve on CFU dosage in predicting time to count recovery posttransplant. From these data, it also appears that a dose of 20 \times 10^4 CFU/kg predicts rapid engraftment of neutrophils post-PBPC transplants. This dosage is less reliable in predicting platelet recovery, perhaps reflecting the fact that we assessed CFU-GM and BFU-E but not megakaryocyte precursors in our peripheral blood harvests. Juttner et al have also observed a relationship between CFU numbers infused and posttransplant recovery times.

The assessment of CFU numbers takes approximately 2 weeks, making its use to assess the quality of collections impractical in many clinical situations. We and others have assessed the possibility of using CD34+ cell numbers to indirectly assess the numbers of progenitors in peripheral blood collections. Because CD34+ cells are present at such low numbers as to be difficult to detect in normal blood, this method cannot be used for steady-state collections. However, when mobilization techniques such as cyclophosphamide with or without GM-CSF are used, the proportion of CD34+ cells increases dramatically, allowing their reliable enumeration (Table 2). In such samples, the number of CFU shows strong correlation with CD34+ cell numbers (r = .95). However, LTC-IC numbers show only a very weak correlation (r = .28). Thus, in mobilized PBPC collections, CD34+ cell numbers can allow rapid assessment of the CFU content of the autograft.

Growth factors other than GM-CSF are being used to mobilize PBPC. For example, Sheridan et al have used G-CSF–mobilized PBPC to supplement bone marrow autografts for patients with advanced malignancy. In such patients, there was a dramatic increase in the speed of platelet recovery and a concomitant decrease in platelet transfusion requirements as compared with that for patients receiving autologous marrow followed by G-CSF administration. This improvement in platelet recovery appears to be significantly better than what has been observed historically with GM-CSF–mobilized cells, and illustrates the possibility of achieving different effects with PBPC according to the way in which they are mobilized and collected.

**SUMMARY**

Hemopoietic progenitors circulate in human blood and can be collected by apheresis. Their

* Steady-state collections.
concentration in peripheral blood can be increased by a variety of maneuvers including cytotoxic chemotherapy or growth factors such as GM-CSF or G-CSF. The quality of the cells collected depends on factors such as the previous chemotherapy or radiotherapy received by the patient and the technique used to mobilize the cells. The cells responsible for the very rapid count recovery that is typically seen after PBPC transplants appear to be relatively mature, lineage-committed progenitors, and the number of such CFU in PBPC collections generally predicts speed of engraftment. The presence of true "stem cells" in PBPC collections from man has not been formally demonstrated. However, their presence in the blood of animals and the finding of LTC-IC, primitive hematopoietic progenitors of CFU, in human blood suggest that marrow-repopulating cells are likely to be present in the peripheral circulation in man, as well.

FUTURE DIRECTIONS

The usefulness of new growth factors for PBPC mobilization, alone and in combination, is being explored by many investigators. Combinations of factors that prove too toxic or impractical to use in vivo may be used more effectively for ex vivo expansion of progenitor numbers. The possibility of autologous PBPC transplants could make the recruitment and management of unrelated stem cell donors more successful by eliminating the need for the general anesthetic required for marrow harvests.

Ultimately, it is hoped that the use of PBPC transplants will decrease the morbidity and mortality associated with the hematologic toxicity seen with aggressive therapy for malignant disease. Reduction of such toxicity should allow dose escalation of cytotoxic therapy for patients with drug-sensitive cancer, hopefully translating into improved cure rates for such tumors.

Finally, PBPC may prove to be convenient targets for genetic modification either to generate progenitors as vehicles to deliver immunomodulatory molecules such as cytokines or growth factors to human tumors or metastases, or as targets for gene therapy for inherited human disorders.

The usefulness of PBPC for hematopoietic support has been clearly demonstrated over the last several years. The next few years should define the extent to which this role will expand in clinical medicine.

ACKNOWLEDGMENT

These studies were approved by the Clinical Screening Committee for Research and Other Studies Involving Human Subjects of the University of British Columbia. Informed consent was obtained from all patients and volunteer blood donors participating in these studies.

Discussion

Dr. Winkelstein: We have been using G-CSF to prime peripheral blood and can verify your observation of very rapid recovery of platelet counts. Most of our patients have recovered platelet counts within 20 days after myeloablative therapy using G-CSF-primed peripheral stem cells alone. They often get through with one or no platelet transfusions, which is quite impressive when compared with autologous bone marrow. My questions deal with some other markers of the LTC-IC. Other investigators have proposed that two other markers, CD38 and CD33, might be useful. You commented on the DR composition of these cells and the rhodamine. Do you have any information as to whether they are CD33 or CD38 positive or negative, and do you think this is relevant?

Dr. Hoggie: They are negative for CD33 in our hands. Other investigators have looked at CD34+ subpopulations in the peripheral blood. Investigators from Milan have mobilized peripheral blood stem cells with GM-CSF. Most of the CD34+ cells that were mobilized also appeared to be CD33+, but some were CD33-. These investigators reported that enumerating total CD34+ cells has predictive value in assessing the quality of the graft.

Dr. Winkelstein: In our laboratory, using three-color analysis of these cells, we find that about 4% of the CD34+ cells are CD38- and DR-, so it is a very small percentage. In most cases these are mobilizable cells.

On another point, it seemed that most of your data on the numbers of colony-forming cells referred to chemotherapy plus GM-CSF. Do you have any information about the growth factors alone, and how much of an expansion of the culture-forming cells in the peripheral blood pool these give?

Dr. Hoggie: We have not used the growth factors alone. Others have and clearly see expansion, but in the experience of most people, there is at least an additive effect of combining some kind of chemotherapy with the growth factors.

Dr. Bergstrom: My question about the LTC-IC relates to Dr. Winkelstein's question. Irv Weissman says that a stem cell is a stem cell is a stem cell. Is an LTC-IC an LTC-IC? How much heterogeneity or homogeneity do you see in that group? Do you think there are separate populations, maybe some that are not relevant to transplant at all, that you are including?

Dr. Hoggie: An LTC-IC is defined by the assay. As you can see from the in vitro data I presented, there is heterogeneity among LTC-IC in terms of their proliferative and differentiative capacity. So my feeling is that there may indeed be heterogeneity in this population in their in vivo behavior as well, and that we may find out that they do not all have stem cell potential.

Dr. Bergstrom: In your peripheral blood work have you ever documented that you have increased the number of LTC-IC over time, outside the body, using ex vivo type of treatments?

Dr. Hoggie: No, we have not. We have tried a number of different combinations of growth factors. If you maintain bone marrow cells in LTC, the number of LTC-IC gradually declines over time. When you add growth factors to try to reverse that decline, you can enhance the maintenance somewhat, but we have never achieved net expansion of LTC-IC. Other investigators, for example Steve Emerson, say they have achieved that kind of expansion in slightly different systems.

Dr. Pahwa: Why do you get increased CD34+ cells in peripheral blood after priming with G-CSF, because we know that G-CSF works in terminal differentiation and not in the progenitors—so why do you get so much CD34+ in the peripheral stem cells?

Dr. Hoggie: You are correct in saying that G-CSF acts on terminal granulocyte differentiation, but in our in vitro studies in LTC, we have seen effects of G-CSF on much earlier cell types. In fact, the combination of growth factors that we find most successful in maintaining LTC-IC in culture is a mixture that includes steel factor, interleukin-3, and G-CSF.

Dr. Pahwa: Do you think there is an interaction of G-CSF with other growth factors? Is there a whole cascade of factors that are pushing CD34 cells?

Dr. Hoggie: Well, certainly. Even if you just give one growth factor to a person clinically, there are all sorts of endogenous factors that are going to interact with that factor.

Dr. Gullati: With some of the data that has been
shown, the dosages of drug were not truly myeloablative, and I think people might want to keep this in mind. On another point, what is your feeling about the contribution of previous chemotherapy? Do you think some of the variation is from the burnout of the bone marrow, or is it true enhancement?

Dr. Hogge: It is because of the first point that you raise that I did not try to make any strong claims for the long-term reconstitutive ability of peripheral blood cells. In any kind of autologous transplant setting, unless you do gene-marking studies, for example, it is really difficult to prove that endogenous recovery is not occurring and maintaining hemopoiesis long term. With regard to your second point, our experience and the experience of a variety of investigators is that it is more difficult to mobilize cells from patients who have had a lot of previous chemotherapy. If you count LTC-IC in bone marrow samples, the concentration is only modestly decreased in patients who have received previous chemotherapy as compared with those who have not. However, certainly the clinical experience is that patients heavily treated with chemotherapy behave as though they have had significant reduction of their “stem cell reserve” when PBPC mobilization is attempted.
In vitro collection and posttransfusion engraftment characteristics of MNCs obtained by using a new separator for autologous PBPC transplantation

**BACKGROUND:** A clinical study was performed to evaluate the peripheral blood progenitor cell (PBPC) collection, transfusion, and engraftment characteristics associated with use of a blood cell separator (Amicus, Baxter Healthcare).

**STUDY DESIGN AND METHODS:** Oncology patients (n = 31) scheduled for an autologous PBPC transplant following myeloablative therapy were studied. PBPCs were mobilized by a variety of chemotherapeutic regimens and the use of G-CSF. As no prior studies evaluated whether PBPCs collected on the Amicus separator would be viable after transfusion, to ensure patient safety, PBPCs were first collected on another cell separator (CS-3000 Plus, Baxter) and stored as backup. The day after the CS-3000 Plus collections were completed, PBPC collections intended for transfusion were performed using the Amicus instrument. For each transplant, >2.5 x 10^6 CD34+ PBPCs per kg of body weight were transfused.

**RESULTS:** Clinical data collected on the donors immediately before and after PBPC collection with the Amicus device were comparable to donor data similarly obtained for the CS-3000 Plus collections. While the number of CD34+ cells and the RBC volume in the collected products were equivalent for the two devices, the platelet content of the Amicus collections was significantly lower than that of the CS-3000 Plus collections (4.35 x 10^10 platelets/bag vs. 8.61 x 10^10 platelets/bag, p<0.05). Collection efficiencies for CD34+ cells were 64 ± 23 percent for the Amicus device and 43 ± 14 percent for the CS-3000 Plus device (p<0.05). The mean time to engraftment for cells collected via the Amicus device was 8.7 ± 0.7 days for >500 PMNs per μL and 9.7 ± 1.5 days to attain a platelet count of >20,000 per μL—equivalent to data in the literature. No CS-3000 Plus backup cells were transfused and no serious adverse events attributable to the Amicus device were encountered.

**CONCLUSIONS:** The mean Amicus CD34+ cell collection efficiency was better (p<0.05) than that of the CS-3000 Plus collection. Short-term engraftment was durable. The PBPCs collected with the Amicus separator are safe and effective for use for autologous transplant patients requiring PBPC rescue from high-dose myeloablative chemotherapy.

**ABBREVIATION:** PBPC(s) = peripheral blood progenitor cell(s).

going autologous hematopoietic reconstitution. It included
time to engraftment and, to the degree possible in an
autologous transplant, short-term durability of the hematopoietic graft. To ensure that the Amicus device was suitable for
clinical use, each donor/patient was monitored to en-
sure the lack of any serious adverse events during the col-
collection, transfusion, and posttransfusion engraftment period.

MATERIALS AND METHODS

Informed consent
Written informed consent approved by the Yale University
Human Investigation Committee was obtained from all
patients who met Yale University School of Medicine and
Yale Cancer Center protocol entry criteria.

Patient criteria
Patients acceptable for entry into the study were males or
non-pregnant females who were 18 years or older. Histo-
logic confirmation of malignancy was required, as was a
Karnofsky score of >80 percent and a hematocrit of >20
percent prior to study entry. Exclusion criteria included:
- The absence of a signed informed consent
- Impaired hepatic function as evidenced by a total biliru-
bin of >2.5 mg per dL
- Renal dysfunction with a serum creatinine of >2.0 mg per
dL
- A positive transfusion-transmitted disease marker
- Active bacterial or fungal infections at the time of study
entry
- Altered mental status
- Pregnancy or lactation in females.
Except for two HCV antibody-positive patients, all patients
enrolled in the protocol were negative for anti-HIV-1/2,
anti-HCV, anti-HBC, anti-HTLV-I/II, HBsAg, HIV p24 Ag, and
a serologic test for syphilis. Protocol waivers on the two
HCV-positive patients were obtained from the study spon-
sor and from the two patients. These two patients were
entered into the protocol when their oncologists requested
that they be considered under provisions of the Americans
with Disabilities Act. Appropriate administrative approvals
were obtained to permit these patients to enter the study.

Patient demographics
Of the 31 patients studied, 14 were male and 17 were female.
Their diagnoses were breast cancer (n = 8; multiple myeloma
(n = 8); non-Hodgkin’s lymphoma (n = 10); Hodgkin’s disease
(n = 4); and ovarian cancer (n = 1). The average age was 46 ±
14 years for males, and 50 ± 8 years for females. For males,
the mean height was 182 ± 9 cm and for females 162 ± 9 cm.
Weight in kg was 89 ± 16 for males and 69 ± 12 for females.

Protocol design
There were four study goals, three in vivo and one in vitro.
The goals were to: 1) demonstrate that collection of pro-
genitor cells from the autologous donor/patient using the
Amicus separator was safe; 2) show that the CD34+ PBPCs
engrafted within the time frame established in the litera-
ture; 3) demonstrate that short-term engraftment was dura-
able; and 4) determine if one could be 95 percent confident
that at least 99 percent of the PBPC products would have
platelet counts less than 4 × 10^4. The study population size
was chosen on the basis of Baxter calculations suggesting
that a sample size of at least 30 patients allows a statement
with a 95 percent confidence that at least 99 percent of the
platelet counts in Amicus-collected PBPC products would
be less than 4 × 10^4 per unit. The platelet count parameter
was used to determine sample size because a low platelet
count was necessary to ensure that the collected product
could be processed efficiently on the cell selection device
(Isolex, Nexell, Irvine, CA). Evaluation of the Isolex device,
however, was not a part of this protocol. Thus, although
CD34+ cell count was important, the platelet count was also
considered to be of great importance. The CD34+ cell count
in the Amicus collection bag was compared with the CD34+
cell count in the back-up system (CS-3000 Plus, Baxter
Healthcare) collection bag, and the number of collections
required to achieve an engraftable dose was comparable.

While all practicing oncologists at Yale were eligible to
ter refer patients, patients entered into the protocol were
referred from one of three oncologists. Pre-study chemothera-
py varied with the patient. G-CSF was started 24-72 hours af-
after the mobilizing chemotherapy was given. The G-CSF
was continued daily at a dose of 5-10 μg per kg subcutaneously
until the end of the apheresis collections. A dose of 5 μg per
kg was used for eight breast cancer patients and 10 μg per
kg was used for all other patients as per the orders of the
referring oncologist. The number of G-CSF doses admin-
istered (i.e., the number of days of G-CSF treatment during
mobilization) was individualized for each patient. After
the patient’s CD34+ cell count rose above 20 per μL, a
central venous apheresis catheter was inserted. A short-term
double-lumen 11.5 Fr × 13.5 cm hard-shelled catheter
(Mahurkar, Quinton Instrument Company, Bothwell, WA)
was preferred. The level of 20 per μL was chosen to ensure
that the patient was able to mobilize CD34+ cells into the
peripheral blood. The actual CD34+ cell counts present in
the patient at the time of apheresis varied substantially and
the mean value ±1 SD is listed in Table 1. The G-CSF
was continued at a dose of 5-10 μg per kg per day subcutaneously
until the apheresis collections had ended and the
CD34+ cell goal determined by the oncologist (usually 5-10
× 10^6 CD34+ cells/kg) had been reached. After catheter
insertion, the patients underwent a series of leukapheresis
procedures.

To ensure patient safety, the study design mandated
that the order of machine apheresis collection not be ran-
domized. The protocol called for the first engraftable dose
to be obtained using the standard PBPC leukapheresis col-
collection machine (CS-3000 Plus) used at Yale. An engraftable

Apheresis collections

Machine operational parameters monitored included the number of cycles and cycle volume (Amicus device only), milliliters of ACD used, run time in minutes, liters of whole blood processed, and CD34+ cell collection efficiency (see Table 2). The CD34+ cell dose to be collected was specified by the referring oncologists. PBPCs were collected on the CS-3000 Plus device according to the following operating parameters specified by the manufacturer:

- CS-3000 Plus Interface Offset Detector setting at a mean of 110 for the collections (range 100-150)
- Whole blood flow rate setting of 70 mL per minute (range 60-80 mL/minute)
- Standard 12-15 liter volume as the amount of blood processed for each PBPC collection, small-volume collection chamber (60 mL)
- Blood citrate ratio of 12:1
- Collection of 100-150 mL of donor plasma during processing

If the collection chamber overfilled during the procedure, the bag was emptied into an open-system attached sterile bag, the small-volume collection chamber was filled with saline, and the collection resumed. A calcium gluconate drip was used if the patient complained of symptoms of citrate toxicity during the procedure.

The Amicus instrument was also operated using the manufacturer's instructions. The PBPC collection is controlled via the MNC collection computer software. The Amicus device collects progenitor cells by employing a single chamber design; the collection process, however, occurs in stages. Whole blood enters through the inlet line and immediately is separated into RBCs and plasma. The plasma carries platelets out of the chamber for return to the patient (Fig. 1). For the separation stage in the Amicus centrifuge, some plasma is recirculated and an auto-elutriation process enhances separation of platelets from MNCs and reduces platelet content in the PBPC product. PMN cells exit the chamber with the high hematocrit RBCs while the MNCs remain in the chamber during each cycle. During the harvest stage of each cycle, the hematocrit of the chamber is increased to isolate the MNC layer and the position of the chamber interface is increased until the MNCs begin to exit through the plasma line (Fig. 2). Thus, the collection of progenitor cells is an intermittent process. The MNCs collected by the device are diverted into a plastic storage bag (PL2410, Baxter) integrally attached to the collection harness, and located outside the centrifuge.

Amicus machine parameters were set as follows:

- Mean of nine cycles (range, 8-12)
- 1000 mL cycle volume
Fig. 1. Platelet collection. Platelet-rich plasma (PRP) is separated from the RBCs and carried out of the chamber. High-efficiency platelet separation occurs due to plasma recirculation and auto-elutriation.

Fig. 2. White cell collection. PMNs settle to the high-G wall and exit with RBCs. MNCs initially settle toward the high-G wall but eventually float up to the interface. They are then drawn back toward the low-hematocrit inlet region where they resettle again toward the high-G wall.

- RBC offset value of 6.5-7.5
- Interface set point of 0.60
- A flow rate of 60-80 mL per minute
- A citrate transfusion rate of 1.5 mg per kg per minute
  (12:1 ratio of blood to citrate)

The procedure included collection of 100-150 mL of donor plasma.

Patient parameters
Donor/patient samples were collected from the apheresis catheters immediately before and after the collection. Patient data included: hemoglobin, hematocrit, WBC count, and platelet count (Coulter STK-S, Raritan, NJ; Hialeah, FL), and CD34+ cell count. CD34+ cell samples were incubated with 20 μL of CD34+ reagent and with 20 μL of control reagent to assess the amount of nonspecific antibody binding. Both circulating CD34+ cells and CD34+ cells in the collected apheresis products were processed and counted the same way with the exception that product samples with a WBC count >50,000/μL were diluted as necessary. The number of CD34+ cells present were counted on a flow cytometer (FacsCalibur using the ProCOUNT Progenitor Cell Enumeration Kit, Becton Dickinson Immunocytometry Systems, San Jose, CA). This technology is FDA-approved and the technique directly references the Sutherland method in the guidelines of the International Society of Hemotherapy and Graft Engineering.

Adverse event monitoring
Patients were monitored for adverse events during the apheresis collections. Adverse events were categorized as mild, moderate, and severe (see Table 3). For circulatory or limb paresthesias, mild events were defined as those that resolved with administration of oral calcium supplements. Moderate paresthesias, with or without muscle cramps, were those that required interruption of the procedure in conjunction with use of oral calcium supplements. Severe paresthesias were categorized as those that failed to respond to the above-mentioned therapies and required treatment with intravenous calcium and magnesium supplements. For sneezing, mild reactions were those that required no therapy; moderate to severe symptoms were those treated with antihistamines. Headaches were considered mild or moderate if they resolved with oral administration of acetaminophen. Severe headaches were those that failed to resolve with analgesics and required medical consultation by a physician. Chills were mild or moderate if they responded to warming blankets. Chills were severe when patients showed evidence of true rigors that failed to respond to conservative therapy, resulting in cessation of the procedure in addition to medical assessment. Mild or moderate nausea required brief interruption of the procedure and use of anti-emetics. Severe nausea required anti-emetics, cessation of the procedure, and medical assessment by a physician.

PBPC product analysis
Analysis of the PBPC product collected included measurement of volume of RBCs collected, platelet count \( \times 10^9 \) per bag, granulocyte and MNC counts \( \times 10^8 \) per bag, and CD34+ cell counts \( \times 10^7 \) per bag. Hematology assays and CD34+ cell counts were performed as described above. The PBPC volume was determined by weighing the full bags, subtracting the tare weight of the empty bag, dividing by the specific gravity of the progenitor cell product (1.050), and calculating the volume of the progenitor cell product.

The instrument CD34+ cell collection efficiency was calculated according to the formula:

\[
\text{CD34+ Efficiency (\%)} = \frac{\text{Total CD34+ Yield}}}{} 
\times 100
\]

\[
\text{CD34+ Yield} = \frac{\left(\frac{\text{Donor Pre-CD34+} - \text{CD34+/μL} \times \text{Whole Blood (μL)} \times 1000}{2}\right) - \frac{\text{Donor Post-CD34+} - \text{CD34+/μL} \times \text{ACD (μL)} \times 1000}{2}}{\text{Whole Blood (μL)}}
\]

Transfusion protocol
Most PBPC transfusions were performed on an outpatient basis. Patients generally completed high-dose chemotherapy at least 24 hours before transfusion of PBPCs, but
the standard conditioning regimens varied and were disease-dependent. All patients received only autologous cells collected via the Amicus device (>2.5 × 10^8/kg). On the day of transfusion, the frozen cells were placed in a plastic overwrap bag and thawed at the bedside in a 37°C waterbath. Within 15 minutes of thawing, PBPCs were transfused over 20 to 30 minutes through a 260-micron standard blood filter; the filter was flushed with saline to ensure that all cells were transfused. All patients were given hydration therapy, were premedicated with 50 mg diphenhydramine and 650 mg acetaminophen, and were monitored during the transfusion. Following transfusion and subsequent hydration, asymptomatic patients were discharged from the clinic once their urine became heme-negative by dipstick. The patients took prophylactic oral antibiotics and monitored themselves for fever. Patients received G-CSF 5 to 10 μg per kg per day subcutaneously, after the transfusion until the total WBC count exceeded 5000 per μL. Patients were generally seen daily in the clinic until they achieved engraftment. Patients with <500 granulocytes per μL and a temperature over 101°F were admitted to the hospital with a diagnosis of neutropenic fever and given intravenous antibiotics. RBC transfusions were given when the hemoglobin fell below 8 g per dl or the patient became symptomatic; platelets were given for a count below 20,000 per μL or if bleeding occurred. These criteria are within the Yale institutional guidelines for blood component usage. Because the Yale guidelines in place during the study recommended a transfusion threshold of <20,000 per μL for platelet transfusions, and the engraftment criterion for platelets was >20,000 per μL, 100 percent of the platelets transfused met institutional guidelines. All patients were monitored for time to engraftment and for long-term follow-up. WBC engraftment was defined at an absolute neutrophil count of >500 per μL and platelet engraftment was defined as being the first of three consecutive days with the platelet count >20,000 per μL, unsupported by platelet transfusion.

Statistical analysis

Results were analyzed and expressed as mean ± 1 SD. Comparisons between machines or collections were performed using a two-tailed, paired or unpaired t test, as appropriate for the comparisons being made. Significance was taken to be p<0.05.

RESULTS

Apheresis machine operational parameters

The two instruments used similar amounts of ACD and processed equivalent volumes of whole blood (Table 2). The Amicus device (run time, 231 minutes) took an average of 47 minutes longer to process the same 11.9 L as did the CS-3000 Plus machine (run time of 184 minutes, p<0.05). However, the collection efficiency was statistically greater for the Amicus device (64 ± 23 percent) than for the CS-3000 Plus device (43 ± 14 percent, p<0.05).

Apheresis collections

As mentioned above, except in two patients, the CS-3000 Plus device was chosen for initial collection of the back-up transfusable dose for purposes of ensuring patient safety. Thus, the Amicus collections were obtained over the subsequent 1-2 days depending on the size of the dose transfused. The starting hematocrit/hemoglobin, platelet count, and number of CD34+ cells per μL were equivalent for the donors undergoing the Amicus collections vs. those undergoing collection via the CS-3000 Plus (Table 1). However, the starting WBC counts were higher for the Amicus collections (p<0.05) because the patients had received an additional 1-2 injections of G-CSF and more time had elapsed since the myelo-suppressive chemotherapy. Adverse reactions related to the donation process were few in number and clinically mild to moderate. During collection, no serious adverse donor events attributable to either of the two separators were seen (see Table 3).

PBPC product analysis

There were differences in the composition of the PBPC products prepared by the two instruments (Table 4). PBPCs collected with the Amicus instrument had a hemoglobin level of 2.2 g per dl in 241 mL. PBPCs collected with the CS-3000 Plus instrument had a hemoglobin level of 6 g per dl in 78 mL. When adjusted for volume, however, the hemoglobin values were 5.2 g per bag for the Amicus collections and 4.9 g per bag for the CS-3000 Plus collections (p<0.05). A significantly lower platelet count was noted for the Amicus PBPC collection (4.4 ± 2.4 × 10^9 platelets/bag) versus the CS-3000 Plus collection (6.6 ± 6.3 × 10^9 platelets/bag, p<0.05). The number of granulocytes and MNCs collected by the Amicus separator was greater than that collected by the CS-3000 Plus separator (p<0.05), but the number of CD34+ progenitor cells × 10^9 per bag collected with the two

† CD34+ cells collected per kg donor body weight (p>0.05).

Transfusion results
The mean dose of CD34+ cells transfused was 8.03 ± 6.50 × 10^6 per kg (Table 5). The range of CD34+ cells transfused into the enrolled study patients varied. A total of four patients received a dose of 2.5 to 3.5 × 10^6 CD34+ cells/kg; five received a dose of 3.6 to 4.6 × 10^6 per kg; 13 patients received 4.7 to 7.0 × 10^6 per kg; seven received 7.1 to 12.0 × 10^6 per kg; four received 12.1 to 20.0 × 10^6 per kg; and one patient received 38 × 10^6 per kg. The engraftment time needed to achieve >500 PMNs per μL for the PBPCs collected on the Amicus device was equivalent to published literature values (Table 5). Similarly, engraftment time to achieve over 20,000 platelets per μL was comparable to engraftment times published in the literature. These results are also equivalent to the neutrophil and platelet engraftment times seen by the authors (time to reach PMN > 500/μL, 9.3 days; time to reach platelet count > 20,000/μL, 10.9 days), using other cell separators (Spectra, Cobe, Lakewood CO, and CS-3000 Plus, Baxter) at Yale (n = 400).

One patient with ovarian cancer and six patients with breast cancer received double transplants (1 to 3 months apart) with PBPCs collected via the Amicus instrument. Each patient's first and second transplants engrafted within the same time frames described earlier.

While no serious adverse events directly related to the progenitor cell collection were noted, two patients did experience serious complications in the peritransplant period. Two days after transfusion of cells collected via the Amicus device, a 42-year-old male patient with a diagnosis of non-Hodgkin's lymphoma, was admitted to the hospital for shortness of breath and chest pain with a presumptive diagnosis of a pulmonary embolism; this diagnosis was never confirmed. He was treated with a standard anticoagulant regimen, however, and his symptoms resolved. He engrafted within 9 days and is currently alive 12 months after transfusion, with no evidence of disease. The other patient, a 50-year-old female with breast cancer, presented to the clinic for PBPC transfusion complaining of a swollen neck; she was diagnosed with superior vena cava syndrome. She, too, was admitted to the hospital, where her symptoms resolved with treatment. After her PBPCs were transfused, she engrafted on Day 8. This patient died 5 months later, however, of recurrent breast cancer. Both patient incidents were classified as unrelated to Amicus collection or PBPC transfusion.

For a total of 34 cell transplants, 68 RBC units and 225 random-donor platelet units were required for transfusion therapy during the preengraftment period. The mean number of RBC units transfused was 2.0 (10 patients received no units, three received 1 unit, eight received 2 units, four received 3 units, four received 4 units, and five received 5 or more units). The mean number of random-donor platelet units transfused was 6.6 (eight patients received no units, 15 received up to nine units, 10 received between 10 and 20 units, and one patient received over 20 units).

DISCUSSION
The data demonstrate that the Amicus separator is safe and effective for collection of CD34+ PBPCs. The Amicus device provided an acceptable product that reliably produced engraftment without the occurrence of serious adverse events. PMN engraftment occurred predictably by 8.7 days (PMN > 500/μL) and platelet engraftment by 9.7 days (platelets > 20,000/μL). These values are equivalent to those published in the literature, and are comparable with the authors' experience with other cell separators.

The collection of CD34+ PBPCs for use in autologous hematopoietic progenitor cell transplants has become accepted as a standard of care for some malignancies. It has essentially replaced a marrow harvest for restoration of marrow function after myeloablative chemotherapy. Refinements of apheresis collection protocols include increasing the CD34+ cell collection efficiency, decreasing the number and duration of collections, and improving purity of the final product by decreasing the number of non-CD34+ cells collected, such as:

as platelets. Requiring fewer collections to achieve an effective dose would provide substantive patient benefit. It would permit earlier central venous catheter removal, and this would, in turn, decrease the risk of infection or hemorrhage due to an indwelling foreign body (catheter) in an infection-prone patient. It would also mean fewer doses of G-CSF or other hematopoietic growth factors, thus reducing side effects and costs associated with its use. Fewer collections would also result in decreased freezer storage needs and thus increase the cost-effectiveness of the treatment program.

While most other collection parameters were essentially equivalent, the length of time needed for a collection cycle on the Amicus device increased collection time on that device by 5 to 10 minutes per cycle. This could extend the collection time by as much as 60 minutes, depending on the donor/patient CD34+ cell count and WBC count. For patients with WBC counts >10,000 per µL, the cycle volume can be lowered to maximize collection efficiency; this would also shorten the time required for the overall collection. Adjustment of the elutriation and concentration aspects of the Amicus MNC collection process may permit more efficient collection for patients who mobilize poorly and who might never develop a CD34+ cell count above 30 to 40 per µL; more research is needed in this area. The Amicus device also provides more computer control and the menu-driven computer touch screen interface offers an overall more user-friendly design than does the CS-3000 Plus device. Engraftment of cells collected via the Amicus device reliably occurred in 8 to 10 days. This posttransfusion time frame is equivalent to the time expected for PBPCs collected using other cell separator devices.

The transfused dose of PBPCs collected via the Amicus equipment was always greater than 2.5 x 10^6 per kg. Some doses were much larger than this. Further studies are needed to evaluate engraftment characteristics of a lower dose of these cells such as 1.5 x 10^6 per kg, or less. It is possible that the lack of randomization necessitated by patient safety concerns affected the efficiency results. Further clinical studies of the CS-3000 Plus and the Amicus devices involving full randomization would be revealing in this regard. This manuscript reports on a clinical comparison of the Amicus and the CS-3000 Plus Instruments. No comparison data for the Amicus and other cell separators exist at this time. A comparison study of the Cobe Spectra and the Amicus separator is in progress by the authors.

The Amicus device collects CD34+ cells more efficiently, although at a slower rate than does the CS-3000 Plus device. Platelet content was lower in the Amicus collection products than in the CS-3000 Plus collection products. This is important because development of donor thrombocytopenia is an ongoing concern with a variety of cell separators and their computer programs.11,12 Because it is more efficient than the CS-3000 Plus, the Amicus separator would be more useful for collecting PBPCs from patients who are poor mobilizers and who have marginal circulating CD34+ cell counts. PBPCs collected with the Amicus device engraft in a time frame equivalent to that in the literature. Short-term engraftment durability was 100% in that no one became aplastic. Thus the Amicus Separator appears to be safe and effective for collection and transfusion of PBPCs from oncology patients undergoing progenitor cell rescue following myeloablation.

Following immunohaematopoietic stem cell transplantation, it is of importance to determine whether the new blood forming system is of recipient or donor origin and such phenotypic characterisation is called chimerism analysis. This is a dynamic process, which may be complete, mixed or split between compartments and in this way, plays an increasingly important role in predicting outcome for engraftment, rejection or residual disease predating the need for pre-emptive immunotherapy. Based on recent workshop recommendations, peripheral blood cells have been used in the short tandem repeat (STR) assay to serially characterise the haematologic course and so evaluate the usefulness of this system. Forty-six patients from a single centre were followed serially for periods ranging between 3 and 60 months. The analysis was initially performed using the Applied BiosystemsProfiler Plus Kit; currently, the Promega Powerplex 16 system is used. The overlap between the two assays has allowed for continuous comparison. The initial analysis was performed at 14 days post-transplant and repeated monthly. Stored DNA from the patient and donor was used to establish the pre-transplant profile. All post-transplant analyses were performed using peripheral blood. The results obtained were expressed as a percentage of the donor profile. To illustrate the ability of this technology, three representative profiles are described. In the first, stable engraftment is confirmed at 20 months with only donor pattern present. The second is intermediate, and while the patient is clinically disease free, there exists stable mixed chimerism at about 75% of donor cells. The third patient initially engrafted but the reappearance of recipient alleles presaged a haematological relapse; the latter is an indication for salvage with donor lymphocyte infusion and here this assay will be used to show the effectiveness of the intervention. These preliminary results show this to be a useful additional tool in monitoring post-transplant engraftment. As a basis for pro-active therapy, a larger study integrating the results of haematological and cytogenetic markers is planned.

Introduction

Early studies recognised the importance of establishing chimerism in patients after bone marrow transplantation but investigators had to rely on techniques such as red cell phenotyping.\textsuperscript{1,2} Those techniques were limited by their lack of polymorphism and sensitivity. However, one method still of value in gender mismatched transplantation is fluorescent in situ hybridisation (FISH) for X- and Y-chromosomes.\textsuperscript{3}

In contrast, short tandem repeat (STR) polymorphism, a human identification marker initially used in forensic pathology, can be employed to monitor chimerism in post-transplant patients.\textsuperscript{4} These are repeated units of nucleotides usually two to four base pairs in length and individuals have a variable number of repeats at each locus tested, thereby ensuring his or her unique profile. The advantages of this methodology include sensitivity, reproducibility of results, small amounts of sample needed and the relative speed as well as cost effectiveness of the test.

The present study was designed to assess the use of this technology to monitor chimerism in patients following unrelated allogeneic bone marrow transplantation.

Material and methods

DNA was extracted from EDTA-preserved whole blood and bone marrow, following standard extraction methods making use of the DNAzol\textsuperscript{®} reagent supplied by Invitrogen, or Qiagen.

After quantification of the DNA yield, approximately 0.5 to 1 µl of DNA template was amplified in a single step 5 µl reaction volume, using one of two DNA profiling kits namely AmpFISTR Profiler Plus (Applied Biosystems) or PowerPlex\textsuperscript{®} 16 System (Promega). DNA amplifications were performed on the GeneAmp\textsuperscript{®} PCR system 9700 thermal cycler following the supplier protocols. Amplified products were profiled with an ABI 310 DNA sequencer using sequenced allelic ladders. Interpretation of the results was performed using Genotyper\textsuperscript{®} software.

The results are expressed as a percentage of donor profile.

Assessment of chimerism

Chimerism of post-transplant samples was assessed by comparing the pre-transplant patient DNA profile, the donor DNA profile and the post-transplant patient DNA profile.

If a ‘stutter peak’ corresponded to a donor or patient DNA allele, it was only reported if the allele represented more than 5% of the total DNA per marker system.\textsuperscript{3}

Quantification of the patient and donor DNA contribution to a mixed DNA profile was calculated semiquantitatively by summing the total peak height and peak area of all alleles per marker system and then calculating the percentage DNA contributed by each individual allele of the system. Homozygous alleles were averaged.

Results

Initially, 61 patients were enrolled in the study. Fifteen were lost to follow up. Thirty-three male and 13 female patients whose ages ranged from 5 years to 64 years and who received either related or unrelated bone marrow transplants for a variety of haematologic malignancies (see Figs 1 and 2) were monitored serially for periods ranging between 3 and 60 months.

The results of three representative profiles are shown in Tables 1, 2 and 3. These patients were transplanted with human leucocyte antigen (HLA) matched unrelated donors. The results of an acute myeloid leukaemia (AML) patient (DS) who was monitored regularly for 20 months after transplant are shown in Table 1. No chimerism was detected. Chimerism was detected in a paroxysmal nocturnal haemoglobinuria (PNH) patient (WB) at 6 months post-transplant. The percentage of donor cells present was calculated and has remained at approximately 75% for 21 months (Table 2). The third representative profile, shown in Table 3, is that of a chronic myeloid leukaemia (CML) patient (MA). The

Patient’s pre-transplant STR profile; °re-emerging patient alleles, post-transplant.
haemoglobinopathies to both benign and haematologic diseases or solid tumours. Post-transplantation monitoring is used to predict negative events such as graft failure or rejection, disease relapse or graft-versus-host disease. In this context, haematopoietic chimerism is of value and in addition, this assists detection of minimal residual disease. The frequency with which studies should be done varies, with indication being monthly for secondary graft failure.

In the present study, the applicability of molecular techniques was serially evaluated and our experience adds to that previously reported from other centres.

There is particular interest in the post-transplant data both for patients transplanted with matched unrelated donors and reduced intensity conditioning with modifications consequent upon prophylactic donor lymphocyte infusion. Finally, these measures allow exploration of some of the newer interests, including cell transfer in mesenchymal transplants and circulating endothelial progenitors.

Summary and conclusion
It is concluded that this methodology is of established value in clinical transplantation to monitor engraftment status and expose early disease relapse.

Minimal number of circulating CD34+ cells to ensure successful leukapheresis and engraftment in autologous peripheral blood progenitor cell transplantation

BACKGROUND: The number of peripheral blood (PB) CD34+ cells has been widely used to monitor the timing of leukapheresis for autologous transplantation. However, no cutoff value for CD34+ cells in PB has been defined as a guideline for the identification of patients in whom the harvest would be effective and those in whom there was a high probability of failure.

STUDY DESIGN AND METHODS: The present study investigated the best threshold of CD34+ cells in PB for successful harvesting and engraftment, using 263 PB samples with their corresponding leukapheresis components. In addition, that measure has been compared to other commonly used criteria such as the white cell count, the number of mononuclear cells, and the number of colony-forming units–granulocyte macrophage in PB.

RESULTS: Time to engraftment of both granulocytes and platelets was significantly influenced by the number of CD34+ cells transfused, but all patients receiving \( \geq 0.75 \times 10^6 \) CD34+ cells per kg achieved engraftment within a reasonable number of days (>0.5 x 10/L granulocytes by Day 11 and >20 x 10/L platelets by Day 13). A clear correlation between the number of CD34+ cells per µL in PB and of CD34+ cells per kg collected was found at each apheresis (\( r = 0.9, p<0.0001 \)). Moreover, the number of CD34+ cells per µL measured in PB the day the first leukapheresis was initiated displayed an excellent correlation with the total amount of CD34+ cells per kg finally collected (\( r = 0.81, p<0.0001 \)). On the basis of the regression curve obtained and the clinical engraftment results, it was found that the presence of \( >5 \) CD34+ cells per µL in PB ensured a good yield from the harvest in 95 percent of patients and would avoid an unsuccessful harvest in 81 percent of cases.

CONCLUSION: A dose of only 0.75 x 10^6 CD34+ cells per kg guarantees hematopoetic recovery within a reasonable number of days. To initiate a leukapheresis from which enough progenitor cells may confidently be obtained, a minimum of 5 CD34+ cells per µL in PB is required.

Peripheral blood progenitor cells (PBPCs) have become the most widely used source of stem cells with which to rescue patients undergoing myeloablative therapy. Most transplant groups have established their own minimal number of CD34+ progenitor cells required within the harvest to ensure a rapid and permanent engraftment. Although these figures vary among centers, depending on their internal control values, in most studies the speed of recovery correlates with the number of CD34+ cells and of colony-forming units–granulocyte-macrophage (CFU–GM) transfused.15 Because this value is apparently critical to predicting engraftment, an obvious question is how to predict the number of progenitor cells expected from the harvest. For this purpose, different peripheral blood (PB) values have been used to reach a decision on when to initiate apheresis; the most commonly used are the white cell (WBC) count, the number of mononuclear cells (MNCs), the number of circulating CD34+ cells, and the number of CFU–GM.6,7 In particular, these last two values have been shown to correlate with the amount of progenitor cells finally collected in the harvest component.8,9 The measurement of CFU–GM in PB is not practical in clinical decision making, as results are obtained only after 14 days of culture. On the other hand, the estimation of the circulating CD34+ cells offers three major advantages: 1) results are obtained within a few hours; 2) it has high intralaboratory reproducibility; and 3) there is permanent documentation of the results.10 Accordingly, at present, most groups use this value to monitor the timing of

ABBREVIATIONS: CFU–GM = colony-forming units–granulocyte-macrophage; MNCs = mononuclear cells; PB = peripheral blood; PBPC(s) = peripheral blood progenitor cell(s); WBC(s) = white cell(s).

The use of peripheral blood stem cells (PBSC) as a source of hematopoietic stem cells is steadily increasing and has nearly supplanted bone marrow. The present article reviews mobilization and collection of PBSC as well as its side effects. Specialized harvesting strategies such as large volume leukapheresis (LVL) and pediatric PBSC collection are included in this overview. Under steady state conditions, less than 0.05% of the white blood cells (WBC) are CD34+ cells. Chemotherapy results in a 5-15-fold increase of PBSC. Combining chemotherapy and growth factors increases CD34+ cells up to 6% of WBC. In the allogeneic setting, granulocyte-colony stimulating factor is used alone for PBSC mobilization. Several factors affect the mobilization of PBSC: age, gender, type of growth factor, dose of the growth factor and in the autologous setting, patient's diagnosis, chemotherapy regimen and number of previous chemotherapy cycles or radiation. Harvesting of PBSC can be performed with various blood cell separators using continuous or discontinuous flow technique. Continuous flow separators allow the processing of more blood compared with intermittent flow devices resulting in higher yields of CD34+ cells for transplantation. LVL can be used to increase the CD34+ yield in patients with low CD34+ pre-counts. Processing of more blood in LVL is achieved by an increase of the blood flow rate and an altered anticoagulation regimen. Specialized strategies were developed for pediatric PBSC collection considering the main limiting factors, extracorporeal volume and vascular access. Adverse events in PBSC collection can be subdivided in apheresis associated and mobilization associated side effects. Citrate reactions due to hypocalcemia are frequent during apheresis, especially in pediatric PBSC collection and LVL. Thrombocytopenia is often observed in patients after termination of apheresis due to platelet loss during PBSC harvesting. Muscle and bone pain are frequent adverse events in allogeneic stem cell mobilization but are usually tolerated under the use of analgesics. Spleen enlargement followed by rupture is a serious complication in allogeneic donors.

Peripheral blood stem cells

Mobilized blood cells vs bone marrow harvest: experience compared in 171 donors with particular reference to pain and fatigue

L Karlsson1, D Quinlan1, D Guo1, C Brown1,2, S Selinger2, J Klassen2 and JA Russell1,2

1Alberta Bone Marrow Transplant Program and Departments of Medicine, Nursing and Epidemiology, Tom Baker Cancer Centre, Calgary, Alberta, Canada; and 2Alberta Bone Marrow Transplant Program and Departments of Medicine and Nursing, Foothills Hospital, Calgary, Alberta, Canada

Summary:

This prospective study compared the donor experience of blood cell (BC) mobilization and leukapheresis (n = 116) with that of bone marrow (BM) harvest (n = 55). Internal jugular catheters were inserted electively in 89% of BC donors. Most (80%) BM donors had a harvest with general anesthesia; 20% had epidural or spinal anesthesia. Pain and fatigue were frequent with both procedures and were compared in responses to questionnaires. A total of 85% of BM donors reported moderate or severe pain compared with 68% of BC donors (P = 0.02). The median duration of pain was 14 days for BM donors compared with 3 days after BC mobilization (P < 0.0001). More BM donors had pain for more than 7 days (75% vs 0%, P < 0.0001). Severe fatigue was experienced by more BM donors (49% vs 16%, P < 0.0001). Fatigue lasted significantly longer in BM donors (median 11 vs 4 days, P < 0.0001) and more BM donors were fatigued for more than 1 week (60% vs 0%, P < 0.0001). A total of 11 donors had both BM and BC collection; seven preferred the latter. Simply considered with respect to pain and fatigue, BC donation appears better tolerated by donors. However, there are other sequelae of both influencing the acceptability for individual donors.

In recent years, there has been a substantial increase in the use of cytokine-mobilized blood cells (BCs) or peripheral blood stem cells (PBSC), as an alternative to bone marrow (BM) for allogeneic stem cell transplantation (SCT). Over 40% of the related donor SCTs in adults reported to the IBMTR in 1998–2000 were BC transplants (BCTs)1. While serious complications have been reported, the experience generally appears to be safe for the donor.2,3,4 There is limited information regarding the subjective experience of BC donors compared with those giving BM.5,6 We initiated a single center prospective study in 1993 to assess BC donor experience. In 1995, we began to compare donor experiences with the two collection procedures and to record any adverse effects in the years after BC donation.

Donors and methods

A combined total of 171 donors participated in the study. The 116 BC donors were recruited between April 1993 and November 1997. A total of 55 marrow donors were recruited from September 1995 to November 1997. No donors refused to participate in the study. Donors were from the adult outpatient service of a provincial BC and BM transplant program. The study began using only BC donors, and then expanded to compare the two donor populations. There was no randomization. In general, BM donors were giving to recipients who were unrelated or were related with chronic myelogenous leukemia (CML) or nonmalignancies.

BC donors

Table 1 gives some characteristics of the 116 BC donors and summarizes their mobilization and collection procedures. All donors had a full history and physical examination, blood counts, serum chemistry, and viral serology. Electrocardiogram and chest X-ray was done on donors over 40 years of age. A pregnancy test was performed on women of childbearing age.

The past medical history of BC donors revealed thalassemia minor (2), hemochromatosis (1), cervical cancer (1), Graves' disease treated with 131I (1), diabetes (4), and asthma (6). Cardiovascular problems included prior myocardial infarct and angioplasty (1), arrhythmias (3), hypertension (9), and valve dysfunction (3).

As a program standard, G-CSF was given as a multiple of 300 and 480 µg vials. In a preliminary dose-finding study, doses ranged between 5 and 16 µg/kg; a final daily dose of 7.5–10 µg/kg was selected.4 In all, 22 donors had less than 7.5 µg/kg, 13 had more than 10 µg/kg. Blood CD34+ cell counts were monitored daily and leukapheresis was performed on day 3 or 4, with day 0 being the day of the
first injection. Early in the study, some donors had peripheral venous access, but we shortly established a routine to insert internal jugular catheters under a local anesthetic, using radiologic guidance. The details of BC mobilization and collection are reported elsewhere. A total of 13 BC donors had a prior or subsequent BM harvest; in nine of these, BM harvest took place before the study, the other four were included in both BC and BM donor group studies. Eleven were asked if they had a preference for one of the procedures.

**BM donors**

The characteristics of BM donors are shown in Table 1. Pre-transplant screening was conducted by BC donors. The medical problems included: hypertension (I), asthma (3), arrhythmia treated with digoxin (1), and sleep apnea (I). In all, 45 donors had general anesthetic, nine had spinal anesthetic (donor request), and one donor who was 16 weeks pregnant was given an epidural anesthetic.

Marrow harvest was conducted using multiple large-bore needle punctures with no more than 10 ml aspirated from any one site. Target yields depended on the clinical circumstances, but were a minimum of $2 \times 10^4$ kg recipient weight. Donors were given a prescription for acetaminophen with Codeine (or an alternative in the event of intolerance).

In all, 17 marrow donors had autologous blood stored; 16 had the units infused back following the harvest. One unrelated donor refused to have the unit reinfused.

Donors were day surgical patients and usually discharged home in the afternoon.

**Data collected from donors**

Donors began recording information on the first day of G-CSF injections or the marrow harvest day. A checklist required donors to evaluate the degree of pain and fatigue (scored as mild, moderate or severe) and to record the presence of other symptoms, as listed in Figure 2 and Table 2. In addition, nursing records of the mobilization and collection were reviewed. Day 0 in this study refers to the first day of G-CSF injections in BC donors and the marrow harvest day in BM donors. On the day after the procedure, a nurse met with the donor and reviewed the data collected. Donors recorded symptoms until they were symptom free. A nurse phoned the donors weekly to ask about their well being until symptoms disappeared. BC donors were followed yearly by a letter or phone call; a blood count was requested at this time. Three nurses were responsible for data collection, data entry, and follow-up.

**Informed consent**

All donors and patients signed the consent forms approved by the University of Calgary Conjoint Ethics Review Board. BC donation was not an option for unrelated donors. Patients with malignant disease other than CML in chronic phase were eligible for studies of BC transplantation. One such patient had a BM transplant because of donor preference.

**Statistical analysis**

The proportion of BC or BM donors experiencing different intensities of pain and fatigue were compared using Fisher's exact test. The duration of pain and fatigue was evaluated using the Wilcoxon rank sum test. Analysis was performed using S-Plus 2000 software (Mathsoft Inc., Seattle, WA, USA).

**Results**

The frequent complications common to both procedures were bone pain and fatigue.

**Pain**

Bone pain in BM donors was at the site of the multiple needle aspirations, whereas that experienced after G-CSF in BC donors was widespread.

Bone pain was in the back in 68 BC donors, hips in 43, legs in 26, sternum in 19, generalized in 12, and other areas in the remainder. In all, 23 donors had pain in only one site; the remainder had pain in more than one site.

All except three BM donors had severe pain on the first post operative day. Although most donors (96% BM, 92% BC) experienced some discomfort, pain was more intense and lasted longer in BM donors. A total of 85% of BM donors experienced moderate/severe pain.

</table>
donors reported moderate or severe pain compared with 68% of BC donors \((P=0.02, \text{ Figure 1})\), with the corresponding figures for severe pain of 32 and 20%, respectively \((P=0.12)\). Pain lasted a median of 14 days (range 2-56) in BM donors compared with 3 days (range 1-6) in BC donors \((P<0.0001, \text{ Figure 2})\). In total, 75% of BM donors had more than 1 week of pain compared with no BC donors \((P<0.0001)\).

**Fatigue**

Fatigue was commonly reported with both procedures, by 88% of BM donors and 77% of BC donors \((P=ns)\). In all, 71% of BM donors experienced moderate or severe fatigue compared with 49% of BC donors \((P=0.05, \text{ Figure 1})\). The figures for severe fatigue considered separately were 49 and 16%, respectively \((P<0.0001)\). Fatigue lasted significantly longer in BM donors, a median of 11 days (range 1-38) compared with 3 days (range 1-6) after BC donation \((P<0.0001, \text{ Figure 2})\). Altogether, 69% of BM donors had fatigue for more than 1 week compared with no BC donors \((P<0.0001)\).

**Other sequelae**

Figure 3 illustrates the frequency of symptoms with an incidence greater than 10% in one or both groups.

![Figure 1](image1.png) Distribution of maximum degree of pain and fatigue. BM represented by solid bars, M/S = moderate/severe.

![Figure 2](image2.png) Comparison of duration of pain and fatigue.

Headache was mostly seen in BC donors and was less severe than bone pain. Of the 74% of BC donors with headache, 53% described it as mild, 31% moderate, and 16% severe. Headache was generalized in 33 donors, frontal in 23, and occipital in 11. Some less common sequelae are summarized in Table 2.

One BC donor was found to be pregnant following the BC collection. A pregnancy test taken 3 days before G-CSF was negative. At 5 days after the collection, a home test was positive. This test result was confirmed in the laboratory. The donor was advised that the risks of G-CSF were unknown, but she decided to have an abortion largely for financial reasons.

**Blood counts**

The median precollection platelet count for BC donors was \(247 \times 10^9/\text{l} \) (range 156-467), falling to a median of \(132 \times 10^9/\text{l} \) (range 30-283) the day after collection. In 14 cases (12%), platelets fell below \(100 \times 10^9/\text{l} \) on the day after BC collection, and three fell below \(70 \times 10^9/\text{l} \) to levels of 30, 56, and \(68 \times 10^9/\text{l} \).

In BM donors, the median presurgical hemoglobin level was \(141 \text{ g/l} \) (range 107-171) and the median the day after the harvest was \(116 \text{ g/l} \) (range 85-146). In five donors, the hemoglobin count fell below 100 g/l, the lowest being 85 g/l. Platelets were unaffected in these donors, none of whom received G-CSF.

**Donors undergoing both procedures**

Of 11 donors who had both BM and BC collection, seven preferred the latter. Pain, fatigue, and recovery time were given as reasons. Of the four donors preferring BM harvest, three cited the discomfort of venous access (two jugular, one femoral). The fourth felt that too much time was required for G-CSF injections.

**Long-term follow-up**

Two BC donors refused further participation in the study as their recipients had died, and the recall for blood counts was a painful reminder. Nine donors were lost in follow-up. The remaining 105 were followed for 1-5 years (median 2).
Two BC donors developed cancer; one (aged 69) developed colon cancer, the second developed bladder and prostate cancer and is now deceased. A 34-year-old BC donor developed Guillain–Barre syndrome and another became hyperthyroid.

In all, 85 BC donors had 1–5 annual blood counts (median 2), with no significant changes compared with counts before donation.

Discussion

The trend toward the use of allogeneic BCT will doubtless continue in the light of recent randomized studies, some of which demonstrate a relative advantage of this source, at least in some patient subgroups. However, in many circumstances, BM remains an acceptable source of stem cells. The relative morbidity of BM or BCTs over the long term, particularly from chronic GVHD, has yet to be evaluated. Given the lack of demonstrable differences in the risk to donors, the issue of perceived tolerability of obtaining stem cells from BM or BC collections therefore remains important.

We found that the intensity and duration of both pain and fatigue were significantly greater in BM donors. Clearly, the nature of the pain was different for the two groups. Other effects of the procedures, either common to both or largely restricted to one or the other, were observed and are similar to other reports of BM and BC donation. We cannot evaluate the contribution of these to the tolerability of the procedures as a whole or determine their influence on the preferability of one procedure over the other.

There are some published reports available, comparing the procedures in concurrently observed groups in the context of randomized studies. Fortanier et al compared anxiety and pain in BM and BC donors. Severe pain from G-CSF, measured on a visual analogue scale, was recorded in 36% of donors compared with 20% in our study. However, they did not observe a difference in pain level between BC and BM donors. The duration of pain was not recorded. A small randomized study by Heldal et al found that the total burden of complaints and analgesic usage was higher in BM donors compared with those giving BC. Finally, Rowley et al reported that BC and BM donors experienced similar peak levels of pain, but that pain lasted longer in BM donors. Fatigue does not appear to have been compared directly. We found that it was a frequent complaint and, in BM donors, is probably attributable in part to anaemia.

This institution's practice of routinely inserting an internal jugular catheter into BC donors is relatively unusual and controversial. Line insertion under imaging seems to be safe; since the closure of this study, more than 200 additional donors have had these catheters inserted, with no major complications. It is noteworthy, however, that the preference for BM donation expressed by three donors was related to discomfort from line insertion. Significant distress can be alleviated in most BC donors with appropriate anaesthesia, sedation, and operator technique. Jugular line access allows the vast majority of collections to be performed in a single leukapheresis, and avoids the additional distress of large vein cannulation if peripheral access fails.

Our study indicates that both procedures are reasonably well tolerated, with all donors recovering within a few weeks. The tolerability of stem cell collection for the donor is but one factor influencing the choice of product. If there is a demonstrable advantage to the patient for one source or the other, the procedure should be selected on this basis. In the absence of such evidence, our data suggest that, at least with respect to pain and fatigue, BC donation is easier to tolerate. No serious consequences attributable to giving G-CSF have been identified in the early years after BC donation; this is consistent with most other reports, although severe effects have been described.

Information from this study is now incorporated into our standard teaching brochure to educate future donors about the potential side effects and expected recovery time with each procedure. This includes a recommendation about the effective contraception in women of childbearing age.

Mini review

The whys and hows of hematopoietic progenitor and stem cell mobilization

A Kessinger¹ and JG Sharp²

¹Department of Internal Medicine, University of Nebraska Medical Center, Omaha, NE, USA; and ²Department of Genetics, Cell Biology and Anatomy, University of Nebraska Medical Center, Omaha, NE, USA

Summary:

Intentional mobilization of hematopoietic/stem cells into the circulation has improved the efficiency of their collection. Transplantation of mobilized blood stem cells to patients with marrow aplasia results in a faster pace of hematopoietic recovery than transplantation of marrow-derived stem cells. Autologous and allogeneic hematopoietic stem cell transplantation are increasingly performed with blood-derived cells. Donors of both autologous and allogeneic blood stem cells do not always respond well to therapies designed to produce mobilization. Autologous donors may respond poorly as a result of myelotoxic damage inflicted by prior antitumor therapy, but this explanation is not valid for allogeneic donors. The mechanism(s) involved in the process of mobilization are incompletely understood. Until these mechanisms are elucidated, methods to improve mobilization vigor on a rational basis will not be obvious. In the meanwhile, clinical observations may provide some hints regarding the whys and hows of mobilization and permit incremental improvements in this process.

doi:10.1038/sj.bmt.1703837

Keywords: mobilization; progenitor; stem cell

In contrast to beliefs persisting into the 1960s that hematopoietic stem cells normally existed only in the bone marrow,¹ the evidence favoring the existence and usefulness of circulating stem/progenitor cells has a long and progressive history (Table 1).³ ¹³

Buoyed by reports that circulating leukemic stem/progenitor cells could be successfully transplanted,² two syngeneic transplants were attempted in 1979 and 1980 with normal blood stem cells.¹⁴ ¹⁵ The cells were collected during steady state and infused over 14 days in the first transplant⁴ and over 8 days in the second.¹⁵ After nearly 2 months with no evidence of engraftment, syngenic marrow transplants from the same donors restored hematopoiesis, resulting in admonitions regarding the clinical use of normal circulating blood stem/progenitor cells for transplantation. Some years later, infusion of autologous cryopreserved blood cells collected during steady state and containing both fewer colony-forming units granulocyte macrophage (CFU-GM) progenitors and mononuclear cells than the failed syngeneic transplants resulted in hematopoietic recovery.¹⁶ Thus, the protracted infusion time of the syngeneic products may have negatively influenced engraftment.

Mobilization of hematopoietic stem/progenitor cells to the circulation

Between 1986 and 1991, autologous peripheral blood stem cell graft products were collected either in steady state or after chemotherapy-induced mobilization (Table 2). As expected, fewer apheresis procedures were needed to collect mobilized vs steady-state stem cells, but mobilized cells provided an unanticipated benefit, faster hematopoietic recovery after transplantation.²⁵ This still incompletely understood phenomenon was responsible for the eventual shift from bone marrow to blood as the preferred source of autologous hematopoietic stem cells for transplantation.

In 1988, two hematopoietic cytokines, granulocyte–macrophage colony-stimulating factor (GM-CSF)²⁶ and granulocyte colony-stimulating factor (G-CSF)²¹ were shown to mobilize hematopoietic stem/progenitor cells to the blood stream. When the cytokines were administered after myelosuppressive chemotherapy, the mobilization effect was even greater.²⁰ Thus, in current clinical practice, chemotherapy is no longer used alone as a mobilizing agent but is combined with a hematopoietic cytokine, most often G-CSF. The mobilizing chemotherapy is either cyclophosphamide in doses of 1.5–7 g/m² or chemotherapy specific for the underlying malignancy. In those situations where administration of chemotherapeutic agent(s) is not appropriate, for example, allogeneic donors and some autologous donors in complete remission, cytokines alone are used to induce mobilization (Table 2).²³

Usefulness of specific mobilization therapies

Chemotherapy plus cytokine(s)

Prospective and retrospective inquiries have shown that chemotherapy, especially when given as part of the specific therapy of the underlying malignancy, followed by a

cytokine or cytokine combination yields higher numbers of autologous CD34+ cells than cytokines alone. One randomized trial that supports these observations was designed to limit as much as possible the variables associated with mobilization efficacy. Patients each received two different mobilization regimens, which were alternately administered first or second. Cyclophosphamide plus G-CSF mobilized CD34+ cells more effectively than GM-CSF plus G-CSF regardless of whether that therapy was given as the first or second mobilizing strategy.

Several randomized studies have approached the issues of which cytokine or cytokine combination and at what doses given after chemotherapy provide the best mobilization. A higher (16 g/kg) rather than a lower (8 g/kg) dose of G-CSF was more effective in patients with a variety of malignancies. G-CSF or GM-CSF followed by G-CSF was more effective in patients with solid and hematologic malignancies than GM-CSF. In contrast, for patients with non-Hodgkin’s lymphoma (NHL), GM-CSF followed by G-CSF permitted more efficient collection of a target number of CD34+ cells than did GM-CSF, while G-CSF was the least efficient of the three cytokine strategies. However, cyclophosphamide plus either G-CSF, GM-CSF or GM-CSF plus interleukin 3 (IL-3) mobilized equally well in another trial. Studies including erythropoietin (EPO) have found that it did and that it did not increase mobilization when added to G-CSF after chemotherapy. When added to GM-CSF followed by G-CSF, EPO provided more mobilization than when added to G-CSF. The sometimes conflicting outcomes of these prospective studies (Table 3) are confounded by known and unknown variables in the populations studied (for example, different mobilizing chemotherapy regimens, different underlying diseases, previous treatment with different antitumor agents for different lengths of time) and suggest that a single regimen will not prove optimal for every autologous donor.

**Cytokine(s) alone**
Chemotherapy cannot be added to cytokines for mobilization purposes in normal donors and cytokines alone are

*Statistically higher number of CD34+ cells.

Blood stem cell mobilization
A Nessinger and JG Sharp

employed. G-CSF is the most commonly used cytokine for this purpose. Higher doses of G-CSF and administration of the cytokine twice rather than once daily appear to mobilize more allogeneic CD34+ cells. The combination of G-CSF and GM-CSF did not increase CD34+ cell mobilization in normal donors when retrospectively compared with mobilization with G-CSF alone, but a combination of G-CSF plus GM-CSF was reported to mobilize allogeneic CD34+ cells more effectively than G-CSF alone.

The use of cytokines alone for mobilization in autologous donors with malignancies in remission, who might benefit by avoiding the risks of myelosuppressive chemotherapy holds some attraction. In a retrospective comparison, higher doses of G-CSF (32 μg/kg/day) mobilized more CD34+ cells than lower doses (10 μg/kg/day) in patients with characteristics predicting poor mobilization. Stem cell factor (SCF), a cytokine that acts on primitive hematopoietic stem cells and is available in most countries as an investigational agent, added to G-CSF may also provide a more vigorous mobilization than G-CSF alone. More patients who had been heavily pre-treated for lymphoma collected insufficient cells for transplant after receiving G-CSF (26%) than after receiving G-CSF plus SCF (15%) in a randomized study. Another prospective randomized comparison of G-CSF and G-CSF plus SCF for mobilization in patients with breast cancer showed that those receiving the combination required fewer apheresis procedures to collect progenitor cells for transplant. GM-CSF-mobilizes cells adequately and is an alternative to G-CSF as a single cytokine mobilizer. Other single cytokines have been explored as autologous mobilizers, including EPO, IL-3, a fusion product of GM-CSF and IL-3, FLT3 ligand, and IL-6. They all had modest activity but were not as useful as G-CSF or GM-CSF. These two cytokines, and especially G-CSF, remain the mainstay mobilizing cytokines and no new or novel cytokine seems likely to be adopted for this use in the near future.

Mobilization efficiency and outcome

Approximately 5 x 10^6 transplanted autologous CD34+ cells/kg can be relied upon to provide optimal red and white blood cell recovery, although lower CD34+ doses have performed equally well. The pace of circulating platelet recovery increases with higher doses of CD34+ cells. A total of 15 x 10^6 or more autologous CD34+ cells/kg resulted in a recovery of circulating platelet counts to 50 x 10^3/l in a median of 11 days post transplant as compared with 14 days for patients receiving fewer CD34+ cells but at least 2.5 x 10^6/kg. These patients also maintained platelet counts of >20 x 10^9/l beginning a median of 10 days post transplant compared to a median of 8 days for those receiving the higher doses. Unless patients are bleeding, platelet transfusions are not usually used for counts >20 x 10^9/l. The benefits of recovery of circulating platelet counts earlier than 10 days after transplant may not be outweighed by the increased resources required to collect more than 2.5-5 x 10^9 autologous CD34+ cells/kg.

Whether identifying the most efficient mobilization therapy among the several demonstrated effective strategies is possible, important or even necessary is an intriguing question. If one strategy routinely produces sufficient number of cells in a single apheresis procedure to assure rapid and reliable hematopoietic recovery, is another strategy that provides twice as many cells preferable? The answer would be yes if infusion of higher doses of circulating mobilized stem/progenitor cells provide added benefit beyond rapid durable engraftment without added toxicity.

Some indirect evidence for added benefits of transplantation of higher numbers of allogeneic stem/progenitor cells
than needed for rapid hematopoietic recovery came from a randomized prospective study comparing mobilized blood-derived stem cell vs marrow-derived stem cell transplants. Patients transplanted with blood stem cells had better outcomes as regards disease-free survival and overall survival.\(^\text{51}\) Whether the improvement was related to the larger number of stem/progenitor cells in a blood stem cell vs a marrow stem cell graft product\(^\text{52}\) was neither discounted nor demonstrated. A second smaller randomized study of allogeneic marrow vs mobilized blood stem cell transplantation found that patients who received fewer than \(2 \times 10^6\)/kg CD34+ cells, regardless of the cell source, experienced higher mortality and poorer survival.\(^\text{53}\) Another potential benefit of transplantation of higher stem cell doses in the allogeneic setting is a more complete recovery of circulating lymphocytes.\(^\text{54}\) In the autologous arena, a study of bone marrow transplantation in CML patients revealed that higher numbers of CD34+ cells infused was associated with a decreased risk of death and decreased +100 day transplant-related mortality. Whether this observation translates to the blood stem/progenitor cell arena is unknown.\(^\text{55}\) Thus, clinical benefits to very high doses of CD34+ cells for transplantation in the autologous setting may exist but none have been positively identified. As regards any additional toxicities associated with transplantation of more cells than required for rapid hematopoietic recovery, increasing allogeneic CD34+ cell doses correlated with a higher likelihood of clinical extensive chronic graft versus host disease, suggesting that increasing the CD34 cell numbers in mobilized graft products may be counterproductive.\(^\text{56}\) Transplanted allogeneic CD34+ positively selected cell doses of \(1-3 \times 10^6\)/kg have been associated with increased survival compared with higher doses.\(^\text{57}\) Taken together, these few studies do not establish whether higher doses of hematopoietic stem/progenitor cells are of any additional advantage but may provide a disadvantage in the allogeneic setting. Consequently, the optimal number of infused blood-derived stem/progenitor cells remains uncertain.

Mobilization of malignant cells

In addition to mobilizing hematopoietic stem/progenitor cells, cytokines\(^\text{58}\) and chemotherapy plus cytokines\(^\text{59}\) have also mobilized malignant cells in the blood stream, although tumor cell mobilization has not been identified in every studied autologous collection.\(^\text{60,61}\) Autologous hematopoietic stem cell donors with follicular NHL were more likely to have detectable tumor cells in their apheresis products if they mobilized CD34+ cells poorly (42%) rather than well (17%), regardless of the mobilizing therapy used.\(^\text{62}\) One study found that poor mobilizers were more likely to experience lymphoma relapse post-transplant, but the infused products were not assayed for tumor cells.\(^\text{63}\) Other investigators, however, found no differences in event-free survival, overall survival or relapse when the outcomes of good mobilizers and poor mobilizers with NHL treated with high-dose therapy and transplantation were compared.\(^\text{64}\) These results support an earlier finding that patients with low-grade NHL who received either mobilized or steady-state blood stem/progenitor cells following high-dose therapy had similar event free and overall survival.\(^\text{65}\) While avoiding increased tumor cell contamination in autologous mobilized blood stem cell collections seems intuitively desirable, no evidence exists to suggest that infusion of mobilized (in contrast to nonmobilized\(^\text{11}\)) tumor cells in the graft product increases the incidence of relapse of NHL,\(^\text{66}\) multiple myeloma\(^\text{67}\) or breast cancer\(^\text{68}\) following transplant.

Poor response to mobilization therapy

Autologous donors

The response of individual donors to mobilizing therapies is variable and incompletely predictable.\(^\text{69}\) A total of 21-48% of patients with NHL have exhibited poor mobilization after administration of chemotherapy and G-CSF.\(^\text{63,64,69}\) Of these patients, 16-33% were unable to mobilize enough collectable stem/progenitor cells for transplantation.\(^\text{63,69}\) Factors predicting for a higher likelihood of poor mobilization include increasing numbers of cycles of prior antitumor chemotherapy administration,\(^\text{70}\) prior radiation therapy,\(^\text{70,71}\) follicular rather than diffuse NHL as the underlying disease,\(^\text{70}\) and the presence of overt marrow metastases.\(^\text{25}\) In donors with lymphoma, low numbers of circulating natural killer (NK) CD3-16+56+ cells prior to administration of mobilizing therapies have predicted poor mobilization,\(^\text{72}\) as have low platelet counts on the first day of autologous blood stem/progenitor cell collection.\(^\text{73}\) Older age was associated with poor autologous mobilization in some patient groups,\(^\text{80,74,75}\) but not in others.\(^\text{74,76}\) Even though some donors with predictors of poor mobilization respond quite well to mobilizing therapies,\(^\text{77}\) poorly mobilizing autologous donors are assumed to have sustained an injury to the hematopoietic stem cell system that is responsible for the poor effect (see Table 4). In support of this premise, autologous donors with breast cancer who had received more chemotherapy and radiation or had tumor metastases in the marrow also had fewer stem/progenitor cells in apheresis products collected during steady state than donors who were less heavily pretreated and had no marrow metastases.\(^\text{78}\) Such damage may not account for all of the poor mobilization encountered in autologous donors.

example, patients who had received rituximab within 6 months of mobilization therapy mobilized less vigorously than rituximab-naïve patients. The use of rituximab during mobilization therapy for in vivo purging has not negatively affected mobilization.

**Allogeneic donors**

In the mid-1990s, normal donors with no history of cancer therapy began to receive mobilizing cytokines as allogeneic peripheral blood stem cell transplantation became more commonplace. Of these donors, 4-20% were noted to be poor mobilizers. The varying percentages are likely due, in part, to differences in the definition of poor mobilization. Nonetheless, these observations in normal donors established that a stem cell pool compromised by prior therapy, metastases or aging is not the only explanation for poor mobilization.

The causes of poor allogeneic stem cell mobilization are elusive, but some hints have recently come to light. DBA-strain mice exhibit rapid and vigorous mobilization when treated with G-CSF, Balb/c mice demonstrate delayed but vigorous mobilization and C57Bl/6 mice mobilize poorly. When plasma from C57Bl/6 mice was injected into Balb/c mice just prior to administration of mobilizing cytokines, mobilization was inhibited. Plasma from Balb/c and DBA mice was less inhibitory, suggesting that a genetically controlled circulating factor in the blood could be responsible for regulating the vigor and timing of mobilization.

A mouse model of poor mobilization was constructed by exposing Balb/c mice to lower-half-body irradiation prior to administration of mobilizing cytokines. These mice did not exhibit mobilization following cytokine administration. When plasma from part-body irradiated mice was injected into intact mice before cytokine administration, no mobilization resulted, suggesting that a circulating factor was responsible for the inhibition. Injection of plasma from poorly mobilizing human donors into mice prior to administration of mobilizing cytokine also inhibited mobilization. Whether this circulating factor(s) is operative in the clinical situation of poor mobilization in allogeneic and autologous donors is unknown. Since the survival of poorly mobilizing autologous patients with NHL was inferior to that of rapid mobilizers post-transplant and tumor relapse was more likely for poor mobilizers, identification and inactivation of any circulating factor that inhibits mobilization could improve patient outcome (Table 2).

**Molecular markers of mobilization**

Methods to improve the vigor of mobilization are virtually impossible to design on a rational basis since the mechanisms involved in the process are largely unknown. Stem cells reside in marrow adherent to marrow stromal cells via αβ integrin-mediated adhesion, that is, very late antigen 4 (VLA-4) on the stem cell and vascular cell adhesion molecule-1 (VCAM) on the stromal cell. Interruption of adhesion releases stem cells to the circulation. A higher percentage of CD34+ cells expressing VLA-4 was observed among the mobilized stem/progenitor cells of good mobilizers with NHL than in those of poor mobilizers. Marrow stromal cells produce a chemokine, stromal-derived factor 1 (SDF1), whose receptor, CXCR4, is present on CD34+ cells. Patients with NHL treated with chemotherapy plus cytokine(s) who mobilized well had significantly lower plasma levels of SDF-1 and lower percentages of CD34+ cells in the collections expressing CXCR4 than poor mobilizers. High plasma levels of flt3-ligand prior to administration of mobilizing therapies predict poor mobilization of autologous, but not allogeneic CD 34+ cells. Prospective studies are needed to confirm that molecular markers can accurately identify poor autologous mobilizers prior to administration of mobilizing therapies (Table 5).

**Harvesting enough cells for transplant from poor mobilizers**

Reports of maneuvers to harvest more stem/progenitor cells from donors who responded poorly to initial mobilizing therapies will be reviewed, but translation of the results to clinical practice is confounded by multiple variables. For example, a graft product anticipated to provide rapid, complete and durable restoration of marrow function at one center could be considered unacceptable at another. Failure to reach targets between 1 x 10^6/CD34+ cells/kg and 3 x 10^6 CD34+ cells/kg has defined products unsuitable for transplant at individual institutions. Methods to detect poor mobilization also vary and include sampling peripheral blood rather than determining the

Bone Marrow Transplantation
number of cell population subsets such as CD34+ cells and/or CFU-GM in an apheresis product. Some centers perform several apheresis procedures if needed to procure the target numbers of cells, while others do not. The volume of blood processed by the blood cell separator for each collection has varied from 310 to 351 and more. Keeping these differences in mind, maneuvers reported to bolster collection numbers for donors who mobilized poorly following various mobilization therapies are discussed.

**Poor autologous mobilization response to myelosuppressive chemotherapy**

Chemotherapy alone was used for mobilization before hematopoietic cytokines were available. Remobilization with higher cyclophosphamide doses in a small group of poor mobilizers with a variety of malignancies provided increased numbers of CFU-GM in the apheresis products while remobilization with the same dose of cyclophosphamide did not. Although chemotherapy without cytokines is no longer used for mobilization purposes, the observation that increasing doses of chemotherapy correlated with increasing vigor of mobilization could be useful when designing remobilization strategies.

**Poor autologous mobilization response to myelosuppressive chemotherapy plus cytokines**

Autologous donors with lymphoma, myeloma and Ewing's sarcoma who were treated with chemotherapy and G-CSF, and did not attain a suitable graft product with three apheresis procedures were remobilized with essentially the same mobilizing therapies. More CD34+ cells and CFU-GMs were collected during the second mobilization than the first from most donors. When collections from the first and second mobilizations were combined, 70% of the patients had sufficient cells for transplant. In another instance, a group of autologous donors with a variety of malignancies who mobilized poorly after treatment with disease-specific chemotherapy plus 5 μg/kg G-CSF were remobilized with either the same therapy or with 10 μg/kg G-CSF alone. Those receiving G-CSF alone yielded significantly higher numbers of CD34+ cells and CFU-GM than during their initial mobilization, while those remobilized with the same therapy yielded similar cell numbers to those with the first mobilization. However, the numbers of cells collected during either of the remobilization strategies were approximately the same. The value of cytokines alone as remobilizing therapy was also studied in another group of 23 autologous donors with solid tumors and hematologic malignancies who collected insufficient cells for transplant after up to five apheresis procedures. Initial mobilization had been accomplished with chemotherapy, G-CSF or a combination of chemotherapy and G-CSF. Remobilization therapy was initiated within 35 days using a combination of G-CSF and GM-CSF. The median number of CD34+ cells collected during remobilization was significantly higher than during the initial mobilization, although four of the 23 donors studied had poorer collections with remobilization. The largest study of remobilization in poorly mobilizing autologous donors described 119 patients with a good performance status whose initial mobilization therapy was either G-CSF and chemotherapy or G-CSF alone. The initial collections contained less than 2.5 x 10^6 CD34+ cells/kg. Remobilization was accomplished with either chemotherapy and G-CSF or G-CSF alone. Significantly, more CD34+ cells were collected during the second mobilization attempt than during the first, regardless of which remobilization therapy was used; G-CSF alone was as effective as chemotherapy plus G-CSF in remobilizing CD34+ cells. Thus, for patients who mobilized poorly with chemotherapy and cytokine, remobilization using the same therapy again, using cytokine alone at higher doses, or a combination of cytokines alone when a single cytokine was originally combined with chemotherapy, was successful in most but not in all patients.

**Poor autologous mobilization response to cytokines**

Studies specifically addressing the question of remobilization in autologous donors who mobilized poorly following cytokine administration are sparse. Since chemotherapy plus cytokine has been shown to mobilize more effectively than cytokine alone, this strategy might be tried for remobilization, provided neutropenia is an acceptable risk for the patient. Since good mobilizers have responded better to higher doses of cytokines than lower doses, and donors who mobilized poorly after chemotherapy plus cytokines have responded better to higher doses of cytokine or cytokine combinations, these strategies could be viable options for remobilization. For those few patients with obvious disease progression who mobilize poorly with cytokines alone, remobilization with disease-specific chemotherapy plus cytokines has often resulted in a better mobilization response in the experience of the authors.

**Autologous bone marrow harvests from poor mobilizers**

Marrow has occasionally been harvested from poorly mobilizing autologous donors in an attempt to construct a suitable graft product. A total of 13 patients with a variety of malignancies failed to mobilize target numbers of CD34+ cells prior to initiating apheresis and underwent marrow harvesting rather than blood stem cell collection. Nine were transplanted with the marrow after high-dose therapy and experienced delayed platelet recovery compared to a group of autologous marrow transplant patients that served as a historical control. Whether a suitable graft product could have been collected from the peripheral blood of those patients is unknown, but the marrow-derived graft product was inferior. Autologous bone marrow harvests with good cellularity but unknown numbers of CD34+ cells were harvested from another group of patients who had mobilized poorly. The marrow cells were added to the blood-derived progenitor cells and transplanted to 11 evaluable patients. Delayed hematopoietic recovery and a high (42%) procedure-related mortality resulted, leading to the conclusion that marrow harvested from poor mobilizers is an unreliable product. The number of publications regarding marrow harvests in
poorly mobilizing donors is small, but available data suggest that the transplantation quality of the marrow is poor.

**Poor allogeneic mobilization response to cytokines**

Little information is available regarding strategies to improve the vigor of mobilization in poorly mobilizing allogeneic donors. However, remobilization in good mobilizers to obtain a second allogeneic graft product has been described. In a single case report, retreatment with a mobilizing cytokine 3 days after completing a successful apheresis collection resulted in a poor CD34+ cell yield, suggesting that a longer time period is needed before retreatment with mobilizing cytokines. This observation was confirmed in a report of 13 allogeneic donors who underwent remobilization at a median of 3 months (range 1–13 months) after the initial mobilization and the number of CD34+ cells harvested during the first and second mobilization were comparable. Another group of 10 donors were mobilized twice with G-CSF for allogeneic blood stem/progenitor cell collection. The median time between the first and second mobilization was 41.5 days (range 16–385 days). Shorter time intervals between the two mobilization events were associated with fewer CD34+ cells collected during the second mobilization period. However, after 60 days, the CD34+ cell content of the first and second collections were similar. The only patient who received twice as much cytokine during the second mobilization than the first had more CD34+ cells in the second collection. Taken together, these reports suggest that if a poorly mobilizing allogeneic donor is considered for remobilization, a time interval of a month or two should be considered between the two collections if possible. If a month’s wait is not feasible, then remobilization with a higher dose of growth factor might be helpful.

**Transplantation of cells from poorly mobilizing donors**

A minimum of $1 \times 10^6$ CD34+ cells/kg is considered essential to assure hematopoietic recovery following transplant, with higher doses providing more rapid platelet recovery. A total of 18 patients who collected $< 1 \times 10^6$ kg mobilized CD34+ cells/kg and $< 1 \times 10^4$ CFU-GM were transplanted with those cells after high-dose therapy. Six patients received only those cells and five experienced delayed engraftment. A cellular marrow harvest was added to the cells for transplant to the remaining 12 patients. Of 11 evaluable patients, four had delayed neutrophil and eight delayed platelet engraftment, suggesting suitable graft products cannot be reliably constructed by adding marrow harvests to inadequate numbers of poorly mobilized blood stem/progenitor cells.

Three reports regarding transfusion of re-mobilized cells are instructive. A group of 23 patients whose mobilized collections contained fewer than $3 \times 10^6$ CD34+ cells/kg were remobilized with G-CSF and GM-CSF. Cells collected during both mobilization attempts were combined and transplanted following high-dose therapy. In all, 20 patients received at least $2 \times 10^6$ CD34+ cells/kg and recovered neutrophils at a median of at least 13 days and platelets at a median of at least 27 days. A second report of transplantation using remobilized cells described 27 patients who collected less than $2 \times 10^6$ CD34+ cells/kg and/or less than $10 \times 10^4$ CFU-GM/kg during the first mobilization. Both cell collections were combined and 24 received high-dose therapy and transplantation of $1.03-5.85 \times 10^6$ CD34+ cells. All but one patient recovered hematopoietic function by a median of 26 days (platelets, reticulocytes and neutrophils) after infusion. A third group of 49 patients who failed to collect $1 \times 10^6$ CD34+ cells after the first mobilization was remobilized and the collected cells were combined. The patients were treated with high-dose therapy and $0.88-6.74 \times 10^6$ autologous CD34+ cells/kg were infused. Recovery of $0.5 \times 10^9$/granulocytes to the circulation occurred at a median of 11 (9-16) days for 48 evaluable patients and platelet recovery occurred at a median of 14 (6-85) days for 47 evaluable patients. These three reports suggest that, with remobilization, enough hematopoietic stem/progenitor cells can be collected from most poorly mobilizing autologous donors to construct a transplant product that provides timely hematopoietic recovery.

**A mobilization strategy**

Taken together, these studies can support more than one evidence-based algorithm for mobilization of hematopoietic progenitor/stem cells. One general approach is to identify donors at high risk for poor mobilization and provide them with therapies aimed to provide maximum mobilization vigor, accepting any increased time, cost, resource utilization and/or donor risk for morbidity that might be associated with the selected therapy. A second general approach is also supportable, recognizing that while groups of autologous donors can be categorized as being at high risk for poor mobilization, individual autologous and allogeneic donors who will mobilize poorly cannot be accurately identified prospectively. Since most donors are good or adequate mobilizers, all donors are treated with therapies known to produce useful mobilization in most cases, saving the more rigorous and/or costly therapies for those who respond poorly.

Cytokine administration produces sufficient mobilization to harvest $1.5-4 \times 10^6$ CD34+ cells/kg in one to four apheresis procedures for most donors at the University of Nebraska Medical Center. The entire collection process from the time of administration of the first dose of cytokine until the final apheresis procedure is complete in 5–9 days when cytokine administration begins on Thursday and the first apheresis procedure begins the following Monday. If chemotherapy is given specifically for mobilization, the process will require 14–16 days from the date of chemotherapy administration until the graft product is collected. If chemotherapy given as part of disease-specific therapy is also used for mobilization, the time saving is optimal. Remobilization is performed for those patients who do not amass a sufficient number of cells for transplant during the first mobilization attempt (Table 6).

Conclusion

Cytokines alone or chemotherapy plus cytokines mobilize hematopoietic stem cells to the circulation. Mobilized hematopoietic stem/progenitor cells provide rapid hematopoietic recovery following transplantation. While most donors mobilize well, a percentage of both allogeneic and autologous donors respond poorly to mobilizing therapies. A single solution to poor mobilization is unlikely to exist, since the reasons for the problem are multiple and differ from one donor to the next. Until the causes are accurately defined, solutions are unlikely to be found. The issue is important not only for current transplant needs, but also for future needs if, as early reports suggest, these circulating hematopoietic cells are capable of transdifferentiation and will be used to engineer nonhematopoietic cells and tissues. Hopefully, additional research will optimize mobilization to the extent that a sufficient number of cells for any need can be harvested with a simple phlebotomy.

JACIE Accreditation in 2008: demonstrating excellence in stem cell transplantation

Penwood Pamphil, Jane F. Apperley, Diana Samson, Ineke Slaper-Cortenbach, Eoin McGrath

JACIE was initiated as a small pilot project in Spain in 2000 and launched as a formal Europe-wide inspection program in January 2004. Since 2000, over 150 applications for accreditation have been received by the JACIE Office and more than 130 inspections have been completed in European centers and facilities. Almost all of these were found to be functioning at a high level of excellence, with the majority having only minor deficiencies in compliance with the standards. In one-third of centers there were more significant deficiencies. The most common deficiencies were in quality management. Following correction of deficiencies 86 centers have to date achieved full accreditation and many more are nearing the completion of the process. Implementation of JACIE involves a significant investment of time and resources by applicant centers. The majority require at least 18 months to prepare for accreditation and 85% have needed to employ a quality manager and/or data manager on an ongoing basis. However, all centers felt their program had benefited from the implementation of JACIE. JACIE is also working closely with other international organisations related to cellular therapy as part of the Alliance for the Harmonisation of Cell Therapy Accreditation (AHCTA), which is examining the differences in existing standards and aiming to develop international standards for all aspects of stem cell transplantation. In particular the requirements for safety of imported tissues and cells has emphasised the need for global harmonisation. The recent implementation of Directive 2004/23/EC and the associated Commission Directives 2006/17/EC and 2006/86/EC has provided an impetus for the implementation of JACIE in European Union (EU) member states. It will be important in the future to examine how JACIE can co-operate with the EU Competent Authorities (CA) to ease the burden of the inspection process for haematopoietic stem cell (HSC) transplant programs.

The Joint Accreditation Committee of ISCT-EBMT (JACIE) is a non-profit body first established in 1998 for the assessment and accreditation of hematopoietic stem cell (HSC) transplantation programs. The Committee was founded by the European Group for Blood and Marrow Transplantation (EBMT) and the International Society for Cellular Therapy (ISCT), the two leading scientific organizations involved with HSC transplantation in Europe. JACIE modelled itself on the US-based Foundation for the Accreditation of Cellular Therapy (FACT), established in 1996 by the ISCT and the American Society for Blood and Marrow Transplantation (ASBMT). JACIE works closely with FACT through a joint committee structure to establish standards for the provision of quality medical and laboratory practice in HSC transplantation. JACIE conducts inspections, accredits transplant programs and encourages health institutions and facilities performing HSC transplantation to voluntarily meet these standards to demonstrate their high levels of quality of care.

The primary aim of JACIE is to improve the quality of HSC transplantation in Europe by providing a means whereby clinical transplant centers, HSC collection facilities and processing facilities can demonstrate excellence. This is supported by its co-ordinating role in the provision of training courses in quality management for applicant centers and training courses for inspectors. An additional and wider aim is to ensure harmonisation between JACIE standards and other national/international standards, including the EU Tissues & Cells Directive 2004/23/EC and the related implement-
JACIE accreditation is voluntary, but provides a means whereby transplant facilities can demonstrate that they are working within a quality system covering all aspects of the transplantation process and thus show compliance with the requirements of insurance companies or national and/or international regulatory authorities.

The JACIE program was run as a pilot program in Spain between 2000 and 2002 and formally launched on an international basis in January 2003 with support from the European Union under the Public Health Program (2003-2008) (http://ec.europa.eu/health/ph_projects/2003/action2/action2_2003_05_en.htm). Between January 2000 and November 2008, 139 centers or facilities have been inspected for the first time and 16 have been re-inspected. The number of applications/inspections per country is Austria 2/3, Belgium 8/3, Czech Republic 3/1, Finland 3/3, France 22/20, Germany 27/20, Italy 17/11, The Netherlands 20/16, Poland 1/0, Saudi Arabia 1/1, Spain 10/7, Switzerland 10/16, Turkey 1/1, and the United Kingdom 33/37 (Figure 1 shows initial applications by country). This experience has enabled JACIE to identify areas of common difficulty for applicant centers, to assess what assurance centers need in order to achieve accreditation, and has also raised some general issues relating to national and international regulation.

The FACT-JACIE Standards

The 4th edition of the joint FACT-JACIE standards covers all aspects of clinical transplant programs, collection facilities (bone marrow [BM] and peripheral blood progenitor cell [PBPC] collection) and processing of HPC, as shown in Table 1. These superseded the 3rd edition at the start of November 2008. The 4th edition will be the standard against which programs are inspected from 1st February 2009. The updated standards are applicable to cellular therapy products (CTP) but where applicable only to hematopoietic progenitor cells (HPC), this is specifically referenced. The standards also apply to the use of therapeutic cells (TC) derived from blood or marrow, including donor lymphocytes. Important changes in the 4th edition are as follows:

1. Quality Management (QM): the standards have been realigned to reduce redundant references to QM topics and have been organized in each section on a topical basis. Standards pertaining to operational quality controls have been relocated to the relevant operations sections
2. Standard Operating Procedure (SOP) review: the requirement has been changed from annual to biannual (or upon the introduction of changes in procedures, whichever is sooner).

3. The donor selection, evaluation, and management sections in the clinical program and collection facility sections have been modified to reflect the way that these responsibilities are divided between clinical programs and collection facilities. The collection facility standards focus more on donor evaluation and management, with less emphasis on donor selection activities. In some situations the collection facility is primarily responsible for donor selection activities, and the standards now state that in these situations, collection facilities are required to comply with the applicable clinical program standards.

4. Early discharge from the transplant center. It was agreed by the FACT-JACIE Standards Committee that it is against the spirit of the standards to inspect and accredit the center performing the transplant procedure as the "transplant center" without considering post-transplant care.

With this in mind the 4th edition of the standards states that Clinical Programs shall ensure planned discharges are to facilities adequate for post-transplant care. This means that it is the responsibility of the transplant center to ensure compliance with items such as the provision of isolation facilities, staffing and training and policies and procedures. JACIE will require documentation of compliance and this might in the future include inspection of the hospital providing post-transplant care.

5. Appendices have been revised to clarify requirements and simplify the standards. Those that are external tables and forms have been removed and replaced with a reference table indicating the websites where the current versions can be found. This is in response to situations in which external tables and forms are updated within months of publication of FACT-JACIE standards, which causes the appendices to become out of date be-
special communication

Figure 3. Cumulative numbers of initial applications and total inspections between 2000-2008.

Figure 4. Initial applications for inspection by year between 2000-2008.

before the next edition is published.

6. Expanded requirements: an effort has been made to simplify the standards since they are intended to define minimum standards rather than best practice. Some requirements have been expanded and specific examples include:

- Written agreements - the responsibility of ensuring external entities comply with standards and governmental laws and regulations is placed on the clinical program/collection facility/processing facility as appropriate.
- Disaster plans - explicitly states in standard

the requirement to include the response of the clinical program/collection facility/processing facility as appropriate.

- Concurrent plasma and samples are required to have the same identifier as the cellular therapy product.

7. Terminology: in several cases the use of specific terminology was clarified to reduce misinterpretations commonly found during the inspection and accreditation process and to account for international variations. Specific examples include:

- Change from HPC to CTP where applicable. In instances where only HPC applies it is specifically referenced.
- Board eligibility/certification references changed to specialist certification to accommodate international education.
- References to specific governmental agencies and accrediting bodies, e.g. the United States Food and Drug Administration (FDA) etc have been changed to appropriate governmental authorities or certified as required by governmental authorities as appropriate.
- Validation has been redefined to include only processes (including intended uses of equipment) and qualification to include only equipment, supplies, and reagents (in alignment with FDA interpretation).

There are also a number of specific sectional changes which are not described here.

The complete standards and the accompanying guidance manual are available on the FACT and JACIE websites. They are broadly consistent with the requirements of the Tissues and Cells Directive (2004/23/EC) and accompanying Commission Directives (see above) as regards donation, procurement and processing of stem cells, but in addition, cover the clinical transplant program. Accreditation of clinical programs includes the clinical use of cord blood (CB) stem cells but the JACIE program does not accredit CB collection and banking facilities as this process is currently carried out by FACT against the Netcord-FACT Standards.

The FACT-JACIE Manual and Inspection Checklist

The manual contains the standards together with detailed guidance on the interpretation and measures required to demonstrate compliance. Each standard is followed by specific questions relating to that standard and these questions form the basis of the inspection checklist, which must be completed prior to inspection by the applicant center and verified by the inspector during the
inspection. The checklist has recently changed format from Microsoft Word to Microsoft Excel to facilitate the completion of the checklist by both the applicant and the inspector and to make analysis of the answers easier by using automatic colour-coding and including filters (Figure 2).

The Accreditation Process

Preparation by Center
The center implements measures as described in the FACT-JACIE accreditation manual, and then applies for inspection by submitting basic information about the program/facility and a number of supporting documents including a self-assessment checklist. The application information and checklist must be submitted in English but all other documentation, including SOPs is accepted in the language of the center.

Inspection
An on-site visit is carried out by a team of trained inspectors, usually one per facility (clinical / collection / processing). Inspectors are medical, scientific or other professional persons working in HSC transplantation, with specific qualifications and experience for inspecting clinical, collection and / or processing facilities. Inspectors must attend a JACIE-sponsored training course and pass an examination. Where a clinical program performs adult and paediatric transplants, an adult and a paediatric inspector will attend. Inspectors may also be from another country but should be either native or fluent speakers of the relevant language. An inspection visit usually lasts 1.5 days and involves discussion with staff during their work, review of documents / records and completion of a detailed checklist relating to the standards.

The report is prepared in English, notes any areas of non-compliance with the standards and is reviewed by the JACIE Office and Accreditation Committee, the latter established in 2006. This report indicates all non-compliances with specific standards and makes specific recommendations for corrections and improvements. The distinction between minor deficiencies and more significant deficiencies is not strictly defined, but in general terms, specific deficiencies in documentation are considered minor while more general problems with documentation or problems with processes or facilities are considered significant. The center is allowed up to 9 months to correct deficiencies, depending on the amount of work required.

Center Response
The center must indicate acceptance of the findings and then in due course submit documentary evidence to confirm corrections or amendments. The original inspectors review the documentation. Review by the inspectors rather than by the Accreditation Committee is required because of language issues. In some cases a full or limited re-inspection may be required to show that deficiencies have been corrected. The inspectors confirm to the JACIE Office that all necessary corrections have been made or indicate that there are still outstanding areas for completion.

Accreditation
The JACIE Office and Accreditation Committee reviews all the reports and relevant documentation and if satisfied that all deficiencies have been corrected, makes a recommendation to the JACIE Board that the center be awarded accreditation. If approved, accreditation is awarded, valid for 4 years, subject to an annual report from the center noting any significant changes in personnel or processes and including annual activity figures and an interim audit at the end of the second year of accreditation.

Summary of JACIE Inspection Activity
To date, 156 facilities have formally applied for accreditation. Ninety-nine centers applied for accreditation for a combination of clinical, collection and processing facilities; 20 centers applied for clinical only; 1 for bone marrow harvest only; 4 for apheresis collection only; 2 centers for collection and processing only; and 12 for processing only. Between January 2000 and November 2008 139 centers were inspected (Figure 3) including

Figure 5. Provisional data showing the proportion of centers reporting transplants to the 2007 EBMT Activity Survey that have applied for JACIE accreditation and meet the minimum transplant requirements.
both first-time and reaccreditation inspections. The number of first-time or initial applications rose to 33 in 2007 and 31 applications have been received to date in 2008 (Figure 4) although the overall number of applications is higher as a result of requests for reaccreditation. Figure 5 shows the overall proportion of transplant centers reporting to the EBMT that are now JACIE registered.

Common Deficiencies
The most common deficiencies were in documentation, labelling and in the quality management program. This is consistent with the initial experience of the FACT accreditation program in the United States and is described in more detail in the next section. Minor failures of compliance were frequent, usually involving problems with documentation. Examples include:
- SOPs not containing key references
- Pregnancy assessment not documented during donor evaluation

More significant failures of compliance were less common. Examples include:
- Program not functioning as a single program (e.g. SOPs not uniform across different clinical sites, for example where allogeneic and autologous patients, or adult and paediatric patients were treated on different sites)
- Outpatient facilities inadequate (e.g. no provision for isolation of infectious patients)
- Inadequate quality management program
- No continuous temperature monitoring of freezers in processing facility
- Temperature not monitored during transport of HSC from processing facility to clinical unit
- Engraftment data not monitored by processing facility

Some of these significant deficiencies arose from lack of resources, e.g. size of laboratory inadequate for workload or lack of an experienced quality manager.

Analysis of Deficiencies
Deficiencies in the quality management program were by far the most common cause of failure of compliance with the standards and, including problems with policies and procedures (SOPs), accounted for 37% (636 of 1732) of total cited deficiencies (Figure 6). Deficiencies included:
- Problems with the formatting and content of SOPs, example:
  - missing examples of worksheets/forms/labels
  - missing references (where relevant)
  - failure to include range of expected results (where relevant)
- Lack of procedure for documenting deviations from SOPs
- Lack of regular review process for SOPs
- No SOPs for critical procedures e.g. bone marrow collection
- Inadequate document control procedure
- Lack of validation of equipment/procedures in collection and processing facilities
- Inadequate audit activity e.g.
  - no SOP for audit,
  - no written program for planned audits
  - no documentation of results of audits
  - no formal process for disseminating results
- Inadequate adverse event (AE) reporting/reviewing.

Centers often used a hospital-based incident reporting system, but in many cases it appeared from the number of reported AEs that this was not adequate to meet the needs of the HSCT program. Often it was not clear that all AEs were reviewed by the program director and/or that a report was issued to the patient’s physician.

Other significant problems included those related to donor selection and testing, labelling and process control. The commonest problems as documented for the clinical program, collection and processing facilities are summarised in Table 1. A list of common deficiencies is available on the JACIE website.

Centers often have problems in designing JACIE-compliant labels. This has been addressed by the International Cellular Therapy Coding and Labeling Advisory Group which has published terminology
special communication

and designed suitable labels for CTPs which are based on the ISBT 128 standard for stem cell component identification. An implementation plan has also been published by this group. Further information is available at http://iscbha.org/cellulartherapy_home.html. A Workshop of the EU Normalisation Committee (CEN) has agreed to recommend a modified version of the ISBT 128 system to the EU Directorate General for Public and Consumer Health (DG SANCO).

Current status of centers including time taken for correction /accreditation

Eighty-two centers have been awarded accreditation at least once. Of these, 58 are currently accredited including 4 reaccreditations and 7 of the remaining 10 centers whose accreditation has expired have presented themselves for reaccreditation (of the remaining 3 centers, one center has ceased transplantation and the other two centers have not yet requested reaccreditation). These 7 centers are among the 48 programs that are either awaiting reports, correcting deficiencies or who have presented evidence of corrections for assessment. One center abandoned the accreditation process but subsequently reapplied alongside a clinical unit.

The time taken by centers to present documentary evidence of corrections of deficiencies in 2007 varied from 18 to 297 days with an average of 130 days. In general the maximum amount of time allowed to correct deficiencies is 9 months (from the time the center receives the Accreditation Committee’s report.)

Experience of centers implementing JACIE

It was anticipated that implementation of the JACIE standards would pose some difficulties for applicant centers, particularly in relation to establishing a QM system and accompanying documentation. While QM is well established in laboratory practice, and most processing facilities will already have an established QM program, QM programs were rarely in place in clinical units. It was also anticipated that there would be resource implications in terms of staff time because of the amount of detailed documentation that is required to demonstrate compliance with the standards.

We undertook two surveys designed to assess the difficulties experienced by centers in preparing for accreditation. The results of these surveys have been published in detail before. Briefly, in the first survey we found that, in most centers, at least 18 months was needed for preparation. Twenty-two centers had additional staff other than the Program Director to manage project implementation, but these staff were only part-time in 13 centers and only 11 had any experience in quality management. The area of greatest difficulty for most centers was in the clinical program. Most difficulty was found in implementing the QM system, adverse event reporting system and other documentation. Some centers already had written policies and SOPs, an audit system and an adverse event reporting system, but in all cases further development was needed to bring these aspects of QM up to the required standard.

The results of the survey were consistent with the findings of the inspectors that the most common deficiencies were inadequacies in the QM system. Our findings also indicated that these arise from lack of trained staff and absence of QM culture, particularly in the clinical setting. There is clearly an important need for training of clinical staff (doctors and nurses) in quality management. It is also important for centers to have a designated quality manager who has appropriate experience in quality management systems.

In a second survey all responding centers indicated that they had benefited from implementing the JACIE standards. The areas of greatest perceived benefit were in procedure and practices, staff motivation, control of adverse events, and co-ordination between different areas of the program. Significant benefits were also perceived in patient satisfaction, facilities, patient care and safety and training of new and existing staff. The areas where little or no benefit was noted were in costs, compliance with requirements of health insurers/social security and in government recognition. It was evident that implementation and maintenance of a quality system increases the running costs of a program. Eighty-one percent of the centers reported that implementation of the QM system had highlighted a need for changes in the implementation of the transplant program and all felt that accreditation was worth the effort invested.

The requirements of Directive 2004/23/EC became law in EU member States on April 7th, 2006. The implementation of the parent Directive is supported by two Commission Directives (2006/17/EC and 2006/86/EC) which set out the detailed technical requirements. They cover (i) donation, procurement and testing, and (ii) coding, processing, preservation, storage and distribution and were published on February 8th 2006 and 24th October 2006, respectively. The current JACIE standards conform to the requirements of the Directive as regards donation, procurement and processing of stem cells, although JACIE is more detailed in many areas and JACIE standards also cover clinical transplant programs. However in some areas more ex-
The precise wording of the JACIE standards is required to fulfill the requirements of the Directive and appropriate changes were incorporated into the 3rd and 4th editions of the FACT-JACIE standards.

While support for accreditation among the professional transplant community is high, there are varying levels of engagement with JACIE by the regulatory authorities in different countries. It has proven very difficult to build up a standard picture of official support across the EU due to significant differences in regulatory structures, varying readiness to implement the Directive and political issues. However, it can be said that in a number of countries there has been support from the regulatory authorities, both direct and indirect, for the JACIE accreditation system. This is the case in Austria, Belgium, France, Italy, The Netherlands, and the United Kingdom.

In Spain, the National Transplant Organization (ONT) has signed a formal agreement with JACIE and national scientific societies which gives official support to voluntary accreditation by transplant units and will recognize accredited programs as meeting quality and safety requirements. (http://www.ont.es/contenido.jsp?id_nodo=306&keyword=&auditoria=F)

Outside the EU, a Swiss law on regulating transplants enacted in July 2007 directly cites JACIE in relation to HSC transplants and JACIE is cited as part of the law on compulsory health insurance requiring HSC centers to be certified by the Swiss Transplant Workgroup on Blood And Marrow Transplantation (STABMT) in accordance with JACIE Standards. All 10 HSC centers in the country have undergone inspection and the majority are now accredited.

Global harmonization of standards

JACIE, FACT, Netcord, AABB (formerly the American Association of Blood Banks) and the World Marrow Donor Association (WMDA) are working together to promote consistent interpretation of the requirements of the standards and guidance produced by each organization. A detailed comparison of the requirements of the EU Directives with the FACT-JACIE, Netcord-FACT, AABB and WMDA standards is being undertaken. It is a fundamental aim of JACIE to ensure that the FACT-JACIE standards as far as possible are harmonized with other applicable national and international requirements, including those of the EU. This is particularly important to prevent difficulties in importing and exporting tissues across international boundaries, which could occur if there were to be differences in the standards adopted in different countries.

One of the results of this collaborative approach has been the establishment of the Alliance for the Harmonisation of Cellular Therapy Accreditation (AHCTA) whose members include AABB, American Society for Blood & Marrow Transplantation (ASBMT); European Group for Blood & Marrow Transplantation (EBMT); Foundation for the Accreditation of Cellular Therapy (FACT); International Netcord Foundation; International Society for Cellular Therapy (Europe) (ISCT); Joint Accreditation Committee ISCT-EBMT (JACIE); and WMDA. AHCTA has developed a position paper on issues arising out of the import and export of HSC, together with a brief definition of the minimal standards that might be used to assess the provenance of imported HSC. The documents are accessible at www.ahcta.org. Within the EU discussions are now beginning on the establishment of a register of HSC collection centers and how this might be supported and hosted.

Conclusions

The FACT-JACIE accreditation system is now firmly established in Europe and the experience of centers that have been inspected is that implementation of the JACIE standards has led to significant improvements in different aspects of their transplant programs. JACIE has further assisted with a number of training courses for preparing centers for accreditation and has recently published a practical guide to quality management in transplant units. JACIE has also developed a close working relationship with other organizations involved in cellular therapy, which will form the basis for a new global approach to harmonization of standards and accreditation systems worldwide. This collaboration represents an innovative and proactive approach to solving the problems of international exchange of tissues and cells as these relate to the stem cell transplant community.

SPECIAL REPORT

Current status of JACIE accreditation in Europe: a special report from the Joint Accreditation Committee of the ISCT and the EBMT (JACIE)

D Samson, I Slaper-Cortenbach, D Pamphilon, E McGrath, F McDonald and A Urbano Ispizu

JACIE Accreditation Office, EBMT Secretariat, Hospital Clínico de Barcelona, Barcelona, Spain

JACIE (Joint Accreditation Committee of the ISCT and the EBMT) launched its first official inspection programme in January 2004. Since then, 35 centres in Europe have been inspected. Almost all were found to be functioning at a high level of excellence, with the majority having only minor deficiencies in compliance with the standards. In one-third of centres there were more significant deficiencies. The most common deficiencies were in quality management, and a survey of the applicant centres confirmed this was the area where centres experienced most difficulty in preparation for accreditation. Following correction of deficiencies, 28 centres have at the time of writing achieved full accreditation. Implementation of JACIE required a significant investment of time and resources by applicant centres. The majority required at least 18 months to prepare for accreditation and 85% needed to employ a quality manager and/or data manager on an ongoing basis. However, all centres felt their programme had benefited from the implementation of JACIE. In addition to the inspection and accreditation of individual centres, JACIE maintains an educational programme including training courses for inspectors and for centre preparation. JACIE is also working closely with other international organisations working in cellular therapy to develop international standards for all aspects of stem cell transplant. The recent implementation of Directive 2004/23/EC has provided an impetus for the implementation of JACIE in EU member states and in particular the requirements for safety of imported tissues and cells have emphasised the need for global harmonisation.

Bone Marrow Transplantation (2007) 39, 133-141. doi:10.1038/sj.bmt.1705564
Keywords: transplant; accreditation; standards; inspection; regulation

Introduction

JACIE is a non-profit body established for the purposes of assessment and accreditation in the field of haematopoietic stem cell transplantation (HSCT). The committee was founded in 1998 by the European Group for Blood and Marrow Transplantation (EBMT) and the International Society for Cellular Therapy (ISCT), the two leading scientific organisations involved with HSCT in Europe. JACIE modelled itself on the US-based Foundation for the Accreditation of Cellular Therapy (FACT), established in 1996 by the ISCT and the American society for Blood and Marrow Transplantation (ASBMT). JACIE actively collaborates with FACT in establishing standards for the provision of quality medical and laboratory practice in HSCT. JACIE conducts inspections, accredits programmes and encourages health institutions and facilities performing HSCT to meet these standards voluntarily in order to demonstrate their high levels of quality of care. The current organisation of JACIE is shown in Figure 1. The structure ensures wide consultation, with 20 European countries now represented on the Board in addition to nursing, paediatrics and cord-blood representatives.

The primary aim of JACIE is to improve the quality of HSCT in Europe by providing a means whereby transplant centres, cell collection facilities and processing facilities can demonstrate high-quality practice. This is supported by coordinating training courses in quality management for applicant centres and courses for inspectors. An additional and wider aim is to ensure harmonisation between JACIE standards and other national/international standards, including the EU Tissues & Cells Directive (Directive 2004/23/EC) and the related implementing Directives. The increasing use of unrelated donor cells for transplants highlights the need for further work in this area.

Accreditation of HSCT facilities is through online submission of documentation and an on-site visit by a team of trained inspectors. Centres may apply for accreditation as complete programmes comprising a clinical programme, a collection facility and a processing laboratory or, for example, as a single collection or processing facility serving a number of clinical programmes. JACIE accreditation is voluntary, but provides a means whereby transplant facilities can demonstrate that they are working within a quality system covering all aspects of the
transplantation process and thus show compliance with the requirements of insurance companies or national and/or international regulatory authorities.

Following a programme of four pilot inspections in Spain between 2001 and 2003, where FACT inspectors performed the first on-site visit, the JACIE programme was fully implemented in January 2004 with support from the European Union under the Public Health Programme (2003-2008). Between January 2004 and August 2006, 35 centres were inspected. These included two in Austria, two in Finland, six in France, one in Italy, five in The Netherlands (an additional Dutch centre was inspected in 2004 as part of national pilot project but this centre was not the subject of a formal accreditation review), 10 in Switzerland and nine in the UK. This experience has enabled JACIE to identify areas of common difficulty for applicant centres, to assess what assistance centres need in order to achieve accreditation, and has also raised some general issues relating to national and international regulation.

The JACIE standards

The JACIE standards cover all aspects of clinical transplant programmes, collection facilities (BM collection and peripheral blood progenitor cell collection) and processing, as shown in Table 1. The standards also apply to the use of therapeutic cells derived from blood or marrow, including donor lymphocytes.

Within each subsection are detailed lists of specific standards; for example the standard on donor evaluation and selection contains 33 specific items relating to clinical evaluation, laboratory testing, informed consent, etc. The complete standards and the accompanying guidance manual are available on the JACIE website. Work on the third edition of the standards is now complete and they will be released shortly.

JACIE standards conform to the Tissues and Cells Directive as regards donation, procurement and processing of stem cells, but also cover clinical transplant programmes. Accreditation of clinical programmes includes the clinical use of cord blood (CB) stem cells but the JACIE programme does not accredit CB collection and banking facilities as this process is currently carried out by Netcord-Fact.

The JACIE manual and inspection checklist

The manual contains the standards together with detailed guidance on the interpretation and measures required to demonstrate compliance. Each standard is followed by specific questions relating to that standard and these questions form the basis of the inspection checklist, which must be completed before inspection by the applicant centre and verified by the inspector during the inspection (Figure 2).

The accreditation process

Preparation by centre

The centre implements measures as described in the JACIE accreditation manual, and then applies for inspection by submitting basic information about the programme/facility and a number of supporting documents including a

self-assessment checklist. The application information and checklist must be submitted in English, but all other documentation, including Standard Operating Procedures (SOPs), is accepted in the language of the centre.

**Inspection**

An on-site visit is carried out by a team of trained inspectors, usually one per facility (clinical/collection/processing). Inspectors are medical, scientific or other professional persons working in HSCT, with specific qualifications and experience for inspecting clinical, collection and/or processing facilities. Inspectors must attend a JACIE-sponsored training course and pass an examination. Where a clinical programme performs adult and paediatric transplants, an adult and a paediatric inspector will be assigned. Inspectors may also be from another country, but should be either native or fluent speakers of the relevant language. In countries where it is not possible to assign an inspector who speaks the language, a local expert is requested to assist with translation of interviews and documents as necessary.

An inspection visit lasts 1–1.5 days and involves discussion with staff during their work, review of documents/records and completion of a detailed checklist relating to the standards. The inspectors write a report in English, noting any areas of non-compliance with the standards, which is reviewed by the JACIE Office. Based on the inspectors’ findings, a supplementary report from the JACIE Medical Director (MD) is prepared indicating the current level of compliance (Table 2) and making specific recommendations for corrections and improvements. The distinction between minor deficiencies and more significant deficiencies is not strictly defined, but in general terms, specific deficiencies in documentation are considered minor whereas more general problems with documentation or problems with processes or facilities are considered significant. Between 3 and 12 months is allowed for the centre to correct deficiencies, depending on the amount of work required. The Inspection report and Medical Director’s (MD) report are approved by the JACIE Executive Committee and then issued to the applicant centre. Recently, the JACIE Accreditation Committee was established, which will take over this role.

**Centre response**

The centre must indicate acceptance of the findings and then in due course submit documentary evidence to confirm corrections or amendments. The original inspectors review the documentation. Review by the inspectors rather than by the Accreditation Committee, MD or JACIE office alone is required because of language issues. In some cases, a limited revisit may be the best way to show that deficiencies have been remedied. The inspectors confirm to JACIE that all necessary corrections have been made or indicate that there are still outstanding areas for completion.

**Accreditation**

The Medical Director reviews all the reports and relevant documentation and if satisfied that all previous deficiencies have been corrected, the JACIE Executive Committee (in future the JACIE Accreditation Committee) makes a recommendation to the JACIE Board that the centre be awarded accreditation. If approved, accreditation is awarded, valid for 3 years, subject to an annual report from the centre noting any significant changes in personnel or procedures and including annual activity figures.

Since 2006 the numerical gradings are used only by JACIE for internal purposes and do not form part of reports to centres.

Outcome of inspections

To date, over 80 facilities have formally applied for accreditation. Between January 2004 and August 2006 35 centres were inspected. Twenty-nine centres applied for accreditation for a combination of clinical, collection and processing facilities. One centre applied for clinical and collection only, three centres applied for collection and processing, one for apheresis collection only and one for processing only.

Almost all were found to be functioning at a high level of excellence. Fifty-seven per cent were assessed as initially compliant at level 2, 40% at level 3, and 3% at level 4. In four centres assessed at level 3 a limited re-inspection was recommended as the simplest means of demonstrating compliance because of general problems in the quality management system (QMS) of the clinical programme.

The most common deficiencies were in documentation, labelling and in the quality management programme. This is consistent with the initial experience of the FACT accreditation programme in the United States.

Common deficiencies

Minor failures of compliance were frequent, usually involving problems with documentation. Examples include:

- SOPs missing references.
- Pregnancy assessment not documented during donor evaluation.

More significant failures of compliance were less common. Examples include:

- Programme not functioning as a single programme (e.g. SOPs not uniform across different clinical sites, for example, where allogeneic and autologous patients, or adult and paediatric patients were treated on different sites).
- Outpatient facilities inadequate (e.g. no provision for isolation of infectious patients).
- Inadequate QMS.
- No continuous temperature monitoring of freezers in processing facility.
- Temperature not monitored during transport of cells from processing facility to clinical unit.
- Engraftment data not monitored by processing facility.

Some of these significant deficiencies arose from lack of resources, for example, size of laboratory inadequate for workload or lack of an experienced quality manager.

Analysis of deficiencies

QMS. Deficiencies in the QMS were by far the most common cause of failure of compliance with the standards and, including problems with policies and procedures (SOPs), accounted for 35% (201 of 570) of total cited deficiencies (Figure 3).

Deficiencies in QMS included:

- Problems with the formatting and content of SOPs, for example,
  - missing examples of worksheets/forms/labels,
  - missing references (where relevant) and
  - failure to include range of expected results (where relevant).
- Lack of procedure for documenting deviations from SOPs.
- Lack of regular review process for SOPs.
- No SOPs for critical procedures, for example, bone marrow collection.
- Inadequate document control procedure.
- Lack of validation of equipment/procedures in collection and processing facilities.
- Inadequate audit activity, for example,
  - no SOP for audit,
  - no written programme for planned audits,
  - no documentation of results of audits and
  - no formal process for disseminating results.
- Inadequate adverse event (AE) reporting/reviewing. Centres often used a hospital-based incident reporting system, but in many cases it appeared from the number of reported AEs that this was not adequate to meet the needs of the HSCT programme. Often it was not clear that all AEs were reviewed by the programme director and/or that a report was issued to the patient's physician.
**Patient/donor issues**

Deficiencies in documentation were frequent.

- No verification of patient's initial diagnosis from primary records.
- No formally documented criteria for defining suitable donor.
- Failure to document vaccination history, transfusion history or travel history.
- Pregnancy not always assessed in female donors of childbearing age.

**Labelling of components**

JACIE standards for labelling of components require detailed information to be shown on the label. In the majority of centres, it was found that labelling of products during collection and processing was not compliant with the standards in a variety of ways, accounting for 15% of all cited deficiencies (83 of 570), for example,

- time of end of collection/processing missing,
- volume of anticoagulant missing, and
- unique identifier (alphanumeric number) not used at collection.

It appears that centres have a common problem in designing JACIE-compliant labels. This is being addressed by the International Cellular Therapy Coding and Labeling Advisory Group, which is aiming to design suitable labels for general use and incorporating the requirements of the ISBT 128 standard for stem cell component identification and has provisionally set May 2007 as the date by which to complete its final documents and recommendations. Further information on the work of this group is available at http://iccbba.org/cellulartherapy_home.html.

The analysis of common deficiencies in Figure 3 shows that quality management and component labelling are the most frequently observed sources of deficiencies. Incomplete donor evaluation was also frequent. The frequency of deficiencies involving quality management and AE reporting are consistent with the reported difficulties experienced by centres (see below). A list of common deficiencies is available on the JACIE website.

**Current status of centres including time taken for correction/accreditation**

At the time of reporting 28 of the 35 inspected centres have completed correction of all deficiencies and achieved accreditation with a further four recommended to the Board for accreditation, as shown in Table 3. One additional clinical programme is awaiting accreditation of...

their human leukocyte antigen typing laboratory by the European Federation of Immunogenetics EFI (a requirement under standard B2.190) before full accreditation can be awarded but is otherwise fully compliant with the JACIE standards. Five programmes are still in the process of correcting deficiencies. The time taken to document correction of deficiencies has varied from 5.5 to 19 months, with a median of 11.5 months. In future, the maximum amount of time allowed to correct deficiencies will be 12 months (from the time the centre receives the initial report).

Experience of centres implementing JACIE.

It was anticipated that implementation of the JACIE standards would pose some difficulties for applicant centres, particularly in relation to establishing a QMS and accompanying documentation. Although QM is well established in laboratory practice, and most processing facilities will already have an established QM programme, a QM programme is rarely in place in clinical units. It was also anticipated that there would be resource implications in terms of staff time because of the amount of detailed documentation that is required to demonstrate compliance with the standards.

An initial survey was designed to assess the difficulties experienced by centres in preparing for accreditation. All centres were asked to complete the survey immediately following inspection and return to the JACIE Office. The survey was completed online and respondents were given the choice of including their centre name or submitting the survey anonymously.

The survey included questions addressing the following issues:

- Motivation for applying.
- Time period from decision to apply to date of inspection.
- Level and experience of staffing responsible for project management.
- Part of programme (clinical, collection, processing) where most difficulty was experienced.
- Level of difficulty experienced in different areas (e.g., implementing QMS, training).
- Extra resources specifically required to implement JACIE.
- Impact of implementation of JACIE in terms of the functioning of the programme.

A second survey was designed to assess the effect of implementation of JACIE. Centres were asked to complete this survey 6 months after inspection. This survey asked for an estimate of the number of additional staff hours per week required for maintaining the JACIE Standards and sought the centres’ views on the benefit or drawbacks of having implemented JACIE. This survey included questions addressing the following issues:

- Whether programme had benefited from implementation of JACIE and if so in what areas.
Did implementation of QMS bring to light any need for changes in the implementation of the transplant programme, and if so in what areas.

- Ongoing resource requirements to maintain standard.
- Overall opinion on value of JACIE implementation.

Survey results
Twenty-six centres have so far returned Survey 1 and 22 returned Survey 2.

Survey 1: common difficulties
The results of the survey were as follows:

- At least 18 months is needed for preparation in the majority of cases (6 months 4%; 1 year 19%; 18 months 42%; 2 years 31%).
- Twenty-two centres had additional staff other than the Programme Director to manage project implementation, but these staff were only part-time in 13 centres and only 11 had any experience in quality management.
- The area of greatest difficulty for most centres (Table 4) was in the clinical programme (clinical programme 62%, bone marrow collection facility 42%, peripheral blood stem cells collection facility 12%, processing facility 15% (some centres ticked more than one choice).
- Most difficulty was found in implementing the QMS, AE reporting system and other documentation. Twenty-four centres already had written policies and 88% had SOPs, an audit system and an AE reporting system, but in all cases further development was needed to bring these aspects of QMS up to the required standard. Lack of a culture of QM was cited as an important problem.
- The extra resources most frequently required were a quality manager (62% centres) and a data manager (35%). Only 19% needed to improve their facilities.
- Some financial support was provided in addition to departmental budget in 69% cases, either from hospital resources (35%), external grant (27%) or, in one case, from pharmaceutical companies.

The results of the survey are consistent with the findings of the inspectors that the most common deficiencies are inadequacies in the QMS. The survey also indicates that these arise from lack of trained staff and absence of QM culture, particularly in the clinical setting. There is clearly an important need for training of clinical staff (doctors and nurses) in quality management. It is also important for centres to have a designated quality manager who has appropriate experience in QMS. One of the major aims of JACIE over the next 1-2 years is provision of more educational material such as model documents and a guide to implementing QMS in a transplant centre.

Survey 2: Impact of implementing JACIE
All responding centres indicated that they had benefited from implementing the JACIE standards. As shown in Table 5, the areas of greatest perceived benefit were in procedure and practices, staff motivation, control of AE and coordination between different areas of the programme. Significant benefits were also perceived in patient satisfaction, facilities, patient care and safety and training of new and existing staff.

Improvements clearly depend on the level of existing services, so that failure to demonstrate improvement in, for example, facilities or data management may reflect good pre-existing resources. In other areas, for example, AE reporting, the systems for monitoring performance were only set up as part of implementing JACIE, so that it is difficult to monitor improvements without an established baseline for comparison. Indeed implementation of JACIE may have the paradoxical effect of seeming to increase AEs because these were not previously adequately reported.

Nevertheless it seems clear that there are definite benefits in many areas of the programme, with a high degree of consistency in replies. The areas where little or no benefit was noted were in costs, compliance with requirements of health insurers/social security and in government recognition. It is evident, as discussed below that implementation and maintenance of a quality system increases the running costs of a programme. Regarding compliance with requirements of health insurers/social security and government

Level of improvements in programme functioning experienced by centres, as reported in Survey 2.
Results are expressed as percentage of responding centres. NA: this question not answered.

Abbreviations: JACIE, Joint accreditation committee ISCT-EBMT; QMP, quality management plan.
Results are expressed as percentage of responding centres. NA: this question not answered.
recognition, this is likely to change in the near future with the impact of the tissues and cells Directive on the requirement to implement inspection and accreditation programmes in member states.

Eighty-one per cent of the centres reported that implementation of the QM system had highlighted a need for changes in the implementation of the transplant programme. The most common areas cited were a need for improved coordination between the different facilities, that is, clinical, collection and processing, and a need for more systematic audit and AE reporting. Other items were a need to improve patient medical records and to improve donor evaluation procedures.

All centres felt that accreditation was worth the effort invested. The majority (59%) replied “The effort is a huge strain on resources but on balance it is worth it” whereas eight said “There is no doubt that accreditation is worth the effort invested” (one failed to comment). With the implementation of the EU Directive on safety of tissues and cells (Directive 2004/23/EC) it is likely that collection and processing facilities will increasingly view compliance with JACIE standards as important in providing evidence that they are complying with the requirements of the Directive.

Ongoing resource requirements

All centres reported a requirement for additional resources on an ongoing basis. Eighty-two per cent (18/22) of the centres needed to employ additional staff on a permanent basis. Sixteen centres employed a new quality manager, full time in two cases and part-time in 14. One centre employed an additional medical staff and one employed a full-time transplant coordinator. Eighteen centres cited a need for ongoing training and extra effort by staff and seven centres reported using external consultation and independent audit as a means of improving their programme. Ongoing funding was obtained from departmental budgets and in many cases also hospital resources.

Comment on survey results

Despite the difficulties experienced by centres in implementing JACIE, there is no doubt that they felt the effort was worth it and that their programme had benefited from the process. There is also no doubt that additional resources are needed on an ongoing basis once the standards have been implemented. In the future there is a need to assess the effect of implementation on a more formal basis, using for example analyses of AEs and patient satisfaction questionnaires in order to allow a cost–benefit analysis of JACIE implementation. The resource implications experienced at one centre were reported in detail by Zahnd et al.9

Implications of EU Directive 2004/23/EC

The requirements of the Directive became law in EU member States on 7 April 2006. In order to support implementation of the Directive, two technical annexes have been drawn up by the EU, which set out the detailed technical requirements of the Directive. The first covers donation, procurement and testing, and the second coding, processing, preservation, storage and distribution. Technical Annex 1 of the Directive was published as Commission Directive 2006/17/EC on 8 February 2006 and Technical Annex 2 was published as Commission Directive 2006/86/EC on 24 October 2006. Updated information will be provided by the European Legal and Regulatory Affairs Committee on the ISCT website (http://www.celltherapy-society.org).

The current JACIE standards conform to the requirements of the Directive as regards donation, procurement and processing of stem cells, although JACIE is more detailed in many areas and JACIE standards also cover clinical transplant programmes. However, in some areas more explicit wording of the JACIE standards is required to fulfil the requirements of the Directive and appropriate changes have been incorporated into the third edition of the FACT–JACIE standards.

JACIE, FACT and the World Marrow Donor Association (WMDA) are working together to promote consistent interpretation of the requirements of the Directive by the regulatory authorities in the different member states. A detailed crosswalk comparing the requirements of the EU Directive and technical annexes with the FACT–JACIE standards and WMDA guidelines is in preparation (details will be available on the JACIE website).

Although support for accreditation among the professional transplant community is high, there are varying levels of engagement with JACIE by the regulatory authorities in different countries. It has proven very difficult to build up a standard picture of official support across the European Union owing to significant differences in regulatory structures, varying readiness to implement the Directive and political issues. However, it can be said that in a number of countries there has been support from the regulatory authorities, both direct and indirect, for the JACIE accreditation system. This is the case in Austria, Belgium, France, Italy, The Netherlands and the United Kingdom. In Spain, the National Transplant Organisation (ONT) has signed a formal agreement with JACIE and national scientific societies, which gives official support to voluntary accreditation by transplant units and will recognise accredited programmes as meeting quality and safety requirements. 31-10-2006 http://actualidad.terra.es/sociedad/articulo/ont_impulsa_acreditacion_centros_transfusion_1178645.htm).

Outside the EU, Swiss national law on regulating transplants already directly cites JACIE in relation to HSC transplants. A new law is currently being drafted that will require all HSC transplant centres to be JACIE accredited with effect from 1 January 2007. JACIE is currently cited as part of the law on compulsory health insurance requiring H SCT centres to be certified by the Swiss Transplant Group with Blood And Marrow Transplantation in accordance with JACIE Standards. All 10 HSC centres in the country have undergone inspection and the majority are now accredited.
Global harmonisation of standards

It is a fundamental aim of JACIE to ensure that the FACT-JACIE standards as far as possible are identical to other applicable national and international requirements, including those of the EU. This is particularly important to prevent difficulties in importing and exporting tissues across international boundaries, which could occur if there were to be differences in the standards adopted in different countries.

JACIE has worked together with FACT on the 3rd edition of the standards and guidance, a draft of which was made available for public consultation in February 2006 and which is expected to be published in late 2006. The new version will be issued as a joint FACT-JACIE document. JACIE and FACT are also working with national and international donor registries and the WMDA to promote the use of international standards for collection facilities for unrelated donor transplants wherever possible, without jeopardising the availability of HSC from unrelated donors.

One of the results of this collaborative approach has been the establishment of an Alliance for the Harmonisation of Cellular Therapy Accreditation, whose members include American Association of Blood Banks, ASBMT, EBMT, FACT, International NETCORD Foundation, ISCT (Europe), JACIE and WMDA.

Conclusion

The JACIE accreditation system is now firmly established in Europe and the experience of centres that have been inspected is that implementation of the JACIE standards has led to significant improvements in different aspects of their transplant programmes. JACIE has further assisted with a number of training courses for preparing centres for accreditation and is currently working on a practical guide to quality management in HPC units. JACIE has also developed a close working relationship with other organisations involved in cellular therapy, which will form the basis for a new global approach to harmonisation of standards and accreditation systems worldwide. This collaboration represents an innovative and proactive approach in solving the problems of international exchange of tissues and cells as these relate to the stem cell transplant community.

Acknowledgements

In 2004, the European Commission part-funded the JACIE Project under the Programme of Community action in the field of public health (2003-2008). The total project budget of €351,695 was also supported by the EBMT and ISCT, and a number of national haematology and HSCT societies. We would like to acknowledge the assistance of Sarah Craig, JACIE administrative officer, and Sara Notley, EBMT administrative officer in the work of JACIE and the preparation of this paper.

bone marrow and peripheral blood stem cell donors who were recruited, selected, harvested, and followed at our institution and the associated donor registry. 40% were females and 60% males, with a median age of 37 years (range: 17-71 years). 318 were family donors and 278 unrelated volunteer donors. 110 donated bone marrow, 472 peripheral blood stem cells after mobilisation with G-CSF and 14 both. 39 donors donated for two harvests, four donors even three. Our preparative procedure consisted of a medical work-up including history, examination, blood and clinical chemistry tests, infectious disease markers, electrocardiogram, chest X-ray, lung function test, and abdominal ultrasound. Follow-up was scheduled at 1 and 6 months, as well as 1, 2, 5, and 10 years after donation of allogeneic stem cells. Results. Within the twelve year period of evaluation, no donor death was recorded, no single case of leukemia has been reported, and no splenic rupture occurred in any of our donors. Five donors experienced severe adverse events: one female bone marrow donor, post-harvesting pain persisted for more than twelve months. A 42 year old female donor developed breast cancer 3 years after G-CSF mobilised stem cell apheresis; however, this was not considered to be of causation relationship. In two donors of peripheral blood stem cells, vascular complications occurred: one donor had to be admitted to hospital due to a perforation of the iliac vein with subsequent ileus which, however, could be ruled out, and subsequently was able to donate bone marrow. Another donor had occurrence of a deep venous thrombosis eleven days after stem cell apheresis, despite sufficient anticoagulation with low molecular weight heparin during G-CSF mobilisation. Finally, a donor with sporadic epilepsy who donated twice, had a generalised seizure few days after each G-CSF mobilised harvest. This is particularly interesting in view of recent in vitro and animal findings of G-CSF receptors on neural tissues and pleiotropic neuroregulatory functions of G-CSF. Conclusions. In our experience, bone marrow and peripheral blood stem cell donors are safe and generally well tolerated, with very few early and virtually no late complications.

0369 ALLOGENEIC STEM CELL TRANSPLANTATION FOR PATIENTS WITH WALDENSTRUM'S MACROGLOBULINAEMIA. ANALYSIS OF 106 CASES FROM THE EUROPEAN BONE MARROW REGISTRY (EBMT)

C. Kyriakou,1 C. Kyriakou,1 C. Canals,2 G. Taghipour,2 J. Cornelissen,2 R. Willemze,3 G. Socie,2 K. Thompson,2 H. Greinix,2 J. Harouseau,2 N. Irahi,4 J. Kienast,4 R. Hamladi,2 M. Kazi,2 P. Jacobs,2 A. Sureda,2 N. Schmitz2

1University College London, LONDON; 1Lymphoma WP of the EBMT, LONDON, United Kingdom

Background. Despite effectiveness of standard chemotheraphy regimens, complete response is infrequent in Waldenström's Macroglobulinaemia (WM) patients and there is no cure. The role of allogeneic stem cell transplantation (Allo-SCT) has not been explored extensively and the available data are limited. Aim. We retrospectively analyzed the results and long-term outcome of a group of 106 WM patients from 65 European centres who underwent an Allo-SCT between 1989 and 2005 and were reported to the database of the Lymphoma WP of the EBMT. Patients and Methods. There were 69 males and median age at transplantation was of 49 years (range: 21-66). Time interval between diagnosis and Allo-SCT was 34 months (0-310) and the median number of lines of therapy prior to Allo-SCT was 3. Nineteen patients (18%) had a failed prior autograft. At Allo-SCT, 10 patients (10%) were in CR1, 29 patients (34%) in PR1, 29 patients (34%) in PR2 and 18 patients (20%) in PR3. Forty-eight (45%) patients developed advanced B-cell chronic lymphocytic leukemia. Seventy-nine patients (74%) were allografted from an HLA-identical sibling donor, 18 (17%) from a matched unrelated donor and the remaining 9 patients from other donors. Conventional conditioning protocols (CT) were used in 44 (41%) patients and reduced intensity conditioning (RIC) regimens in 62 (59%) patients. Results. Forty-eight (45%) patients died, 5 (5%) from disease progression and 30 (28%) from non-relapse mortality (NRM), with an incidence of NRM of 27% and 31% at 1 and 3 years. The progression free survival at 3 years was 19%, 12% after CT and 25% after RIC. Thirty-five (35%) patients died, 5 (5%) from disease progression and 30 (28%) from non-relapse mortality (NRM), with an incidence of NRM of 27% and 31% at 1 and 3 years. The progression free survival at 3 years was 19%, 12% after CT and 25% after RIC. Thirty-five (35%) patients died, 5 (5%) from disease progression and 30 (28%) from non-relapse mortality (NRM), with an incidence of NRM of 27% and 31% at 1 and 3 years. The progression free survival at 3 years was 19%, 12% after CT and 25% after RIC.
The South African Bone Marrow Registry (SABMR): a 10-year review

Ernette D du Toit¹, Terry E-A Schlapoff², Lucille Wood² and Peter Jacobs²

¹Laboratory for Tissue Immunology (LTI), University of Cape Town
²Department of Haematology and Bone Marrow Transplant Unit incorporating the Searl Laboratory for Molecular and Cellular Biology, Constantiaberg Medi-Clinic, Cape Town

The initiative to establish the SABMR in 1991 came from the Laboratory for Tissue Immunology via Professor Ernette du Toit and the Department of Haematology at Groote Schuur Hospital under the headship of Professor Peter Jacobs in association with the Western Province Blood Transfusion service directed by Dr. Arthur R Bird. The SABMR was designated as the Hub centre for South Africa (SA) by the World Marrow Donor Association (WMDA) in October of the same year. Much research was being carried out by the LTI in the field of HLA typing with particular reference to population genetics. These results were the raison d'être for starting this facility that was rapidly expanded to accommodate the inclusion of unrelated donors.

The SABMR is responsible for co-ordinating the provision of HLA-compatible matched unrelated volunteers (MUD) in this country and is the point of contact beyond these borders for seeking such donors. The latter must be between the ages of 18–55 years of age as well as being healthy and committed. By the end of 2001, there were 20,000 HLA typed people on file with these having been recruited with the help of two sub-registries respectively designated the South African and Natal Blood Transfusion Service (SABTS and NBTS). This data is registered with the Bone Marrow Donor World-wide (BMDW) and thus the SABMR donors form part of the >7 million individuals in 49 adult and 25 cord blood listings. Preliminary identification via this mechanism for people in South Africa increased from ±100 in 1992 to ±300 in 2001 with the reverse pattern increasing from 3 in 1992 to 48 in 2001. A donor search has correspondingly risen from 7 in 1998 to a total of 58 by 2001.

WMDA protocols are meticulously observed, dealing, inter alia, with registration, confidentiality, counselling and the transport of grafts. Responsibilities of the Hub centre have also been documented with regard to the patient demographics, searches, review of results, as well as financial and legal liabilities. When considering unrelated individuals a prerequisite is that HLA matching be as close as possible and DNA class I and II is now standard methodology. The first local MUD transplant took place in 1997 and by 2001 a total of 25 patients had received similar grafts (see Fig. 1). In order to retain international status accreditation for the Laboratory is mandatory and was achieved in 1999.

The majority of the patients received bone marrow from international registries, see Fig. 2. The numbers denote the number of protocols received, which include bone marrow, peripheral blood stem cells (PBSC) and donor lymphocyte infusions (DLI). A further step in the growth of the SABMR, was the identification of local donors for SA patients. The first such transplant took place in Cape Town in 1999, and since then a further four local donors have been used.

Because of the extreme polymorphism or variation of the HLA tissue typing system the chance of finding unrelated matches is approximately 1:100,000, necessitating the establishment of large suitably typed panels. This genetic variation is particularly problematic where there exists, additionally, a diversity of populations, including
many of African ancestry that carry with them rare antigens thereby emphasising dependence on international collaboration on the one hand and expanding local donor base on the other.

The main aim of the SABMR is to recruit, maintain and expand availability suitable volunteers for South African patients requiring haematopoietic stem cell transplant. In parallel a priority is to continue conducting and promoting relevant research into this system among the indigenous people of sub-Saharan Africa with their unique genetic constitution seeking to identify new antigens and so contribute to both knowledge and provision of matched unrelated grafts.

The South African Lymphoma Study Group

Peter Jacobs¹, Erna Mansveldt² and Colleen Wright³

¹Haematology Department, Constantiaberg Medi-Clinic, Cape Town
²Haematological, ³Anatomical Pathology, University of Stellenbosch and Tygerberg Hospital

20 years ago Professor Peter Jacobs, from the University of Cape Town, Professor Geoffrey Falkson from the University of Pretoria and Professor Werner Bezwooda of the University of Witwatersrand, supported by Bristol Meyers Squibb with Mrs. Esmé Goodwin as the secretary, established a meeting to be held every second year. The focus was to be on the continued understanding of the clinical haematology and haematopathology of these tumours as a basis for relevant local research on the one hand and dissemination of knowledge and maintenance of internationally acceptable treatment programmes on the other. The intention was that an independent and non-parochial governance would provide an interactive forum for the discussion of Hodgkin’s disease and the remaining lymphomas. To encourage the balance between clinical and laboratory-based studies, at an educational as well as scientific level, the forum was designed around a series of plenary presentations whilst, at the same time, strongly encouraging the presentation of local South African investigations. The importance of paramedical professionals was recognised and holding the congresses at suitable venues without registration fee encouraged the participation of nurses, pharmacists and laboratory technologists. The role of the pharmaceutical industry has been acknowledged and commercial exhibits remain an integral part of the two or three day symposia.

A particularly successful meeting was held in 2000 with a strong local faculty namely Dr. Philip Barlow Mills, Dr. Jack Bergman, Dr. Ellen Bolding, Dr. David Eedes, Professor Arderne Forder and distinguished international authorities including Dr. James O Armitage from Omaha Nebraska, Professor Borje Andersson and Professor Noel Buskard.

The 10th biennial will take place at the Constantiaberg Medi-Clinic in October 2002. The raison d’être will again be to provide broad interaction between clinical and haematopathologic aspects of these challenging groups of lymphoreticular tumours. With rapid progress in the field the particular discussion points will include the utility of fine needle aspiration linking flow cytometry to conventional cytology and immunohistochemistry on the one hand with

Bone marrow transplantation: how important is CD34 cell dose in HLA-identical stem cell transplantation?

S. Heimfeld

Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, WA, USA

A recent analysis of Fred Hutchinson Cancer Research Center data has been undertaken to investigate the association of infused CD34 cell dose with various clinical outcomes after HLA-identical transplantation. Separate assessments for unrelated vs related donors and the use of bone marrow or mobilized G-CSF-primed peripheral blood mononuclear cells (G-PBMC) have been incorporated. The three primary findings are: (1) Higher CD34 dose results in better neutrophil and platelet recovery in all settings. (2) Higher CD34 doses (>8 x 10^6/kg) are associated with the development of more chronic graft-versus-host disease when using related G-PBMC. (3) Higher CD34 dose is correlated with improved survival after unrelated donor bone marrow transplantation. These data suggest that the CD34 content of a graft can have a significant impact on clinical outcome after allogeneic transplantation, but defining an optimal dose is dependent on both the type of donor and the stem cell source.

Leukemia (2003) 17, 866–868. doi:10.1038/leu.2002983

Keywords: allogeneic transplantation; CD34 dose; engraftment; GVHD; survival

Introduction

After allogeneic stem cell transplantation, outcomes such as survival or graft-versus-host disease (GVHD) depend on many patient-specific factors, but are also influenced by the source of stem cells, the make-up of different cell populations within the graft, and the degree of HLA matching between the donor and the recipient.1-3 This is in contrast to the Fred Hutchinson Cancer Research Center's (FHRC) experience with both matched related and related unrelated donors, the use of bone marrow or G-CSF mobilized peripheral blood mononuclear cells (G-PBMC) grafts, and quantitative enumeration of CD34+ hematopoietic stem/progenitor cells in those grafts is correlated with various clinical outcomes. One of the relevant questions that can be addressed with our large database of patient transplants is whether outcomes such as engraftment, GVHD and survival are associated with the number of CD34+ cells infused into the recipient. Data on the association of cell dose with outcome after cord blood transplantation has been recently published, and will not be covered in this paper.4-6

One of the first considerations in this type of analysis are other variables such as the type of donor, related vs unrelated, and the source of CD34+ cells, bone marrow vs G-PBMC. These factors have clearly shown to have an influence on clinical outcomes, and thus an analysis of CD34+ cell dosage effects must take these variables into account. Similarly, different clinical endpoints such as engraftment, GVHD, or survival must also be analyzed separately, as there is no a priori reason that particular CD34+ cell doses will yield identical results in various clinical settings. Finally, statistical methods must be employed to ensure that other patient parameters (age, type of disease) that can also affect these clinical outcomes are accounted for in these correlative studies.

Quantitative flow cytometry is the preferred method to determine the number of CD34+ cells in a bone marrow or G-PBMC graft. There are a variety of different techniques that are employed among clinical laboratories, including the ISHAGE, Milan, and Norway protocols. Each of these methods utilizes slightly different staining combinations and gating strategies that can result in somewhat different values. Thus, when reporting CD34 dose-response relationship, the actual technique used must be acknowledged as that may have an effect on the reported values. It is important to keep in mind that when a specific dose is referred to here in this paper, it may not be exactly the same dose that would be determined by another lab using a different procedure. At the FHRC, we routinely use a three-color combination of CD34-PE/CD14-FITC/7-AAD staining. Samples are first gated on total nucleated cells, followed by exclusion of nonviable 7-AAD+ cells, followed by exclusion of CD14+ high-side scatter populations (previous work has shown that no true CD34+ cells are also CD14+), followed by gating on the brightest expressing CD34+ cell population.66 It is this type of flow cytometry analysis that has been used for the correlative studies reported in this paper.

The FHRC has developed a fairly large database over the last few years in which CD34 dosage information in the grafts has been determined. With respect to the different patient subgroups, there are currently 171 related and 265 unrelated bone marrow donors, while there are 371 related and 75 unrelated G-PBMC donors. The median doses of CD34+ cells vary between the subgroups, for bone marrow donors, related vs unrelated, the medians are 3.0 x 10^6/kg (range 0.8-19) and 2.8 x 10^6/kg (range 0.3-26). For G-PBMC donors, related vs unrelated, the medians are much higher, 8.5 x 10^6/kg (range 1-34) and 8.1 x 10^6/kg (range 1.2-34). Thus, comparing bone marrow vs G-PBMC, the doses of CD34+ cells differ on average by approximately three-fold, which could have a potentially important impact on clinical outcomes.

Engraftment

In terms of short-term neutrophil engraftment, there is a significant difference between G-PBMC and bone marrow even when comparing similar doses of CD34 cells, with G-PBMC generally showing 5-7 days faster recovery times. Within the related G-PBMC subgroup, days to recovery of absolute neutrophil counts (ANC) greater than 500/μl plotted against infused CD34+ cell dose does show an association, higher dose
yielding shorter times to engraftment. However, whether this is a clinically significant effect is somewhat up for debate. There does not appear to be a strict dose–response relation, with at most a 1–2 day maximum difference in terms of ANC recovery between the lower and higher CD34 doses. This may partly be an artifact of clinical trial design. Nearly all FHRC allogeneic protocols require a minimum cell dose of 4 x 10^6 CD34+ cells/kg. Thus, there are relatively few patients below this level, which may be above the threshold value where more significant delays in ANC recovery would occur.

The story with respect to platelet engraftment is very similar. Again there is a statistically significant association with higher CD34 dose yielding faster recovery times, with G-PBMC showing 5–12 days faster engraftment than bone marrow. At lower CD34 doses with related G-PBMC (<6 x 10^6/kg actual patient body weight), 10% of the patients do not recover their platelet counts within 30 days after transplantation, whereas at higher dose ranges (>10 x 10^6/kg), all patients recover their counts above 20 000 by day 20. A similar effect is seen with slightly different kinetics for related bone marrow, where, in this case, patients with the lowest doses (<2 x 10^6/kg) show a longer time for platelet engraftment and a much higher proportion of patients do not recover their platelet counts to 20 000 before day 30.

Chronic extensive GVHD

In the related bone marrow setting, CD34 dose does not appear to correlate with chronic extensive GVHD (cGVHD), and with unrelated G-PBMC, we do not have enough data and long-term follow-up to make any definitive conclusions. With unrelated bone marrow transplantation there is a suggestion that higher CD34 doses do lead to increases in cGVHD, although this has not reached statistical significance. Our best correlation of CD34 dose and cGVHD has been obtained with related G-PBMC. We have previously published that, comparing patients that receive CD34 doses greater than 8 x 10^6/kg vs all others, there is a significant increase in cGVHD from 40 to 50%. We have further explored this association in the current database. Separating the range of CD34 dosages into 20% quintiles, the lower four quintiles show identical levels of cGVHD, while the 5th quintile (>10 x 10^6/kg) again shows a significantly higher rate of cGVHD. The biological explanation for this finding is unclear, one possible hypothesis for increased cGVHD may have to do with better reconstitution of donor dendritic cells from the larger number of CD34+ cells within the graft.12

Overall survival

Within the FHRC data there appears to be no relationship between CD34 doses and overall survival in the case of related bone marrow or related G-PBMC. For related bone marrow, this finding is different from what has been published from other institutions. However, in the case of unrelated G-PBMC there is a suggestion for CD34 dose affecting survival outcomes. Separating the dose of CD34 into quintiles, the two lowest quintiles (<7 x 10^6/kg) show the worst outcomes with survival at 1 year of 30–40%. The third and the fourth quintiles (7–10 x 10^6/kg) do better, with 1-year survival at 60–70%. The fifth quintile (>10 x 10^6/kg) starts out similar to the third and fourth, but then tends to drop off with time so that at 1-year survival was only 40%. This sort of effect may indicate that, in the unrelated G-PBMC setting, an optimum CD34 dose may lie somewhere in the middle. Lower CD34+ cell dose is not optimal, and the highest CD34 doses are also not good, but this may be for a different reason such as increased GVHD (see above). Additional data, further follow-up, and more detailed analyses will be required to better explore this finding.

The most significant association of CD34 dose with survival was observed with the unrelated bone marrow transplants. Again splitting the CD34 dose into quintiles, a clear dose–response relation was observed, with the lowest quintile having 40% survival at 2 years, next quintile at 50%, and the other quintiles at 60–70%. A more extensive multivariate analysis of this data adjusting for patient age and disease risk indicated that
the most significant predictor for overall mortality was the dose of CD34+ cells. This is shown graphically in Figure 1, where the unrelated bone marrow patients have been split into two groups, above and below the median CD34 dose of 2.7 x 10^6/kg. The improvement in overall survival seems to be driven by a reduction in nonrelapse mortality, that is, no difference in the relapse rates was seen between the patients getting the lower vs higher CD34 doses. There was a suggestion of an association with grades 3 and 4 acute GVHD, again with higher doses giving a lower effect. There was no evidence for any effect on chronic GVHD. In this analysis we also looked at a variety of other cell populations: CD14 monocytes, T-cell subset, B-cells, and NK-cells, but these other cell types did not change or improve the model to any significant extent. The best and only cell population that significantly predicted for improved survival was the dose of CD34+ cells.\textsuperscript{15}

Conclusion

A prospective randomized trial has shown that there is a survival advantage for matched related allogeneic transplant recipients who received G-PBMC vs those who received bone marrow as a source of stem cells.\textsuperscript{14} The biological basis for this advantage is not entirely clear. As noted above, G-PBMC have on average three-fold more CD34+ cells than bone marrow. However, this is unlikely to be the whole explanation for the improved survival, in almost every other lineage such as T-cell subsets, monocytes, B-cell, and NK cells, the differences are even larger (10-30-fold; see Figure 2). The association of these other cell populations with clinical outcomes is just beginning to be investigated. In a preliminary analysis for correlation with overall survival, higher doses of NK cells and particularly the TNK type cells seem to be the best predictors for improved survival after matched related allogeneic G-PBMC transplantation. In addition, there can also be qualitative as well as these quantitative differences. G-CSF mobilization and apheresis detection does result in significant changes in gene expression within the CD34 compartment when compared with bone marrow.\textsuperscript{15} Other changes also occur in dendritic cell subsets after G-CSF mobilization.\textsuperscript{16}

In conclusion, we have examined the dose–response relationship of CD34+ cells in related and unrelated donor bone marrow or G-PBMC in terms of clinical outcomes such as engraftment, chronic GVHD and overall survival. In all cases, we can see that higher CD34+ cell doses lead to better recovery of neutrophils and platelets, although the clinical significance of that improved recovery is debatable. With related bone marrow there is no association of CD34+ dose with chronic GVHD or overall survival, but with unrelated bone marrow, higher CD34 dose does result in improved survival. In the related G-PBMC setting, no significant association is seen with overall survival with our present data; however, higher CD34+ doses (> 10 x 10^6/kg) are associated with more chronic GVHD. With unrelated G-PBMC, there is a suggestion that higher CD34 dose is associated with better survival, but more data and more long-term follow-up are necessary before a definite conclusion can be made. Finally, we are continuing to examine the association of other cell populations with clinical outcomes in each of these different clinical settings.

Allogeneic Peripheral Blood Stem-Cell Compared With Bone Marrow Transplantation in the Management of Hematologic Malignancies: An Individual Patient Data Meta-Analysis of Nine Randomized Trials

Stem Cell Trialists' Collaborative Group

ABSTRACT

Purpose
Considerable uncertainty exists regarding relative effects of allogeneic peripheral blood stem cells transplantation (PBSCT) versus bone marrow transplantation (BMT) on outcomes of patients with hematologic malignancies.

Patients and Methods
To provide the totality of research evidence related to the effects of PBSCT versus BMT, we conducted an individual-patient data meta-analysis using data from nine randomized trials enrolling 1,111 adult patients.

Results
Compared with BMT, PBSCT led to faster neutrophil (odds ratio [OR] = 0.31; 95% CI, 0.25 to 0.38; P < .00001) and platelet engraftment (OR = 0.52; 95% CI, 0.44 to 0.61; P < .00001). PBSCT was associated with a significant increase in the development of grade 3-4 acute graft-versus-host disease (GVHD; OR = 1.39; 95% CI, 1.03 to 1.88) and extensive (47% v 31% at 3 years; OR = 1.89; 95% CI, 1.47 to 2.42; P < .000001) and overall chronic GVHD (68% v 52% at 3 years; OR = 1.92; 95% CI, 1.47 to 2.49; P < .000001), but not grade 2-4 acute GVHD (54% v 53%; P = .49). PBSCT was associated with a decrease in relapse (21% v 27% at 3 years; OR = 0.71; 95% CI, 0.54 to 0.93; P = .01) in both late-stage (33% v 51% at 3 years; OR = 0.59; 95% CI, 0.38 to 0.83; P = .02) and early-stage disease patients (16% v 20% at 3 years; OR = 0.69; 95% CI, 0.49 to 0.98; P = .04). Norelapse mortality was not different between groups. Overall and disease-free survival were only statistically significantly improved in patients with late-stage disease (overall survival: 46% v 31% at 3 years; OR = 0.64; 95% CI, 0.46 to 0.90; P = .01; disease-free survival: 41% v 27% at 3 years; OR = 0.63; 95% CI, 0.45 to 0.87; P = .01).

Conclusion
PBSCT is associated with a decreased relapse rate in hematologic malignancies and improvement in overall and disease-free survival in patients with late-stage disease. PBSCT is also associated with a significant risk of extensive chronic GVHD.

J Clin Oncol 23:5074-5087. © 2005 by American Society of Clinical Oncology

While peripheral blood stem cells (PBSC) are used almost exclusively in autologous transplantation, recent surveys indicate that PBSC are used in 50% to 60% of allogeneic stem-cell transplants. Thus, large variation in practice and considerable uncertainty exists with respect to the relative effects of allogeneic PBSC transplantation (PBSCT) versus bone marrow transplantation (BMT) on the outcomes of patients with hematologic malignancies. In order to address this question, several randomized controlled
PBSCT v BMT for Hematologic Malignancies

trials have been conducted. Despite several well designed and executed clinical trials, taken individually, most of these trials were too small to draw definitive conclusions, and not surprisingly, substantial controversy still remains regarding the impact on the occurrence of graft-versus-host disease (GVHD), mortality, disease control, and other important clinical outcomes.

This controversy is typical in health care research and demonstrates the need for a systematic review to assemble the totality of relevant research evidence to determine the relative merits of new interventions and therapies. The "gold-standard" for combining evidence from existing randomized trials is an individual patient data meta-analysis (IPD-MA) in which updated data on each and every participant from each and every relevant trial are centrally collected, processed, and analyzed. Here, we report the first IPD-MA examining the differences in the outcomes between human leukocyte antigen (HLA)–matched, related allogeneic PBSCT and BMT as therapy for hematologic malignancies.

Recommended procedures for the meta-analysis based on the individual patient data were followed. Randomized controlled trials (RCTs) in which adult patients with hematologic malignancies and HLA-matched sibling donors were randomly assigned to PBSCT and BMT were eligible for the analysis. We performed an extensive search of a number of computerized databases (MEDLINE, EMBASE, LILACS, CANCERLIT, The Cochrane Library) and the abstracts of meetings of the American Society of Hematology, European Hematology Association, American Society of Clinical Oncology, IBMT (International Bone Marrow Transplant Registry), and EBMT (European Group for Blood and Marrow Transplantation) from 1990 to 2002. Experts in oncology and hematology were asked about ongoing or closed studies that had not yet been published. Details of the search strategy were published as a Cochrane protocol. Periodic searches were subsequently performed with the cutoff for the trial identification and data collection as of August 2003. Once eligible trials were identified, their principal investigators were contacted, and a central database was formed. Demographic data (patient and donor age and sex, diagnosis and disease status at the time of transplantation, cytomegalovirus serology); information regarding the transplantation procedure (date of random assignment and of transplantation, allocated treatment [PBSCT or BMT], conditioning regimen used [total-body irradiation–based v non–total-body irradiation–based], graft processing and manipulation, number of CD3 cells/kg and C34 cells/kg transplanted, GVHD prophylaxis, use of post-transplantation growth factors); and details of the trial design, including randomization methodology, were collected. The following outcome data were collected for each patient: time to neutrophil and platelet engraftment, date of relapse or disease progression, date of onset and grade of acute GVHD and chronic GVHD, and the date of last follow-up or death. Cause of death was distinguished between relapse-related and non–relapse-related.

Extensive data checking was performed using the methods described previously. Data were checked for obvious inconsistencies and were amended as necessary through intensive correspondence with the responsible principal investigators. Raw data were also compared with aggregate data in available publications. Detailed checks for any imbalance in accrual between two randomized arms, follow-up and length of follow-ups, and the numbers in subgroups were also performed.

All comparisons were based on an intention-to-treat principle. Individual patient data allowed calculation of required statistics using the exact dates of events, which is more statistically reliable and clinically informative than basing the calculations on proportions alive at a particular point in time. Briefly, the number of events observed (O) in the PBSCT arm of each trial is compared with the number expected (E) if the events in that trial had been equally distributed between the PBSCT and BMT arms. The difference between these numbers, O - E, and its variance yields the log-rank test for each trial. The sum of the statistics is first produced for each trial. The individual log-rank statistics from each trial were then combined to give an overall estimate of the effect of PBSCT versus BMT on the outcomes of interest. The important point here is that the analysis is not done by pooling all patients in one mega-analysis, but rather pooling was done by combining individual log-rank statistics to obtain the overall log-rank statistics for all trials, which are then used to calculate reductions of overall odds of death or other outcomes of interest. This means that the methods employed in our analysis preserve the original randomization in each trial since they do not involve any analyses in which patients in one trial are directly compared with patients in another trial. The results are expressed in such a way that the annual odds of event of interest of 0.75 might equivalently be described as an odds ratio, a hazard ratio of 0.75, an odds reduction of 25%, or a 25% reduction in the event rate. Assumption-free methods were used. All P values are two-tailed.

Heterogeneity (ie, variability or differences between studies in the estimates of effect) was also assessed. We evaluated methodological heterogeneity (differences in study design), clinical heterogeneity (differences between studies in key characteristics of the participants, interventions, or outcome measures; Table 1), and statistical heterogeneity. Formal tests for heterogeneity were performed to investigate whether the effect size might be different among the studies/subgroups (ie, if observed variability in results is greater than that expected to occur by chance). All subgroup analyses were defined a priori.

The main endpoints analyzed were: overall survival, relapse/progression, GVHD, disease-free survival, death in remission and engraftment. Time was calculated from the date of randomization; in the case of acute and chronic GVHD it was calculated from the date of randomization, date of transplant, and day + 100 after the transplantation (in case of chronic GVHD). Since the results did not change appreciably, only the latter analyses are shown. Disease-free survival was defined as time to death or relapse, whichever occurred first. Due to small numbers, the analyses according to disease types were not reliable and were, therefore, supplemented with the analysis according to disease prognostic features. A uniform consensus among all trialists was achieved to separate patients into those with "early-stage" (chronic myelogenous leukemia [CML] in first chronic phase, acute myeloid leukemia [AML] and acute lymphoblastic leukemia [ALL] in first complete remission, and refractory anemia/refractory anemia with ringed sideroblasts subtypes of myelodysplastic syndromes [MDS]) and "late-stage" disease (CML in second chronic phase, accelerated phase or blast crisis AML or ALL, refractory or in...

11 of which have been published at the time of the analysis (Table 1). The requirements of the QUOROM (Quality of Reports of Meta-analyses of Randomized Controlled Trials) statement were followed.44 Individual patient data were provided on 1,288 patients from 11 trials (Table 1).

Table 1 presents the characteristics of all trials and patients considered in our analysis. Two trials differed substantially in the design from the rest: the Dutch trial included T-cell depletion of the grafts, while the Australian trial examined PBSC versus granulocyte colony-stimulating factor primed BMT. It was unanimously agreed by all trialists that these trials should not be included in the pooled analysis. While some differences existed among the other trials, it was felt that all trials tested similar interventions for similar conditions under similar circumstances to allow pooling of their data in this meta-analysis.6 Data from one trial (N = 29) were not provided, but were extracted from the published report of this trial when possible.18 Inclusion or exclusion of the data from this trial did not materially alter the results. Thus, data on 1,111 patients from nine trials were included in the final analysis. Overall, treatment groups appeared well balanced according to the most important prognostic features (i.e., age, sex, disease type, and so on; Table 1). Figure 1 shows the patient distribution according to the prognostic features. Median duration of follow-up of patients included in our analysis was 2.7 years (range, 0 to 8.6 years).

The main results of the analysis are summarized in the forest plot shown in Figure 2.

**Engraftment**

There was a highly significant reduction in the number of days to reach the absolute neutrophil count of 0.5 × 10^9/L in the patients receiving PBSC, and a platelet count greater than 20 × 10^9/L. Median time to neutrophil and platelet engraftment was 14 ± 21 days (X^2 = 97.59; P < .0001) and 14 ± 22 days (X^2 = 53.3; P < .0001) in the PBSC and BMT arms, respectively.

**Acute GVHD**

There was no difference in overall incidence in acute GVHD grades 1-4 between the two treatment groups (54%
v 53%; P = .49). Forty percent of the patients developed grade 2-4 acute GVHD with no significant increase in the rate after PBSCT (odds ratio [OR] = 1.14; 95% CI, 0.93 to 1.4; P = .2; Fig 3A). However, grades 3-4 acute GVHD occurred more often after PBSCT (by approximately 6% at 100 days [χ² = 4.58; P = .03]; OR = 1.39 [95% CI, 1.03 to 1.88]; Fig 3B).

**Chronic GVHD**

There was a highly significant increase in the odds of developing both extensive stage (OR = 1.89; 95% CI, 1.47 to 2.42; P < .000001) and overall (any stage; OR = 1.92; 95% CI, 1.47 to 2.49; P < .000001) chronic GVHD in patients treated with PBSCT. At 3 years, 47% and 68% of patients treated with PBSCT developed extensive or any stage chronic GVHD versus 31% and 52%, after BMT, respectively (Figs 4A and B). At 5 years, the corresponding figures for PBSCT versus BMT were 51% v 35% for extensive stage chronic GVHD and 73% v 56% for any stage, respectively. The results remained virtually the same regardless of the start date of calculation of chronic GVHD (ie, whether it was from the date of randomization, date of transplant or day + 100 after transplantation, respectively).

**Relapse, Relapse Mortality, and Nonrelapse Mortality**

Relapsed or progression rate at 3 and 5 years in PBSCT arm was 21% and 24% v 27% and 32% in the patients treated with BMT, respectively (OR = 0.71; 95% CI, 0.54 to 0.93; P = .01; Fig 5). The difference in the early-disease group was 16% v 20% at 3 years, and 16% v 25% at 5 years, respectively (OR = 0.69; 95% CI, 0.49 to 0.98; P = .04). In the late-disease group, the difference was 33% v 51% at 3 years and 44% v 58% at 5 years, respectively (OR = 0.59; 95% CI, 0.38 to 0.93; P = .02; Fig 6), but the test for interaction between the two groups was not significant (P = .6).

Eleven percent and 14% of patients died due to relapse/progression of disease in the PBSCT group, versus 16% and 18% in the BMT arm at 3 and 5 years, respectively (χ² = 5.51; P = .02). Relapse-related mortality followed the same pattern, indicating that once disease relapsed/progressed, a salvage treatment may, on average, not be effective (Fig 7A).
Approximately 30% of patients died in both groups due to nonrelapse causes (OR = 0.99; 95% CI, 0.79 to 1.25; P = 1.0). As expected, most deaths due to treatment occurred early after transplantation (Fig 7B).

**Disease-Free Survival**

Overall, allogeneic PBSC was associated with a statistically significant improvement in disease-free survival over BMT (OR = 0.80; 95% CI, 0.67 to 0.97; P = .02; 59% vs 53%
at 3 years and 54% vs 47% at 5 years, respectively; Fig 8). This difference was more pronounced in patients with late disease (41% vs 27% at 3 years; and 32% vs 21% at 5 years, respectively; OR = 0.63 95% CI, 0.45 to 0.87; \( P = .01 \)) than in patients with early disease (OR = 0.85; 95% CI, 0.67 to 1.08); \( P = .2 \); Fig 9). However, a test for interaction between the two groups was not significant (\( P = .1 \)).

### Survival

There was no statistically significant difference in overall survival between PBSC and BMT (OR = 0.87; 95% CI, 0.72 to 1.06; \( P = .17 \); Figs 10 and 11). However, PBSC was associated with a higher 5-year overall survival probability in the subpopulation with late disease (46% vs 31% at 3 years, and 39% vs 29% at 5 years, respectively; OR = 0.64; 95% CI, 0.46 to 0.90; \( P = .01 \)) but not in patients with early disease (65% vs 64%; OR = 0.97; 95% CI, 0.75 to 1.25; \( P = .8 \); Fig 12). Test for interaction was borderline statistically significant (\( P = .05 \)).

Statistical heterogeneity of treatment effect between trials was noted only for relapse outcome (\( \chi^2 = 14.6; P = .04 \)) and neutrophil (\( \chi^2 = 32.2; P = .000008 \)) and platelet engraftment (\( \chi^2 = 33.6; P = .00005 \)).

### Subgroup Analyses

To elucidate if the effect of the type of transplantation differed among different disease groups, we performed a number of subgroup analyses. Briefly, the most consistent effect is seen in CML, in which PBSC was associated with improvement in relapse in all patients (OR = 0.34; 95% CI, 0.2 to 0.58), and improvement in disease-free and overall survival in patients with late-stage disease (OR = 0.28 [95% CI, 0.11 to 0.73] for disease-free survival, and OR = 0.31 [95% CI, 0.12 to 0.80] for overall survival, respectively). PBSC also led to improvement in disease-free survival (OR = 0.39; 95% CI, 0.21 to 0.72) and overall survival (OR = 0.45; 95% CI, 0.24 to 0.85) in AML patients with late-stage disease. Due to small number of patients (Fig 1), we could not confirm or refute superiority of PBSC versus BMT in other disease categories.

According to international registry data, approximately half of transplant physicians prefer allogeneic PBSC over BMT. To address the question of which source of hematopoietic stem cells might be preferable, we...
conducted the first IPD-MA of prospective randomized trials comparing transplantation of HLA-matched, related allogeneic PBSC and BMT in patients with hematologic malignancies. It is important to realize that our results and conclusions apply only to matched sibling myeloablative allogeneic transplantation and not to the role of nonmyeloablative transplantation or alternative donor strategies.

---

**Fig 6.** Time-to-event plots showing the risk of relapse in patients with hematologic malignancies treated with allogeneic peripheral blood stem-cell transplantation (PBSC) versus bone marrow transplantation (BMT). (A) In early-stage disease and (B) in late-stage disease. Abs diff, absolute difference.

**Fig 2.** (A) Relapse-related mortality. Time-to-event plots showing the absolute risk reductions in relapse mortality in patients with hematologic malignancies treated with allogeneic peripheral blood stem-cell transplantation (PBSC) versus bone marrow transplantation (BMT). (B) Time-to-event plots showing the absolute risk reductions in death without relapse (nonrelapse mortality) in patients with hematologic malignancies treated with allogeneic PBSC versus BMT. Abs diff, absolute difference.
Our analysis should be interpreted within the context of the extreme logistical difficulties associated with performing large randomized trials in allogeneic transplantation. Because hematologic diseases are rare and transplant numbers are relatively low even in large centers, most trials chose to enroll patients with a variety of hematologic malignancies. However, by pooling all existing data, we were able to increase the power of the analysis and provide the most definitive evidence to date.

Our analysis demonstrated that stem cell source is not statistically significant in its effect on overall survival. However, PBSC is associated with an increase in both survival and disease-free survival in advanced-stage disease. PBSC is also associated with significantly more rapid neutrophil and platelet engraftment, a reduced relapse rate and an increase in the risk of chronic GVHD.

Our results suggest that patients with late-stage disease benefit from PBSC rather than BMT. This finding was consistent for all important clinical end points (survival, disease-free survival, relapse). However, statistical tests for interaction did not provide clear evidence of a difference in treatment effect between early- and late-stage disease, and further data are needed to confirm or refute this finding.

In early-stage disease, PBSC was associated with a lower relapse rate but this did not result in statistically significant better overall or disease-free survival. This could, in part, be a consequence of a large number of patients with chronic phase CML, a disease in which relapse after allogeneic transplant does not immediately lead to death, or alternatively, a reflection of the fact that in early stage disease, nonrelapse mortality is higher compared to relapse-related death.

Although all the trials included in this analysis attempted to address a similar treatment question, they also differed in some details (Table 1). This could have introduced both clinical and statistical heterogeneity into the results. However, except for neutrophil and platelet engraftment, heterogeneity between trials was absent or minimal. Even though the degree of the effects on engraftment was heterogeneous, engraftment was uniformly much more rapid after PBSC than BMT in all trials. This result is biologically plausible. Therefore, the observed heterogeneity of treatment effect between trials can be best explained by random fluctuations in the effect size.

One of the main purposes of meta-analyses is to investigate if any bias or play of chance could have affected the results of the analysis. Only if the intervention’s effect is greater than that of any of potential biases can the results be considered credible and reliable. The transplant field has...

Fig 10. Forest plot illustrating the effect of peripheral blood stem-cell transplantation (PBSCT) versus bone marrow transplantation (BMT) on overall survival. Note: inclusion of Egyptian trial (N = 29) from which data on individual patients were not available (data from this trial were extracted from the paper). Inclusion of this trial did not change the results significantly (see the main text for details). NS, not significant; OR, odds ratio; EBM, European Group for Blood and Marrow Transplantation; O = E, observed = expected; Var., variance; Redn., reduction; SD, standard deviation.

traditionally been plagued with selection biases and attrition bias (ie, large imbalance in dropouts between treatment arms). Therefore, paying close attention to the quality of random assignment, which aims to control for selection bias, and accounting for adequate follow-up, to assess for attrition bias is critical. One of the methodological advantages of individual-patient data meta-analysis is to allow assessment of raw data for the quality of random assignment, concealment of allocation, balance in follow-up, drop-outs, confirmation of internal consistency, and performance of intention-to-treat analyses.

We have performed extensive data checking, including sensitivity analysis within each trial. Our analyses indicated no obvious sources of bias and overall consistent data of high quality. However, we have not controlled for observer bias, which is inherent in the assessment of outcomes such as GVHD resulting in poor interobserver agreement. In addition, chance could have affected some of the results because of the large number analyses performed on a relatively small data set.

In the transplantation literature, some trials employ competing risk analysis to address incidence of outcomes such as chronic GVHD. Since the purpose of our study was to compare the effects of PBSCT versus BMT, competing risks analyses were not undertaken as they can be misleading when making treatment comparisons, and methods are not well developed, particularly for use in meta-analysis. Similarly, since the main question being addressed relates to the relative effect of treatments on outcomes, it was inappropriate to evaluate the effect of one outcome (eg, GVHD) on the other (eg, relapse or survival), as well as time-dependent factors.

When choosing between two treatment interventions, a practitioner has to consider both benefits and harms associated with each of the treatment alternatives. Based on
this study, PBSCT is associated with faster engraftment, a decrease in relapse and improved disease-free survival when compared with BMT in HLA-identical sibling transplantation for hematologic malignancies. These outcomes were particularly evident in patients with late-stage disease where improved survival was also seen.

Indeed, the largest effect of PBSCT in terms of improvement of disease-free survival and overall survival was seen in patients with late-stage AML and CML. Unfortunately, we could not collect data on cyto genetics to further delineate effect on specific prognostic categories in AML. With regard to treatment of CML, recently, the new standard—imatinib—has emerged as the initial treatment of choice for the management of this disease.23 Our study was not designed to address the issue of relative merits of imatinib versus allogeneic transplantation. Nevertheless, it does appear that the dramatic shift in the contemporary practice did occur in the sense that fewer patients in the "good" risk category (ie, in chronic phase) are being referred to transplantation. This has resulted in more late-stage CML patients currently undergoing transplantation. Our results show that once patients have progressed to accelerated phase or blast crisis, their disease-free survival and overall survival after allogeneic transplantation are markedly superior after PBSCT compared with BMT.

The incidence of acute GVHD was the same in both PBSCT and BMT although severity (grade 3-4) was greater in recipients of PBSCT. Since more severe GVHD is
associated with increased mortality, this very likely accounts for the failure of PBSC to have a beneficial effect on overall survival, despite a lower rate of relapses. This potentially negative effect of peripheral blood stem cells would likely have a greater impact on survival among patients with less advanced leukemias, where rates of relapse are lower.

PBSC was associated with the increased risk of both limited and extensive chronic GVHD. Extensive chronic GVHD can adversely affect quality of life.25-35 As well as survival,26,27 but none of the trials included in our meta-analysis collected analyzable data on quality of life. Physicians and patients should weigh the higher risk of disease recurrence with BMT against long-term consequences of chronic GVHD when deciding which stem cell source to use,36 since chronic GVHD may be an important marker of an active graft-versus-leukemia response and may have been responsible for the reduction in relapse rates and increase in disease-free survival seen with PBSC. Future research should try to delineate not only harmful effects of chronic GVHD but also its potentially beneficial effects, particularly the impact of milder clinical presentations of chronic GVHD on clinical outcomes in the different clinical subgroups. Ultimately, the choice of treatment should be discussed with the patient, with particular emphasis on these critical trade-offs.

Our analysis reiterates the limitations of small randomized studies.28 By synthesizing the totality of research evidence we were able to: (1) resolve apparent inconsistencies in clinical outcomes reported by individual trials and (2) identify conclusively important clinical effects that had not been uniformly demonstrated with the previously available information. However, long-term follow-up will still be necessary for fuller understanding of the role of the stem cell source on clinical outcomes since overall follow-up of patients included in our analysis was relatively short.

BONE MARROW TRANSPLANTATION IN THE PRIVATE SECTOR

To the Editor: To place differing viewpoints about bone marrow transplantation in perspective, we present an analysis of the first 209 consecutive patients grafted at our unit from 1 January 1995. All data are audited by the International, Autologous and European Bone Marrow Transplantation Registries as a requirement for continued accreditation.

Our current protocol is an extension of that used in the first South African transplant, carried out in December 1972. The increasing application and principles of patient selection and technique have recently been summarised.

A fundamental difference exists between this approach to autologous grafting and other methods. Thus, T-cell depletion as the sole form of immunosuppression is achieved by exposure to a specific monoclonal antibody in the-bag. Engraftment was universal, relapse rates were low and, most notably, graft-versus-host disease was not seen. A further modification has been the discontinuation of bone marrow as the source of haematopoietic stem cells and its replacement by the corresponding immunohaematopoietic population harvested from the peripheral blood. In addition it has been demonstrated that the newly engineered human variant of the antibody designated 1H and 1G is equally effective.

Outcome depends on operation of an optimal physical facility staffed by a motivated multidisciplinary team and incorporating a special and dedicated laboratory for cryobiology, clonogenic assays, flow cytometry and fluorescent in situ hybridisation to support ongoing research and development (P Jacobs, L Wood — unpublished data).

In 1995 14 conventional bone marrow transplants were carried out, approximately half being autologous. Five patients (35.7%) died. There were no immediate procedure-related deaths. Clearly there was no technical or any other impediment to providing such tertiary-level medicine successfully in the private sector. However, the number is too small for designation as a transplant centre, while deaths were skewed by sub-optimal selection of cases treated.

In 1996 the number of transplants rose to 27. Twenty-five were carried out using bone marrow, of which 8 were allogeneic. A further 3 were from blood stem cells harvested from matched siblings and, at the time, represented a further innovation in this country. Six patients (22.2%) died, mostly from disease progression. This current level of activity is appropriate for designation as a transplant centre, using international criteria. The falling morbidity reflects improved patient selection and more cohesive functioning of the nursing and paramedical support staff. The switch to the use of peripheral blood has significantly reduced costs and shortened hospital stay, and has had much greater acceptability by family donors.

1997 saw the programme reach capacity, with approximately one graft carried out each week. At the time of reporting, 6 patients who received allografts and 5 who received autographs have died. For the first time cytomegaloviral pneumonitis was noted, leading to introduction of appropriate monitoring as a basis for early therapy with ganciclovir.

Children are now routinely treated and an increasing number of solid tumours are managed on international collaborative protocols. Of particular note has been the successful introduction of matched unrelated transplants, and these are used where appropriate. A new problem has been the low-level occurrence of erythroderma, presumed to be grade 1 cutaneous graft-versus-host disease and generally readily responsive to corticosteroid immunosuppression. It is postulated that such an immunological event might carry with it a desirable graft-versus-leukaemia benefit which may contribute to a continually low relapse rate.

In 1998 51 transplants have been completed, of which approximately half are allogeneic. Engraftment time has been shortened by over a week to 11 days, and there have been no graft failures. At the time of reporting 8 patients have died. Two were disease-free with a functioning graft, 2 died of strokes, and 1 died of pulmonary embolus. The other deaths were due to a variety of causes.

In 1999 the same level of activity and pattern of response has been maintained, with 38 allogeneic and 27 autologous peripheral blood stem cell grafts successfully undertaken. The year was notable for the increased number of children qualifying for admission to protocol studies and rapidly escalating activity in the matched unrelated volunteer donor transplantation. Many of the initial problems with establishing donor searches and the logistics of safe as well as rapid delivery of appropriate products for the procedures have been overcome. An important advance has been the acceptance of the centre, both for transplantation and harvesting, by the American National Donor Programme. This will markedly broaden the range of available options.

The priorities for the first 5 years of the new millennium are clear. Firstly, to provide a service in keeping with international
standards of practice. Secondly, to refine graft quality and investigate the phenomenon of erythrophagia. Thirdly, to continue studies to characterise recovery of immunological competence, and to extend observations from the CAMPATH users group on an apparent benefit of post-transplant administration of cyclosporin (G Hale — unpublished data). We will also consolidate our increasing use of unrelated volunteer transplants through continued association with the South African and international bone marrow donor registries. Finally, the stage is now set to commence development of refinements such as gene therapy for the more selective correction of defects exemplified by Fanconi anaemia, and here the necessary collaboration with an international accredited laboratory for DNA engineering has been established. In these endeavours we will explore ways of developing collaborative programmes with the State hospitals so that community resources are utilised maximally and responsibly for adults and children. Only through such mutual endeavours will the greatest number of individuals be able to benefit from costly, but nevertheless frequently curative interventions.

We conclude by re-emphasising our commitment to accountability and audit, particularly now that managed health care is increasingly becoming a reality. We respectfully submit, therefore, that peer review must continue to govern these activities, so that all potentially eligible patients can continue to have access to a procedure that, while expensive, is both cost-effective and frequently curative if properly used.

REDDUCING MOTHER-TO-CHILD TRANSMISSION OF HIV

To the Editor: As health workers in government service, we face a dilemma regarding the care of pregnant women infected with HIV. The best available evidence indicates that various relatively inexpensive short courses of antiretroviral therapy are highly effective in reducing mother-to-child transmission of HIV. The Department of Health has chosen not to make this preventive measure available to women in the public health sector, or to inform women of the available evidence so that they have the option to obtain treatment themselves.

Background
In 1998 a pilot study for which funding was available was planned by the Gauteng Health Department to determine the feasibility and cost of implementing a strategy to reduce mother-to-child transmission of HIV at all levels of health care. We supported this programme, which aimed at equity throughout the health service. As part of the pilot study, a system of antenatal counselling and voluntary HIV testing was set up at Coronation Hospital and a primary care referral clinic. After several months of meetings to finalise the protocol, the pilot study was cancelled. We protested in writing about this decision.

While we accept that some therapies cannot be afforded in the public sector, we considered it unethical to withhold from those in our care a life-saving preventive measure without even assessing whether or not it is affordable for all. We therefore decided to make savings in other areas in order to make short-term antiretroviral therapy available to women attending our hospital.

Our experience has been overwhelming positive. Our staff have implemented the programme with such enthusiasm and dedication that our antenatal HIV clinic was jointly awarded the 1999 Gauteng Province Kanyisa award for service excellence. The sense of helplessness of staff and patients in the face of the HIV epidemic has turned to a sense of purpose and optimism, that at least in one area we are able to make a positive contribution to curbing the epidemic. Several women attending our clinic have been trained as lay HIV counsellors. We see the positive approach to the prevention of mother-to-child transmission of HIV as a catalyst for changing community attitudes from hopelessness and denial to a determination to do something about the HIV epidemic.

The question of safety and effectiveness
We have re-evaluated our position in the light of recent government statements regarding safety. Our position is as follows:

1. All drugs have the potential for adverse effects, which must be weighed against the beneficial effects. In the case of short-term courses of AZT, ACT plus 3TC, or nevirapine to pregnant women infected with HIV and their newborn babies,
considered to have had a recurrence at day 1. Leukemia-free survival was defined as survival in continuous complete remission; relapse or death were considered events, and patients surviving in continuous complete remission were censored at last follow-up.

**Statistical Methods**

Patient-, disease-, and transplant-related variables were compared between the two groups using the $\chi^2$ statistic for categorical variables and the Kruskal-Wallis test for continuous variables. Probabilities of leukemia-free survival and overall survival were calculated using the Kaplan-Meier estimator. Cumulative incidence rates (the chance a patient will have experienced a particular event before time $t$, and where death without an event is the competing risk) were calculated using standard technique, for hematopoietic recovery, acute and chronic GVHD, treatment-related mortality, and relapse. We calculated 95% CIs using the SE of the survivor function by Greenwood formula. Adjusted probabilities for outcomes after transplantation were estimated using the Cox proportional hazards method to adjust for patient-, disease-, and transplant-related variables that were included in the final multivariate models.

Multivariate models were built using a stepwise forward selection with a significance level of 0.05. The primary objective of this study was to compare outcomes after PBSC and BM transplantation; therefore, the variable for graft type was held in the model at each step. Other variables considered were recipient age, performance status, sex of the recipient and donor, age of recipient and donor, year of transplantation, conditioning regimen, type of prophylaxis against GVHD, and use or nonuse of growth factor within the first 7 days of allograft infusion to hasten neutrophil recovery. Whenever categories of variables initially classified into more than two categories showed no statistically significant differences between categories, categories were collapsed to create the fewest possible number of groups (such as age 8 to 16 years v 17 to 20 years). Variables were entered using a time-varying covariate method to determine whether the proportional hazards assumption was met. All variables met the proportional hazards assumption. First-order interactions between graft type and each variable of interest were examined by fitting a proportional hazards model, and examining the interaction between the variable of interest and graft type. All multivariate models were examined for center effects using a random effects or frailty model. Completeness of follow-up was assessed using the $\gamma$ statistic, which gives a measure of the proportion of all potential follow-up information available for this study. All $P$ values are two-sided. All analyses were done using PROC PHREG in SAS version 8.0 (SAS Institute, Cary, NC).

**Patient and Transplant Characteristics**

Patient-, disease-, and transplant characteristics are presented in Table 1. All aspects of the transplant regimen, including graft type, were at the discretion of the transplant center. Median follow-up of survivors was 57 months (range, 4 to 92 months) and 40 months (range, 6 to 82 months) after BM and PBSC transplantation, respectively. Completeness of follow-up was 91% and 94% after BM and PBSC transplantation, respectively. Groups were similar in terms of patient sex, performance score, disease, French-American-British subtypes in AML, and immunophenotype in ALL, cytogenetics, conditioning regimen, GVHD prophylaxis, cytomegalovirus serology, and donor-recipient sex match. Groups differed in distribution of age, disease status at transplantation, use of growth factor, total nucleated cell dose, and year of transplantation (PBSC recipients were older and more likely to have advanced leukemia [be in second CR or not in CR at transplant], more likely to receive growth factors and higher cell doses, and have undergone transplantation more recently).

**Donor Characteristics**

PBSC donors tended to be older than BM donors (Table 1). Donor age was highly correlated with recipient age in both groups ($P < .0001$). Data on method of PBSC collection were available for 108 donors. Of these, 19% required placement of a central venous catheter. No collection-related complications were reported in 137 assessable PBSC donors. BM grafts were collected using standard techniques. There were four reported complications among BM donors: hypotension, nausea, vomiting, allergic reaction, and pyelonephritis, as reported verbatim on IBMTR report forms.

**Hematologic Recovery**

PBSC recipients had significantly faster neutrophil and platelet recovery. Median time to neutrophil recovery was 13 days (range, 7 to 34 days) and 18 days (range, 9 to 47 days) after PBSC and BM transplantation, respectively ($P < .0001$, Kruskal-Wallis test). The cumulative incidence of neutrophil recovery at day 100 was 97% (95% CI, 82% to 100%) and 96% (95% CI, 90% to 99%) after PBSC and BM transplantation, respectively. Median time to platelet recovery was 18 days (range, 8 to 92 days) and 26 days (range, 11 to 117 days) after PBSC and BM transplantation, respectively ($P < .0001$, Kruskal-Wallis test). The cumulative incidence of platelet recovery at 1 year was 87% (range, 82% to 92%) and 88% (range, 83% to 93%) after PBSC and BM transplantation, respectively.

**Acute and Chronic GVHD**

Cumulative incidences of grades 2 to 4 acute GVHD at day 100 were 27% (95% CI, 20% to 35%) and 28% (95% CI, 25% to 32%) after PBSC and BM transplantation, respectively. Cumulative incidences of grades 3 to 4 acute GVHD at day 100 were 13% (95% CI, 8% to 20%) and 11% (95% CI, 8% to 13%) after PBSC and BM transplantation, respectively. In multivariate analysis, the relative risk (RR) of grades 2 to 4 acute GVHD were similar after PBSC and BM transplantation (RR, 1.01; 95% CI, 0.72 to 1.43; $P = .9$). Results were similar for grades 3 to 4 acute GVHD. In both groups, acute GVHD was significantly higher after an irradiation-containing conditioning regimen (RR, 1.60; 95% CI, 1.21 to 2.13; $P = .001$).

Abbreviations: ALL, acute lymphocytic leukemia; AML, acute myeloid leukemia; CR, complete clinical remission; PIF, persistent induction failure; Cy, cyclophosphamide; TBI, total body irradiation; Bu, busulfan; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte macrophage-colony stimulating factor, CSA, cyclosporine; MTX, methotrexate, NS, nonsignificant; BM, bone marrow graft; PB, peripheral blood graft; GVHD, graft-versus-host disease; Cy, cyclophosphamide.

*FAB subtypes, immunophenotypes, cytogenetics and disease status: ALL, B-lineage (88% of PBSC and 63% of BM recipients); T-lineage (15% and 23%); undifferentiated (17% and 14%); ALL cytogenetic abnormality, normal karyotype (34% of PBSC and 34% of BM recipients); 19q21, 11q23, 11q24, hyperdiploid (10% and 11%); 11q23, 11q24, 11q22, 10, -12, +21, +19, +14q, hyperdiploid (23% and 29%); AML: M1 (33% of PBSC and 16% of BM recipients); M2 (33% and 34%); M3 (5% and 9%); M4 (24% and 22%); M5 (9% and 11%); M6 (4% and 1%); M7 (2% and 2%); undifferentiated (7% and 5%); AML cytogenetic abnormality, 19q21, 11q23, 11q24, 19q13 of PBSC and 16% of BM recipients; 16q, 18q, 16q, 11q, 8, +21, normal karyotype (30% and 31%); 11q23, 11q22, 11q24, monosomy 7, 7q, 7q, -20/20q, -16q, and 4q; unknown (33% and 29%).

1) Disease status: CR1 at transplantation, ALL: n = 32 PBSC and n = 119 BM; AML: n = 26 PBSC and n = 211 BM; CR2 at transplantation, ALL: n = 42 PBSC and n = 197 BM; AML: n = 10 PBSC and n = 39 BM; Relapse/PIF at transplantation, ALL: n = 14 PBSC and n = 40 BM; AML: n = 17 PBSC and n = 26 BM.

2) Other conditioning regimen BM, cyclophosphamide; other (n = 5), busulfan; other (n = 1), thiotepa; other (n = 4), TBI.

3) Other GVHD prophylaxis: FK506, methotrexate, - steroids.
4) Use of growth factor within the first 7 days after transplantation: BM, G-CSF (n = 133); GM-CSF (n = 15) and G-CSF: GM-CSF (n = 5); PB, G-CSF (n = 59); GM-CSF (n = 3) and G-CSF + GM-CSF (n = 1); missing (n = 6).

Cumulative incidences of chronic GVHD at 3 years were 33% (95% CI, 24% to 42%) and 19% (95% CI, 16% to 22%) after PBSC and BM transplantation, respectively (P = .001; Fig 1). In a multivariate analysis, chronic GVHD was significantly more likely after PBSC transplantation (RR, 1.84; 95% CI, 1.28 to 2.64; P = .001). Other factors significantly associated with chronic GVHD in both groups were age older than 16 years (RR, 1.66; 95% CI, 1.21 to 2.29; P = .002) and donor-recipient sex match other than female donor and male recipient (RR, 0.61; 95% CI, 0.44 to 0.84; P = .003). Among patients with chronic GVHD, grade and organ involvement were similar after PBSC and BM transplantation (Table 2).

### Treatment-Related Mortality

Cumulative incidences of treatment-related mortality at 3 years were 26% (95% CI, 19% to 34%) and 14% (95% CI, 11% to 17%) after PBSC and BM transplantation, respectively (P = .001; Fig 2). Treatment-related mortality was higher after PBSC transplantation (Table 3). The use of growth factor was significantly associated with higher treatment-related mortality after both PBSC and BM transplantation.

### Relapse

Cumulative incidences of relapse at 3 years were 38% (95% CI, 29% to 47%) and 33% (95% CI, 29% to 37%) after PBSC and BM transplantation, respectively (P = .70). Risks of relapse were similar in both groups (Table 3). Advanced disease at transplantation and use of growth factor were
significantly associated with an increased risk of relapse after both PBSC and BM transplantation. We observed a trend toward a protective effect of chronic GVHD in preventing relapse after both PBSC and BM transplantation (RR, 0.69; 95% CI, 0.47 to 1.02; P = .06).

Leukemia-Free Survival

Treatment failure (inverse of leukemia-free survival) was higher after PBSC than after BM transplantation (Table 3). Advanced disease at transplantation and use of growth factor were significantly associated with higher treatment failure after both PBSC and BM transplantation. Three-year probabilities of leukemia-free survival, adjusted for other significant factors (disease status and use or nonuse of growth factor), were 42% (95% CI, 33% to 50%) and 51% (95% CI, 48% to 55%) after PBSC and BM transplantation, respectively (P = .03; Fig 3).

Overall Survival

Mortality was higher after PBSC than BM transplantation (Table 3). Advanced disease and use of growth factor were significantly associated with higher mortality after both PBSC and BM transplantation. Three-year probabilities of overall survival, adjusted for other significant factors, were 48% (95% CI, 40% to 56%) and 58% (95% CI, 54% to 62%) after PBSC and BM transplantation, respectively (P = .01; Fig 4).

Eighty-two (57%) of 143 recipients of PBSC transplants and 277 (44%) of 630 recipients of BM transplants died (Table 4). Recurrent disease was the most frequently
reported primary cause of death in both groups. The only significant difference in causes of mortality between PBSC and BM recipients was in the proportion of deaths related to GVHD occurring more than 100 days post-transplantation—20% in the PBSC group and 5% in the BM group ($P = .0007$, $\chi^2$ test).

Several studies, including randomized clinical trials comparing PBSC versus BM transplantation in adults, report lower early mortality, higher chronic GVHD risk, and a survival benefit in some populations. Though there are no such studies reported in children, PBSC allografts are frequently used instead of BM for pediatric transplantation. The primary objective of this study was to compare outcomes after transplantation using PBSC and BM allografts in children and adolescents with acute leukemia. There were differences in PBSC and BM recipients that might be expected to confound outcomes after transplantation, such as age, type of leukemia, disease status at transplantation, and use of growth factor. We used multivariate Cox regression models to adjust for the independent effects of each potential risk factor. After this adjustment, we found higher chronic GVHD, treatment-related mortality, treatment failure, and overall mortality after PBSC transplantation.

PBSC offer more rapid hematopoietic recovery in children, similar to reports in adults. We also observed similar risks of acute GVHD after PBSC and BM transplants, which was again, comparable to most reports in adults. As observed in some studies of adults, chronic GVHD was significantly higher after PBSC transplantation, probably due to higher numbers of T cells in mobilized peripheral blood. However, among patients who developed chronic GVHD, grade and organ involvement were comparable in the two groups, consistent with reports in adults.

Importantly, we observed an adverse effect of PBSC grafts on treatment-related mortality, treatment failure, and overall mortality after adjusting for other significant risk factors that may influence outcome. This has not been reported previously. Published reports in adults with acute leukemia suggest equivalent survival after PBSC and BM transplants. Higher mortality in children receiving PBSC grafts is likely due to higher chronic GVHD. Chronic GVHD after BM transplantation is lower in children than in adults. Thus in younger PBSC recipients, a higher risk of mortality from chronic GVHD may offset any measurable benefits of more rapid hematopoietic recovery in the early transplantation period.

Higher mortality and treatment failure after PBSC transplantations were independent of age. To address whether the higher proportion of children (aged 17 to 20 years) in the PBSC group affected outcomes, we first examined the effect of age within each graft type and observed no differences in risks of treatment-related mortality, treatment failure, and overall mortality between children aged 8 to 16 years and 17 to 20 years. In multivariate analysis, risks of each of these outcomes after PBSC and BM transplantation were similar in recipients aged 8 to 16 years and 17 to 20 years (i.e., the PBSC/age 8 to 16 years vs BM 8 to 16 years, and the PBSC age 17 to 20 years vs BM/age 17 to 20 years). Formal tests for interaction revealed no significant interactions between graft type and age at transplantation.

Risks of relapse were similar after PBSC and BM transplantation. Thus far, previous studies in adults including randomized clinical trials, also report similar risks of relapse after PBSC and BM transplantations. The observed trend toward a protective effect of chronic GVHD in preventing relapse did not differ by graft type. Our study is limited to patients with acute leukemia, whereas reports that have suggested a stronger graft-versus-leukemia effect after PBSC transplantations have included patients with acute and chronic leukemia.

Disease status at transplantation adversely affected leukemia recurrence, treatment failure, and overall mortality, regardless of the type of graft. Though a higher proportion of patients with ALL underwent transplantation in second

Abbreviation: GvHD, graft-versus-host disease.

CR, this was independent of graft type. In contrast, most patients with AML were transplanted in first CR but were more likely to receive PBSC grafts if they were not in CR at transplantation. We did not observe an association between transplant outcomes and disease type.

Use of growth factor for neutrophil recovery had an adverse effect on relapse and mortality after PBSC and BM transplantations. Studies in animals and human volunteers have shown decreased production of inflammatory cytokines, increased production of interleukin-10, increased mobilization of T-helper-2 (Th2)-inducing dendritic cells, and Th2 immune deviation with G-CSF. In recipients of mismatched T-cell-depleted transplantations, the elimination of G-CSF for hematopoietic recovery has been shown to accelerate immune recovery. It is possible that the use of growth factor may have resulted in slower immune recovery and subsequent higher mortality. We were unable to explain the adverse effect of growth factor on leukemia recurrence. Thus far, larger studies specifically examining the effect of growth factor use in the early post-transplantation period, report mixed results, and although growth factors activate AML cells, most reports support the contention that leukemia growth is not promoted in a clinically meaningful way. A detailed analysis of the effects of growth factor on leukemia recurrence or mortality is beyond the scope of this study.

We did not perform analysis of total nucleated cell dose or CD34 cell dose, as these were surrogates for graft type. PBSC recipients received higher cell doses: 65% received total nucleated cell doses greater than 5 x 10⁸/kg compared with 10% of BM recipients. Nevertheless, most BM recipients received an adequate cell dose and achieved hematopoietic recovery, and this may have minimized any potential benefit of PBSC grafts. We could not analyze the independent effect of donor age as this was highly correlated with recipient age in both groups.

We found no evidence of confounding of main effects (transplant outcome by graft type) by center effects using a random effects model, a test specially designed for situations like the current analysis in which each center contributes relatively few cases. To address this further, we adjusted for the number of transplantations performed per center (1 to 5 vs. 10 to 15 vs. 10) and geographic location (United States vs. Europe vs. other regions) in final multivariate models and found no evidence of confounding of main effects.

Treatment-related mortality, treatment failure, and overall mortality were higher after PBSC transplantation after adjustment for other relevant risk factors that may influence these end points. A retrospective analysis has limitations such as selection bias for graft type and inability to adjust for unknown or unmeasured factors. These data represent the early experience of PBSC transplantation; nevertheless, these data should serve a cautionary note before widespread change in the clinical practice of using BM for allogeneic transplantation in children. Alternative graft sources must be evaluated in a controlled fashion before adoption in a population that already has a relatively good outcome after BM transplantation. We think that there is an urgent need for a properly designed clinical trial to define the role of PBSC in allogeneic transplantation in children.

Appendix

In addition to the authors, other members of the International Bone Marrow Transplant Registry Working Committee on Histocompatibility and Alternate Stem Cell Sources who participated in the study are as follows: M.M. Abecasis, Instituto Portugues de Oncologia, Lisbon, Portugal; B.J. Bowell, Cleveland Clinic Foundation, Cleveland, OH; K.W. Chan, M.D. Anderson Cancer Center, Houston, TX; J. Davis, British Columbia Children's Hospital, Vancouver, BC, Canada; M.A. Diaz, Hospital Nino Jesus, Madrid, Spain; J. Doyle, Hospital of Sick Children, Toronto, ON, Canada; M. Gorner, University of Heidelberg, Heidelberg, Germany; G.A. Hale, St Jude Children's Research Hospital, Memphis, TN; R.E. Harris, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; M. Primed marrow for autologous and allogeneic transplantation: A review comparing primed marrow to mobilized blood and steady-state marrow

Gerald J. Elfenbein and Robert Sackstein

Mobilized peripheral blood collections, obtained following either chemotherapy (with or without granulocyte colony-stimulating factor (G-CSF)) or G-CSF administration alone, are rapidly replacing traditional bone marrow harvests as the source of cells for hematopoietic stem cell transplantation. According to the Autologous Blood and Marrow Transplant and the International Bone Marrow Transplant Registries, for the years 1998 through 2000, blood stem cell (BSC) transplants accounted for about 80% of autologous transplants in the pediatric age group and more than 90% of the autologous transplants among adults. In allogeneic transplantation, where the donor is a healthy family member or normal volunteer, G-CSF-mobilized BSC transplants are being used more and more frequently, accounting for about 20% of allogeneic transplants in the pediatric age range and more than 40% of allogeneic transplants among adults during the same time period. It is not, therefore, too great a stretch to imagine that BSC transplants will soon be, if not already, in the majority for allogeneic transplantation among adults. The principal reason why this is happening is the prevailing view that BSC engraft more rapidly than marrow stem cells (MSC). However, this view is based on comparisons between primed circulating blood cells (BSC) and unprimed resident marrow cells in the steady state (SS-MSC). If the reason why BSC engraft faster than SS-MSC were a consequence of G-CSF used for mobilization, then would priming of MSC by G-CSF (Prim-MSC) accelerate engraftment of marrow as well? We reviewed the literature of the last 10 years to see if there were enough data to answer this question.

© 2004 International Society for Experimental Hematology. Published by Elsevier Inc.

During embryogenesis, hematopoietic stem cells migrate from the yolk sac to the liver and, ultimately, to the medullary cavities of cancellous bones. This migration occurs via the vasculature and, in adult animals, there are persistent but low levels of migrating hematopoietic stem cells in the blood in the steady state. In a canine lethal irradiation model, cross-circulation of blood from an allogeneic dog produced engraftment of donor hematopoiesis as documented by chimeraism [1]. In another canine myeloablative model, allogeneic leukocyte transusions successfully repopulated marrow spaces and blood elements [2]. These two studies, as well as many others, formally demonstrated the repopulating capacity of circulating hematopoietic stem cells in the bloodstream of large animals.

In man, Goldman [3] reported the first use of blood (albeit Philadelphia chromosome (Ph)-positive) cells for autologous transplantation after high-dose cytotoxic therapy in patients with chronic myelogenous leukemia (CML). Köbbing et al. [4] reported the first case of Ph-negative, autologous blood cell transplantation, also in a patient with CML. In a subsequent case report of a patient with Burkitt’s lymphoma, Köbbing et al. [5] introduced the hypothesis that autologous BSC may produce more rapid engraftment than autologous MSC. In both reports by Köbbing, BSC were collected from patients during the overshoot phase of granulocyte-macrophage colony-forming units in the blood during leukocyte recovery after cytotoxic chemotherapy. This was the first example of chemotherapy-induced “mobilization,” one of the two major methods we employ today to enrich autologous stem cells in the blood [6].

The modern era of autologous BSC transplantation, however, began with the report by Kessinger et al. [7], which
documented, with multiple leukaphereses, the presence of sufficient numbers of autologous hematopoietic stem cells in steady-state blood (long after recovery from chemotherapy) to ensure engraftment after myeloablative therapy. Thus, there is little question that adequate hematopoietic progenitors may be obtained from the bloodstream for hematologic recovery after myeloablative treatment.

Growth factor–induced mobilization is the second of the two major methods for enriching stem cells in the bloodstream [8]. G-CSF is widely used to mobilize BSC for transplantation. Numerous reports have hypothesized that G-CSF–mobilized BSC (BSC) engraft more rapidly than steady-state MSC (SS-MSC), much as Körbling had suggested for chemotherapy BSC. Because of the wide acceptance of this hypothesis, G-CSF BSC are being collected more and more often from healthy donors (including unrelated volunteer adult donors) for autologous transplantation after myeloablative therapy [9].

Recent reports concerning the induction of proteolysis in the marrow microenvironment by G-CSF have shed light upon what may be the molecular mechanism of growth factor mobilization of progenitor cells [10–13]. G-CSF induces proteolysis of at least CD106 (vascular cell adhesion molecule-1 or VCAM-1), which results, subsequently, in the release of progenitors, capable of repopulating hematopoiesis into the circulation. What remains unclear at present is why BSC would produce more rapid engraftment than SS-MSC. This review may shed light upon this open question.

Literature search
The search for articles published over the last 10 years in peer-reviewed, English-language journals and authoritative, English-language monographs comparing BSC and MSC was initiated with PubMed on-line. The search was predicated upon the key words: autologous or allogeneic or HLA-identical; transplantation; stem cell; and blood and/or marrow. Several searches at different times putting the key words in different orders were performed. To be included in our analyses, published articles must have reported comparisons of at least two of the three different types of stem cell products—BSC, SS-MSC, and Prim-MSC. Reference lists from all publications so obtained were also reviewed for additional publications germane to the topic that were not detected via PubMed on-line. Published meeting abstracts were excluded from the analyses performed because of the risk of incomplete data. The search concluded in January 2003.

Although meta-analyses are the most sensitive way to detect small differences between study groups, due to the number and heterogeneity of reports examined, it was not feasible to obtain primary data to execute meta-analyses. As an alternative statistical method, which takes into account differences in sample size for different studies, we calculated and report here weighted median stem cell numbers and weighted median days to engraftment of granulocytes (the first of three days when the absolute granulocyte count (AGC) exceeded 0.5 × 10^9/L) and platelets (the first of three days when the platelet (PLT) count exceeded 20 × 10^9/L unsupported by platelet transfusions). Medians were weighted by sample size. In addition, we calculated and report here weighted median T cell numbers and weighted probabilities of five major clinical outcomes: 1) acute graft-versus-host disease (GVHD; Grade II or higher), 2) chronic GVHD (extensive and limited), 3) relapse rate (100% minus percentage of patients, at the median follow-up time, remaining relapse free from Kaplan-Meier time to relapse plots), 4) overall survival (percentage of patients, at the median follow-up time, remaining alive from Kaplan-Meier time to death plots), and 5) disease-free survival (percentage of patients, at the median follow-up time, remaining both free of relapse and alive from Kaplan-Meier time to event plots).

In this report, we term inter-study comparisons “global” analyses. Also, we term intra-study comparisons “delta” analyses. Intra-study delta analyses minimize the contribution of patient heterogeneity that is introduced by evaluating multiple studies at the same time, to each specific endpoint measurement. The assumption made by delta analyses is that patient heterogeneity for both types of stem cell products in a given study will be very similar. Statistical analyses were performed using Statistica software (Tulsa, OK, USA). Medians for granulocyte and platelet engraftment times were not expected to be normally distributed. Assuming nonparametric distributions of medians, comparisons among stem cell product groups were performed using the Kruskal-Wallis ANOVA and median test. Differences between the medians for engraftment times for two different stem cell products were expected to be normally distributed. The null hypothesis was that the average of deltas was zero. The Z test was used to test the null hypothesis. Delta analyses were performed for the subgroup of studies that were randomized controlled trials first, then, if necessary, for all studies comparing two stem cell products “head-to-head.” To determine risk factors for individual outcomes, we employed an ANCOVA method. All p-values presented are from two-tailed tests.

Results

Literature review
The objective of the literature search was to assemble as many articles as possible from the modern literature (past 10 years) to evaluate seven clinical outcomes, i.e., engraftment times for granulocytes and platelets, acute and chronic GVHD, relapse rate, overall survival, and disease-free survival. The ultimate goal of the literature review was to determine if there were differences in any of these seven
clinical outcomes for both autologous and allogeneic transplants based upon anatomic source of stem cells and/or use of G-CSF before collection. As will be seen, the results provide a new perspective to help us formulate a more accurate hypothesis about engraftment relating to the anatomic source of stem cells and the use of G-CSF precollection of BSC (mobilization) and MSC (priming).

Thirty-seven articles were collected, 13 reporting autologous transplants [14-26] and 24 reporting allogeneic transplants [27-50]. It was important to identify articles that reported results not only for comparisons of BSC with SS-MSC but also for comparisons of Prim-MSC with either BSC or SS-MSC, as well.

Autologous transplantation

In the autologous stem cell transplant literature, there were 18 eligible comparisons in the 13 reports. There was considerable heterogeneity among the 18 comparisons. There were 9 prospective comparisons (6 with randomization, 2 with assigned controls, and 1 with concurrent controls) and 9 retrospective comparisons (4 with historical controls, 4 with matched controls, and 1 with sequential patients). Eleven comparisons were from single institutions; 12 comparisons involved lymphoma patients only; 7 comparisons involved a single transplant regimen; and 16 comparisons involved adults only. Eleven comparisons used growth factors during the first 7 days after stem cell infusion (9 with G-CSF and 2 with GM-CSF); growth factors were not administered in 5, and there was no mention of postgrafting growth factors in 2 comparisons.

A grand total of 407 patients with BSC were described. Mobilization of BSC was performed in 16 comparisons involving growth factors in 10 (9 with G-CSF and 1 with GM-CSF), employing chemotherapy and growth factors in 2, and not described in 4 comparisons. When G-CSF was used to mobilize BSC, the median (range) dose was 10 (5-16) μg/kg/day for 4 (4-5) days followed by 2 (1-4) leukaphereses. Mobilization of BSC yielded a weighted median (range) of 2.6 (1.0-6.4) x 10⁸ CD34+ cells/kg.

There were 12 comparisons involving SS-MSC describing 347 patients. The weighted median (range) harvest of CD34+ cells was 2.1 (1.2-2.3) x 10⁹/kg. There were 9 comparisons involving growth factor Prim-MSC (8 with G-CSF and 1 with GM-CSF) reporting 159 patients. When G-CSF was used to prime MSC, the median (range) dose was 10 (1-40) μg/kg/day for 5 (2-5) days followed by a single bone marrow harvest. Priming of MSC yielded a weighted median (range) of 1.5 (0.6-2.3) x 10⁹ CD34+ cells/kg.

Figure 1 is a graphic presentation of four outcomes of autologous transplants: recovery of granulocytes and platelets, overall survival, and disease-free survival. For the first round of analyses no study was excluded. This round was "global" in nature. As can be seen, there was little difference in the numbers of CD34+ cells infused/kg among the three groups—BSC, SS-MSC, and Prim-MSC. The top-to-bottom spread was 2.6 to 1.5 x 10⁹ CD34+ cells/kg, representing a spread of less than a factor of 2. Both AGC and PLT recoveries were, however, delayed for SS-MSC and Prim-MSC as compared to BSC. Prim-MSC recoveries were more rapid than SS-MSC, demonstrating a salutary effect of growth factor priming on MSC despite the fact that Prim-MSC contained about 25% fewer CD34+ cells (per kilogram recipient body weight) than did SS-MSC. Interesting is the observation that Prim-MSC engraft nearly as rapidly as BSC despite having 40% fewer CD34+ cells than BSC. Overall survival at a median follow-up of 3.6 years was essentially identical for BSC and SS-MSC. Disease-free survival at a median follow-up of 2.8 years was similar for all three classes of stem cells with a potential edge for MSC. Altogether this global analysis would speak to faster engraftment for BSC, which would translate into briefer aplasias, reduced infections, and fewer transfusions resulting in lower costs, but without an ultimate long-term survival benefit [51-52].

However, because of the extraordinary degree of heterogeneity among the comparisons, as described above, we felt that the global analysis was, by itself, insufficient to draw conclusions. The second round of analyses ("delta" analyses) evaluated only prospective randomized controlled trials (RCT). In this round, analysis of engraftment involved calculating the delta (signed days of difference in the medians) in engraftment times between the two arms of the RCT. There were 4 RCT [14,16,18,26] that compared BSC and SS-MSC and 2 RCT [19,24] that compared BSC to Prim-MSC. There were no RCT comparing SS-MSC or Prim-MSC. When delta is positive, it signifies faster recovery for BSC relative to its comparator (SS-MSC or Prim-MSC); when delta is negative, the reverse is true. Although a delta
of +1 day for AGC recovery may be mathematically significant due to the tightness of distribution of engraftment times [53]. Such a delta is not clinically meaningful because it signifies, usually, only one more day of antibiotics. Similarly, a delta of +2 days for PLT recovery may be mathematically significant but not clinically meaningful because it represents, ordinarily, only one more platelet transfusion. Figure 2A shows that BSC produced more rapid granulocyte engraftment than SS-MSC in 3 of 4 RCT. Further, in 2 of 2 RCT, BSC and Prim-MSC produced equivalent engraftment times. Figure 2B shows that BSC produced more rapid platelet engraftment than SS-MSC in 3 of 4 RCT. Further, in 2 of 2 RCT, BSC and Prim-MSC produced equivalent engraftment times. In contrast to the global analysis above, this RCT analysis points to equivalence of engraftment potential for both autologous MSC and BSC collected after G-CSF treatment. Furthermore, with respect to overall and disease-free survival, 5 RCT were evaluable. Four of 5 RCT showed equivalence of overall survival while 1 of 5 showed an advantage for BSC [14]. All 5 RCT showed equivalence of disease-free survival for MSC and BSC.

Allogeneic transplantation

In the allogeneic stem cell transplant literature, 24 manuscripts report eligible comparisons. There was considerable heterogeneity among the 24 comparisons. There were 10 randomized prospective studies, 5 studies with historical controls, 4 retrospective registry studies, 2 studies with case controls, 2 sequential studies, and 1 allocated study. Fifteen comparisons were from single institutions; only 2 comparisons involved only one institution (but not the same one); only 7 comparisons involved a single transplant regimen; but 22 comparisons involved adults only. Acute GVHD prophylaxis involved cyclosporine in 22 studies (with 2 making no mention). In addition, methylprednisolone was given to all patients in 15, some patients in 6, and no patients in 2 studies, but was not mentioned in 1 study. G-CSF use during the first 7 days after stem cell infusion was routine in 7, sometimes in 4, not routine in 4, not allowed in 4, but not mentioned in 5 studies.

A grand total of 1949 patients with BSC were described. Mobilization of BSC was performed in 22 comparisons; methodology involved G-CSF in 19 but was not reported in 3 comparisons. To mobilize BSC with G-CSF, the median (range) dose was 10 (5-16) µg/kg/day for 4 (3-5) days followed by 2 (1-4) leukaphereses. Mobilization specifics (dose, schedule, duration, and number of collections) were not completely described in 4 comparisons. Mobilization of BSC with G-CSF yielded a weighted median (range) of 6.1 (3.1-12.3) x 10^6 CD34+ cells/kg.

There were 21 comparisons involving SS-MSC describing 3782 patients. The weighted median (range) harvest of CD34+ cells was 3.2 (1.5-7.5) x 10^6/kg for SS-MSC. There were only 5 comparisons involving G-CSF Prim-MSC reporting 107 patients. To prime MSC with G-CSF, the median (range) dose was 10 (4-10) µg/kg/day for 4 (2-7) days followed by a single bone marrow harvest. Priming of MSC yielded a weighted median (range) of 4.1 (1.6-9.4) x 10^6 CD34+ cells/kg. The regimens involving G-CSF treatment prior to collecting BSC and Prim-MSC were virtually identical.

Figure 3 is a graphic presentation of 7 outcomes of allogeneic transplants: recovery of granulocytes and platelets, acute and chronic GVHD, relapse rate, overall survival, and disease-free survival. The medians for recovery of granulocytes and platelets for each stem cell product for all studies

Figure 2. For allogeneic transplants, delta analysis of engraftment times from randomized controlled trials. Panel A shows the number of days for granulocyte recovery (to >0.5 x 10^9/L) that G-CSF-mobilized blood stem cells (BSC) engraft faster than steady state marrow stem cells (SS-MSC) and G-CSF-primed MSC (Prim-MSC). Biologically significant differences are indicated by days more than the arrow marks (in this case, more than one day). Panel B shows the number of days for platelet recovery (to >20 x 10^9/L) that BSC engraft faster than SS-MSC and Prim-MSC. Biologically significant differences are indicated by days more than the arrow marks (in this case, more than two days).

Figure 3. For allogeneic transplants, CD34+ and CD8+ cell count of grafts and clinical outcomes. Results for 1949 patients who received G-CSF-mobilized blood stem cells (BSC). 3782 patients who received steady state marrow stem cells (SS-MSC), and 107 patients who received G-CSF-primed MSC (Prim-MSC) from 24 different studies [27-50] are shown. Two-tailed values of p are given.
are tabulated in Tables 1 and 2. For the "global" round of analyses no study was excluded. As can be seen, there was little difference in the numbers of CD34+ cells infused/kg among the three groups—BSC, SS-MSC, and Prim-MSC. The top-to-bottom spread was 0.2 to 3.2 × 10^6 CD34+ cells/kg, representing a spread of slightly less than a factor of 2. Both AGC and PLT recoveries were delayed for SS-MSC compared to BSC. As seen in autologous transplants, Prim-MSC recoveries after allogeneic transplants were much more rapid than SS-MSC, also demonstrating a beneficial effect of G-CSF priming on MSC. Interestingly, Prim-MSC contained only about 30% more CD34+ cells than SS-MSC. Most remarkably, AGC and PLT recoveries were identical for Prim-MSC and BSC even though Prim-MSC contained about 30% fewer CD34+ cells than BSC.

One significant difference among stem cell products is that BSC contain nearly sevenfold more CD34+ cells/kg than SS-MSC or Prim-MSC. No significant differences for acute GVHD were reported among SS-MSC, BSC, and Prim-MSC. However, SS-MSC produced less chronic GVHD than BSC and Prim-MSC produced even less chronic GVHD than SS-MSC. Despite the differences in the incidence of chronic GVHD, the probability of relapse at a median follow-up of 2.4 years was certainly not higher for SS-MSC or Prim-MSC than for BSC. Overall survival at a median follow-up of 1.9 years was essentially identical for BSC, SS-MSC, and Prim-MSC. Finally, disease-free survival at a median follow-up of 1.9 years was similar for BSC and SS-MSC. (There were insufficient disease-free survival data to report for Prim-MSC.)

Altogether the global analysis would speak to equivalent engraftment potential for both G-CSF BSC and G-CSF Prim-MSC, both of which are superior to SS-MSC. Even though the numbers of patients receiving Prim-MSC are limited (n = 107), it is safe to say that there is no more acute GVHD with Prim-MSC and perhaps less chronic GVHD than with

---

*For number of patients in each arm, see Table 1.
1 Difference in Days to PLT > 20 x 10^9/L for SS-MSC minus BSC, p < 0.001, BSC faster than SS-MSC.
2 Difference in Days to PLT > 20 x 10^9/L for SS-MSC minus Prim-MSC, Prim-MSC faster than SS-MSC. Sample size too low to be statistically significant.
3 Difference in Days to PLT > 20 x 10^9/L for Prim-MSC minus BSC, p = 0.60, Prim-MSC equivalent to BSC.

Abbreviations: PLT = platelet count; BSC = G-CSF-mobilized blood stem cells; SS-MSC = steady-state marrow stem cells; Prim-MSC = G-CSF-primed marrow stem cells.

BSC. Further, as relapse, survival, and disease-free survival are likely to reflect disease state (remission or relapse number) and transplant regimen as well as the salutary effect of GVHD, it is safe to say that Prim-MSC are likely to produce outcomes as good as BSC. From the global analysis, the only clinically meaningful difference detected between MSC and BSC collected after G-CSF treatment is the reduction in the incidence of chronic GVHD [54].

Again, because of the extraordinary degree of heterogeneity among the comparisons, as described above, a round of delta analyses was performed. In this second round, only prospective RCTs were evaluated. Again, this RCT analysis involved the delta in engraftment times (as described above) between the two arms of the studies. There were 9 RCTs [27,28,38–42,44,45] that compared BSC and SS-MSC but only 1 RCT [32] that compared BSC to Prim-MSC. There were no RCTs comparing SS-MSC to Prim-MSC. By the same criteria (delta > 1 for granulocytes and delta > 2 for platelets) as described above, BSC produced more rapid granulocyte engraftment than SS-MSC in 8 of 9 RCTs. In the sole RCT of its kind, BSC and Prim-MSC produced equivalent granulocyte engraftment times. BSC produced more rapid platelet engraftment than SS-MSC in 9 of 9 RCTs. But in the single RCT, BSC and Prim-MSC produced equivalent platelet engraftment times [32]. Because there was only one RCT comparing BSC to Prim-MSC, it was deemed necessary to perform at least one more analysis.

The third round of analyses extended delta analyses to all comparisons. Utilizing delta engraftment times, studies were arranged by type of comparison and sorted by delta in ascending order. The results for granulocyte engraftment are presented in Table 1 and for platelet recovery in Table 2. As can be seen for granulocytes, 17 of 19 comparisons have a delta greater than 1 for BSC compared to SS-MSC. Also, 2 of 2 comparisons of Prim-MSC vs SS-MSC have delta...
greater than 1. Finally, 0 of 3 comparisons of BSC vs Prim-BSC have a delta greater than 0, let alone delta greater than 1. As can be seen for platelets, all 19 comparisons have a delta greater than 2 for BSC compared to SS-MSC. Also, 1 of 2 comparisons of Prim-MSC vs SS-MSC have a delta greater than 2. Finally, only 1 of 3 comparisons of BSC vs Prim-BSC has a delta greater than 2 (and that delta is 3).

Taking all of these three analyses together, it appears that allogeneic G-CSF Prim-MSC have the same engraftment potential as G-CSF-mobilized BSC. We believe that the functional capacity of Prim-MSC is the best measure of the repopulation potential of the marrow left behind after mobilization of BSC with G-CSF. Therefore, it appears that there should be only minimal concern about donor long-term hematopoiesis. Next, and high-GVID was less frequent with SS-MSC and Prim-MSC than with BSC but overall and disease-free survival were the same. Although chronic GVHD has a well documented graft-vs.-leukemia/lymphoma effect, the reduction of chronic GVHD seen with SS-MSC and Prim-MSC was not associated with an increase in relapse rates.

Factors influencing pace of engraftment

The literature review enabled us to collect data on a variety of clinical factors (from both autologous and allogeneic transplants) that may influence the pace of engraftment of granulocytes and platelets. Factors potentially relevant to the pace of engraftment included anatomic source of stem cells, use of G-CSF pretreatment prior to collecting stem cells from either source, dose of CD34+ cells/kg delivered to patient, use of G-CSF during the first 7 days after transplant, use of methotrexate as part of prophylaxis to prevent acute GVHD, diagnosis, and high-dose chemotherapy regimen. When median times to granulocyte and platelet recovery were plotted on a histogram, we noted that there was a normal distribution (as opposed to our nonparametric assumptions). This permitted us to use ANCOVA methodology to attempt to determine which of these factors, if any, may have had a significant influence upon the median day to recovery of granulocytes and platelets.

For autologous transplantation, the dose of CD34+ cells/kg is well known to be associated with time to engraftment for BSC [55]. The simplest fit mathematical equation describing this relationship is a hyperbolic function in which day of engraftment = constant + 1/(function of cell dose) [56]. Therefore, it was no surprise that, with a univariate analysis of median day to engraftment with CD34+ cell dose was performed, CD34+ cell dose was significantly related to the time of engraftment. However, quite surprisingly, when the use of G-CSF prior to collecting stem cells was entered into a bivariate analysis, CD34+ cell dose was no longer significantly associated with pace of engraftment. When additional variables were added to perform a full multivariate analysis, CD34+ cell dose was again not associated with time to engraftment (see Table 3). Reexamination of Figure 1 gives a graphic overview of this analysis because patients receiving Prim-MSC recovered granulocyte and platelet counts more rapidly than those receiving SS-MSC despite receiving one quarter fewer CD34+ cells (weighted median 1.5 x 10^9/kg vs 2.1 x 10^9/kg). The only factor that had a significant impact on engraftment was the use of G-CSF prior to collecting stem cells from either blood or marrow.

For allogeneic transplantation, the results of the multivariate analyses were very interesting as well. As shown in Table 3, for granulocyte recovery, CD34+ cell dose, the use of G-CSF during the first 7 days after engraftment, the use of methotrexate as part of prophylaxis for acute GVHD, and the stem cell product were all variables significantly and independently associated with pace of engraftment. CD34+ cell dose was important for granulocyte but not platelet recovery. The value of using G-CSF after engraftment has long been known for SS-MSC [57] but has been a subject for debate with BSC. Our analysis pointed to significant and independent role for G-CSF for granulocyte but not platelet recovery (as might be expected). Because use of methotrexate has long been known to delay allogeneic engraftment [55], it came as no surprise that methotrexate negatively but significantly influenced time to engraftment of granulocytes but, quite to our surprise, methotrexate had no impact upon engraftment of platelets. The interaction term told us that G-CSF pretreatment and anatomic source was responsible for accelerating engraftment by BSC and Prim-MSC of both granulocytes and platelets. Reexaming Figure 3, we see that Prim-MSC produced as rapid engraftment as BSC but with roughly one-third lower dose of CD34+ cells (4.1 x 10^9/kg vs 6.1 x 10^9/kg) and Prim-MSC engrafted much faster than SS-MSC with but one-third more CD34+ cells (4.1 x 10^9/kg vs 3.2 x 10^9/kg).

Identifying factors that may influence the kinetics of engraftment must be interpreted with a degree of caution because the studies were not designed to answer this question, nor is the analysis a true meta-analysis. However, these findings are provocative and may provide rationale and incentive for future prospective RCT.

Discussion

In the years 2001 and 2002, six publications appeared in peer-reviewed journals comparing engraftment kinetics of stem cells derived from peripheral blood and bone marrow in allogeneic transplants [27–29,46–48]. In these six publications, blood stem cells were observed to produce more rapid recovery of granulocytes and platelets than marrow stem cells. In all six reports, BSC were mobilized by G-CSF but MSC were collected in the steady state. These data supported the hypothesis that BSC engraft more rapidly than MSC, a hypothesis that was based upon at least 13 publications in the allogeneic literature through the year 2000 [33–45].

</table>

However, there are now five reports in the literature [30–32,49,50] evaluating the engraftment kinetics for Prim-MSC. In two of these five reports, G-CSF Prim-MSC have been shown to engraft more rapidly than SS-MSC. In three of these five reports, G-CSF Prim-MSC engrafted as rapidly as did G-CSF BSC. These five reports suggest that the hypothesis that BSC engraft more rapidly than MSC needs reexamination if not reformulation.

Several reports have appeared in the literature in 2001 and 2002 demonstrating that G-CSF induces neutrophil precursors in the marrow microenvironment that cleave VCAM-1 (CD106), an event that appears to be mechanistically related to the release of hematopoietic progenitors into the circulation. Clinically, this is termed "mobilization" [10–13]. It has also been shown that chemotherapy induces the same proteolytic environment [11]. The proteolytic environment may produce damage to stem cells remaining resident in the marrow or damage to the marrow stroma after routine use of chemotherapy (with or without G-CSF). The consequences of the proteolytic environment are not a critical factor in patients with malignancies, as chemotherapy is necessary to treat their malignancies. However, this proteolytic environment may possibly be one of the explanations why up to 20% of eligible autologous transplant patients cannot have sufficient numbers (qualitatively as well as quantitatively) of stem cells mobilized into the bloodstream to ensure rapid engraftment after high-dose therapy. More importantly, the potential that this proteolytic environment may produce permanent stem cell damage in healthy donors is an issue that needed to be addressed, especially now that unrelated volunteer donors are being mobilized with G-CSF to collect BSC [9]. Gratifyingly, this review shows that this proteolysis does not appear to damage the marrow in a manner that would be detrimental to a healthy donor (e.g., damage to the microenvironment or depletion of stem cells) because Prim-MSC, the very MSC remaining after G-CSF treatment to mobilize and collect BSC, retain their early engraftment potential. The effects of this proteolysis upon the marrow microenvironment remain to be determined.

The literature review examining the engraftment of G-CSF Prim-MSC allows us to achieve a better understanding of the results of early studies about BSC and MSC that, today, seem to be in contradistinction to the prevailing hypothesis that BSC engraft more rapidly than MSC. First, granulocyte recovery after autologous stem cell transplantation was very slow when steady-state BSC (SS-BSC) were employed (median day 22 (11–58)) [7] as compared to when autologous chemotherapy and G-CSF-mobilized BSC were employed (median day 10 (8–52)) [55]. Second, autologous SS-BSC produced apparently slower granulocyte recovery [7] than did allogeneic SS-MSC (median day 14 (10–37)) when methotrexate was not used along with cyclosporine for acute GVHD prophylaxis [55]. And third, in an RCT, there was no acceleration of granulocyte engraftment when autologous SS-BSC were added to autologous SS-MSC as compared to autologous SS-MSC alone (medians 27 vs 20 days) for granulocyte recovery [58]. Data concerning platelet recovery show the same relationships: autologous SS-BSC, median day 23 (14–56); autologous chemotherapy and G-CSF BSC, median day 17 (8–75); and allogeneic SS-MSC,
median day 25 (11–81). Finally, for platelet recovery, autologous SS-BSA combined with autologous SS-MSA did not engraft more rapidly than autologous SS-MSA alone (medians 27 vs 22 days) [58]. Altogether these data suggest that, in terms of engraftment, steady-state BSC have no better engraftment potential than steady-state MSC.

If, as described above, SS-BSA and SS-MSA have equivalent engraftment potential and if, as summarized by this review, Prim-MSA and mobilized BSC have equivalent engraftment potential, then we must develop a new hypothesis about engraftment; to wit, MSC and BSC have equivalent engraftment potential and G-CSF enhances the engraftment potential of both MSC and BSC equally as well. This G-CSF-induced acceleration of engraftment is seen when G-CSF pretreatment is identical before leukapheresis for BSC and before marrow harvest for Prim-MSA.

Autologous transplantation is not the best model system for verifying the validity of this new hypothesis because of the tremendous heterogeneity introduced in the engraftment potential of collected stem cells due to prior chemotherapy and the effects of different transplant preparative regimens upon engraftment [55, 57, 59, 60]. Indeed, at least one group of investigators did not find that G-CSF priming accelerated engraftment of MSC at all [17]. However, this one negative observation cannot outweigh the several positive observations [61]. More importantly, we have previously reported acceleration of engraftment by G-CSF priming of autologous MSC [62] and carried this observation through an RCT, which demonstrated equivalent engraftment for both BSC and Prim-MSA [24]. The argument could be proffered that there are an insufficient number of autologous RCT to support the new hypothesis. The principles of evidence-based medicine hold that RCT (phase II trials) are considered the gold standard in clinical research. However, there are new data that reveal non-RCT (phase II trials) establish biological principles with the same durability of validity as do RCTs [63]. This provides us with an entirely new perspective for examining the published literature.

Allogeneic transplantation is a far better human model because health of donor marrow is not in question as it is in patients with malignancies. In comparative studies, many more allogeneic transplants involving BSC (n = 1949), SS-MSA (n = 3782), and G-CSF Prim-MSA (n = 107) have been reported than autologous transplants involving the same three groups (BSC, 407; SS-MSA, 347; and Prim-MSA, 159). The numbers of Prim-MSA transplants are few but the data are clear. In the global analysis, in the examination of RCT only, and in delta analysis comparisons of all studies, the allogeneic data support the new hypothesis that stem cell engraftment potential is not predetermined by the anatomic site of collection but rather by the effects of G-CSF upon the collected cells.

The new hypothesis we postulate may be confirmed by RCTs in which the following parameters are held constant for all patients in the study: only one age group, a single diagnosis and state of disease (preferably first complete remission for the acute myelogenous leukemia to minimize induction chemotherapy variability), a limited interval between demonstration of remission and transplant, a fixed G-CSF pretreatment regimen, standardized collection of stem cells by leukaphereses and by bone marrow harvest, one transplant preparative regimen, infusion of a specified and equal number of CD34+ cells for both BSC and MSC, a single anti-GVHD immunosuppressive regimen (preferably without methotrexate), and one policy concerning use of G-CSF postgrafting. This is a tall order and, to be accomplished, would likely require a large number of institutions and probably international collaboration. The number of institutions required adds additional variability, but the variability may be manageable by stratification by institution. The likelihood that this will be done in the near future is poor. In the meantime, clinicians need to decide care for their patients with the data at hand. This brings up other observations about outcomes that can be addressed.

Contamination of stem cell collection could be a determinant in choosing the anatomic source of stem cells (BSC vs MSC) for autologous transplantation. But this does not appear to be a major consideration, at least for lymphomas [64]. Healthy donor anxiety and donor choice could be a factor in determining the source of stem cells were there not other important clinical considerations for the patient receiving allogeneic transplantation (vide infra) [65].

For autologous transplantation, relapse rate, overall survival, and disease-free survival are very important clinical outcomes. A recent publication concerning patients with non-Hodgkin's lymphoma (NHL) only, transplanted after a single preparative regimen, showed an overall survival benefit for BSC over SS-MSA but no disease-free survival advantage [14]. Four other RCT, involving germ cell cancer (1), NHL and Hodgkin's disease combined (2), and breast cancer (1), treated by four different high-dose regimens show no disease-free survival advantage for BSC over SS-MSA [16, 23, 24, 26]. Moreover, none of these four RCT shows an overall survival advantage for BSC over SS-MSA. The sentinel article [14] is a perfect demonstration that overall survival is not the best measure of value of a therapy, especially if there are good salvage therapies to prolong life after relapse [53]. As limited as the global analysis may be, there does not appear to be a consistent advantage of BSC over SS-MSA insofar as survival and disease-free survival are concerned. This is all the more meaningful when considering that the median follow-up after autologous transplantation for overall survival was 3.6 years and 2.8 years for disease-free survival.

In allogeneic transplantation, acute and chronic GVHD, in addition to relapse rate, overall survival, and disease-free survival, are very important clinical outcomes. No comparative engraftment study reported so far had primary endpoints of either GVHD, relapse, or survival. Evaluations of secondary endpoints have resulted in reports showing advantage
for SS-MSC over BSC in terms of reduced incidence of chronic GVHD [27,32,54,66]. Our global analysis supports this observation. The mechanism for this effect may be the nearly one log fewer CD34+ cells/kg in SS-MSC compared to BSC and/or vastly fewer regulatory NK-1 cells and/or CD4+ /CD25+ regulatory T cells in BSC compared to SS-MSC, leading to reduction in GVHD potential of marrow T cells [67,68]. Furthermore, pretreatment of the donor with G-CSF may also reduce the potential of Prim-MSC to produce GVHD vis-à-vis SS-MSC [69]. With respect to relapse and survival outcomes, two large RCT suggested that overall survival was improved for recipients of BSC compared to SS-MSC [27,28]. However, looking at all nine of the prospective allogeneic RCT since 1998, there are four (including the two above) that show better overall or disease-free survival results for BSC and five that show equivalence of SS-MSC (n = 2) or better results for SS-MSC (n = 2) or Prim-MSC (n = 1). Moreover, a multicenter RCT comparing CD34+ cells selected from BSC and SS-MSC demonstrated improved survival for patients with hematologic malignancies and myelodysplasia receiving CD34+ cells selected from SS-MSC [70]. Our global analysis reflects this variability in observations by showing no particular overall or disease-free survival for BSC over SS-MSC.

On the one hand, although Prim-MSC appear to have at least equivalent if not better outcomes when compared to BSC, there are too few Prim-MSC patients to draw definitive conclusions at this time. On the other hand, taking all of the observations about GVHD, relapse, and survival together, it would appear that selecting Prim-MSC as the stem cell product may be appropriate because of less chronic GVHD. Less chronic GVHD could mean less graft-vs-malignancy effect, which may translate into poorer overall survival [27,28]. Resolving these issues is why carefully performed studies are required to determine the balance. Increasing the number of patients in the trial we proposed above would improve the power to detect differences in GVHD incidence, relapse rates, and survival outcomes as well.

G-CSF does mobilize stem cells from the marrow, most likely via proteolysis [10–13], but both BSC and the residual MSC (i.e., Prim-MSC) have the same engraftment potential. It appears that BSC collected in the steady state have the same engraftment potential as SS-MSC. Finally, SS-BSC and SS-MSC engraft more slowly than Prim-MSC and BSC. This difference in engraftment kinetics cannot be explained by differences in CD34+ cell doses infused. In fact, Prim-MSC contain on average 30% fewer CD34+ cells/kg than SS-MSC in autologous transplants and only 20% more CD34+ cells in allogeneic transplant. Thus, there must be a “second effect” of G-CSF upon stem cells that enables them to produce more rapid early engraftment.

The “second effect” may very well be, in man as it is in mice, differences in integrin expression between BSC and residual Prim-MSC that were produced by mobilization treatment [71]. Cyclophosphamide and G-CSF induce downregulation of a2 integrin and upregulation of a5 integrin expression in Prim-MSC in mice. BSC bear significantly lower levels than Prim-MSC of several integrins. These differences are associated with a 50% reduction in marrow homing potential of BSC vis-à-vis Prim-MSC in the mouse model. In addition, human BSC grafts contain 50 to 60% more CD34+ cells than G-CSF Prim-MSC. Equal engraftment rates for BSC and Prim-MSC products suggest higher engraftment efficiency for Prim-MSC. Moreover, autologous G-CSF Prim-MSC, collected after failure to mobilize BSC, engrafted rapidly (day +12 for granulocytes and day +13 for platelets) [72]. Finally, the “second effect” may be deciphered from the differential expression of at least 27 genes involved in cell cycle, DNA synthesis, cell-cycle initiation, proapoptosis, and receptors [73].

To conclude, the answer to the original question posed in the abstract of this review is Prim-MSC engraft as rapidly as BSC because of G-CSF treatment before collection. The anatomic site of stem cell acquisition is not the determining factor for pace of engraftment. With the data we have summarized, use of Prim-MSC seems acceptable at the present time. However, we would like to see Prim-MSC studied in direct comparison with BSC.

Progenitor content of autologous grafts: mobilized bone marrow vs mobilized blood

E Dahl, J Burroughs, T DeFor, C Verfaillie and D Weisdorf

Blood and Marrow Transplant Program and the Department of Medicine, University of Minnesota, Minneapolis, MN, USA

Summary:

The progenitor content of autologous peripheral blood progenitor and stem cell collections is a major determinant of prompt hematopoietic recovery following autologous stem cell transplantation. We analyzed unstimulated bone marrow (BM) and peripheral blood (PB) apheresis products in comparison to those collected following G-CSF or GM-CSF stimulation. We quantitated their committed (CFU-GM) and primitive (long-term culture-initiating cells, LTC-IC) progenitors in relation to hematologic recovery in 63 patients undergoing autografting for lymphoid malignancies. G-CSF, but not GM-CSF, substantially enriched the committed progenitor content (2.5-3.6-fold) of both PB and BM grafts. G-CSF also enriched the LTC-IC content of BM and PB compared to control grafts. GM-CSF augmented (11.5-fold) the LTC-IC content of stimulated BM, but not GM-CSF-mobilized PB. Neutrophil recovery was substantially quicker in recipients of BM or PB mobilized with G-CSF or GM-CSF. In contrast, red cell and platelet recovery was accelerated in recipients of GM-CSF-stimulated BM (but not PB) and G-CSF-stimulated PB (but not BM). No direct correlation between progenitor dose and hematopoietic recovery for neutrophils, platelets or red cells was observed. Cytokine stimulation can augment the committed and more primitive multilineage progenitor content of BM and PB grafts, to a differing extent. The uncertain relationship with multilineage myeloid recovery emphasizes the limitations in using clonogenic progenitor analyses to assess the adequacy of an autologous graft prior to transplantation.

doi:10.1038/sj.bmt.1704237
Keywords: hematopoietic progenitors; autologous graft; cytokine mobilization

Cytokine mobilization has been widely used over a decade, most often to collect peripheral blood stem cells (PBSC) as a cellular product used for hematopoietic support during autologous stem cell transplantation. In contrast, cytokine-stimulated bone marrow stem cell (BMSC) autografts are rarely used. We investigated the committed and primitive progenitor content of autologous BMSC and PBSC grafts from patients with malignant non-Hodgkin’s lymphoma (NHL) and Hodgkin’s disease (HD) in order to understand the effects of cytokine stimulation on the BM or PB progenitor content and their relation to post transplant hematologic recovery.

Patients and methods

Patient characteristics

As shown (Table 1), all patients were recipients of autologous hematopoietic stem cell grafts at the University of Minnesota. All but three of the 63 patients were adults and approximately 85% had NHL, with the remaining 15% having HD. A total of 25 patients had unimpaired, unstimulated collections: 15 BM harvest and 10 PBSC apheresis. In all, 38 had cytokine-stimulated collections: 20 with G-CSF and 18 with GM-CSF as described. Patients’ age, gender and primary diagnosis were similar in the six cohorts, those receiving BMSC or PBSC, either control, G-CSF- or GM-CSF-stimulated grafts.

Graft collection and mobilization

BM aspiration harvests were performed under general anesthesia by small volume (5–10 cm³) aspirates from bilateral iliac crest sites to a target collection of 1.5 L. PBSC were collected by continuous flow apheresis using the Baxter–Fenwall CS3000® Plus set up for stem cell collection with a small volume collection chamber. Unstimulated control PBSC were collected in four daily consecutive aphereses processing 10–121 of blood per day. Cytokine mobilization prior to collection used either GM-CSF (250 μg/m²/day) injected subcutaneously round to vial size; for example, 250 μg/day for patients <1.2 m² or 500 μg for patients over 1.2 m²) or G-CSF (250 μg/m²/day rounded to vial size: 300 or 480 μg/day). Stimulated BM harvests were collected on day 6 after 5 days of cytokine. Stimulated PBSC were collected on days 6–9 of daily cytokine therapy. Cytokines used for mobilization were assigned in random fashion. Patients studied represented a
subset of those participating in two trials comparing BMSC to PBSC as control unstimulated or cytokine-mobilized samples.10,11

Transplants were performed as previously reported following preconditioning with cyclophosphamide and total body irradiation (TBI) for patients with NHL or cyclophosphamide, Carmustine and etoposide for HD or for NHL patients ineligible to receive TBI safely.10,11 All previously collected and cryopreserved grafts were infused on day 0 and post transplant all patients received daily G-CSF (5 μg/kg/day rounded to vial size) until neutrophil recovery > 2.5 x 10^9/L for 2 consecutive days. All treatment protocols were reviewed and approved by the University of Minnesota Institutional Review Board and all subjects exercised written informed consent prior to treatment.

**In vitro progenitor culture**

Aliquots of BM harvests or PBSC apheresis collections were cryopreserved in 10% human serum and 10% DMSO using controlled rate-freezing techniques and stored in the liquid phase of liquid nitrogen. The transplants were performed in separate cohorts under different treatment protocols.10,11 All cryopreserved samples were thawed and plated in one series of culture studies using consistent techniques. Aliquots were thawed, washed in sterile media and resuspended in Iscove's modified Dulbecco's medium (IMDM). Committed progenitors (CFU-GM) were cultured in methylcellulose containing IMDM supplemented with 30% fetal calf serum with erythropoietin (EPO, 31U/ml) and 10% supernatant of bladder carcinoma cell line, 5637. After 14 days culture at 37°C in humidified 5% CO2, myeloid colonies (CFU-GM) were counted using an inverted microscope and calculated in relation to the plated cellular inoculum.13 More primitive progenitors, long-term culture-initiating cells (LTC-IC), were determined by plating thawed washed mononuclear cells on irradiated allogeneic BM stroma in IMDM supplemented with 12.5% fetal calf serum, 12.5% horse serum, 2 mmol/l glutamine, 100 U/ml penicillin, 100 U/ml streptomycin and 10^-4 mol/l hydrocortisone. After 5 weeks, all media were removed and overlaid with methylcellulose containing media supplemented with EPO and 5637 supernatant. After 14 additional days of culture, the presence of secondary CFU-GM was scored.12 The progenitor frequency within the BM or PBSC grafts allowed calculation of the graft progenitor content in relation to the nucleated cell dose infused/kg recipient weight. CD34 determinations on the graft aliquots were not routinely performed and not available for analysis.

**Statistical analysis**

Clinical data were collected and monitored by the University of Minnesota Bone Marrow Transplant Database and Biostatistical Support Facility that contains prospectively collected data on all individuals transplanted at our center. Comparative analysis of progenitor content in grafts from different patient cohorts was performed using the general Wilcoxon's test to compare CFU-GM/kg and LTC-IC/kg between groups. For comparisons involving the four collections of PBSC, the mean yield of each patient's PBSC collection was multiplied by four. The ratio of patient group medians was used to estimate the fold increase in progenitors over the unstimulated control groups. Confidence intervals of 95% were then generated around this statistic using bootstrap samples.

Hematopoietic engraftment was defined as the first of three serial post transplant measures of an absolute neutrophil count (ANC) > 5 x 10^9/L, an untransfused platelet count > 20 x 10^9/L and an untransfused hemoglobin > 8.0 g/dl. Correlation analysis of engraftment end points and the progenitor dose infused was performed using Spearman's rank-correlation coefficients. Patients who died before day +42 (n=2) without stable engraftment were excluded when calculating correlation estimates. Survivors beyond day +21 with failure of recovery in 1 or more lineages (n=3) were included in calculations and were assigned the highest rank of time to engraftment. Given that there were numerous comparisons of progenitor content and multilineage recovery, as a correction for
multiple testing, a P-value < 0.01 was used to indicate statistical significance for these clinical correlations. Threshold doses were sought to determine the lowest dose at which the majority of subjects reached hematopoietic recovery at standard times.

Results

Cytokine mobilization of primitive and committed hematopoietic progenitors

Mobilized grafts compared to controls. The progenitor content within the BM and PBSC grafts is shown in Table 2. Cytokine-mobilized BM collections using either G-CSF or GM-CSF contained significantly (11-29-fold) more primitive progenitors (LTC-IC/kg) than resting BM harvests (Table 2b, P = 0.05). Somewhat greater LTC-IC content of G-CSF-stimulated BM was apparent compared to GM-CSF-stimulated BM (P = 0.07). Analysis of the committed progenitor content of BM grafts showed that G-CSF, but not GM-CSF pretreatment, led to significant, 2.5-fold augmentation of the committed progenitor content (CFU-GM/kg) over control, unstimulated BM grafts.

Cytokine stimulation augmented the progenitor content of the PBSC grafts to a lesser extent than that observed in BM. PB grafts mobilized with G-CSF contained 3.6-fold more CFU-GM/kg and 2.6-fold more LTC-IC/kg compared to unstimulated PBSC. In contrast, GM-CSF-mobilized PBSC contained only 0.9-fold more CFU-GM/kg and 1.2-fold more LTC-IC/kg than control PB grafts.

G-CSF stimulated the CFU-GM content of both BM and PBSC grafts to a similar extent. As shown in Table 2, G-CSF-stimulated BM contained a median 2.5-fold increased content of CFU-GM over control BM, while G-CSF-stimulated PB had a 3.6-fold increase over control PBSC. However, G-CSF led to a 28.7-fold median increase in BM LTC-IC/kg, although only a small and nonsignificant increment in PBSC LTC-IC. In contrast, GM-CSF significantly enhanced the LTC-IC content (11.5-fold) over control BM, but did not increase the CFU-GM content of BM (1.1-fold).

PBSC grafts compared to BM. PBSC grafts contained a mean of 1.87-fold more nucleated cells/graft compared to BMSC. As shown in Table 2a, unstimulated PBSC grafts contained 12.8-fold more LTC-IC/kg than control BM grafts, while those primed with G-CSF and GM-CSF contained only 1.17- to 1.35-fold more LTC-IC/kg than BM grafts, respectively. The committed progenitor contents of PBSC and BMSC grafts were similar. PBSC contained 1.06-, 1.51- and 0.85-fold more CFU-GM/kg than BM grafts in control, G-CSF and GM-CSF primed grafts, respectively.

Hematologic recovery using cytokine-mobilized grafts

In serial patient cohorts, autotransplantation was performed using control grafts and using grafts collected after cytokine priming of BM and PB using either G-CSF or GM-CSF. Transplantation was followed by neutrophil engraftment (ANC > 5 x 10^9/L) at a median of 13-16 days in the cytokine-mobilized cohorts compared to a median of 22 days in those receiving unstimulated BM or PB grafts (Table 3). Lister, more variable recovery of platelet and RBC production was observed. As shown, GM-CSF stimulation prior to BM harvests led to platelet and RBC engraftment at a median of 18 and 14 days, respectively, compared to a median of 25 and 20 days in the unstimulated BM controls. G-CSF stimulation of BM grafts yielded platelet and RBC recovery at a median of 27 days.

Transplantation using PBSC led to faster hematologic recovery. Grafts with G-CSF-mobilized PBSC were followed by engraftment of platelets and RBC at a median of 13 and 14 days, respectively. GM-CSF-mobilized PBSC did

Bone Marrow Transplantation
not lead to accelerated hemophagocytosis with time to platelet recovery at median day 42 and RBC day 38, similar to control PBSC transplant platelet and RBC recovery at 38 and 27 days, respectively. Thus, G-CSF or GM-CSF mobilization of either BM or PB was associated with rapid neutrophil recovery. In contrast, GM-CSF, but not G-CSF stimulation of BM grafts led to somewhat more rapid platelet and RBC recovery. G-CSF, but not GM-CSF, mobilization of PB grafts accelerated both platelet and RBC recovery.

**Graft progenitor content in relation to multilineage engraftment**

We analyzed the infused dose of primitive and committed progenitors as potential predictors of the speed of post transplant engraftment. As shown in Table 4, we observed no direct correlation between the infused progenitor dose (CFU/kg) and the speed of hematopoietic reconstitution of neutrophils, RBCs or platelets. No such correlation was observed in either G-CSF- or GM-CSF-stimulated BM or PBSC. Similarly, the infused dose of LTC-IC/kg did not correlate with the speed of multilineage engraftment following either GM-CSF- or G-CSF-stimulated BM or PBSC transplantation.

We also sought evidence for a threshold progenitor dose, above which prompt myeloid engraftment was assured. Disappointingly, we found no such threshold (data not shown). We also investigated a possible relationship between a minimum infused progenitor dose and subsequent delayed platelet or RBC recovery, but again found no such correlation.

**Discussion**

G-CSF and GM-CSF have a distinct functional impact on both the proliferation and translocation of primitive and committed progenitors into the blood and marrow. While either cytokine may accelerate hematopoietic recovery after myelosuppressive therapy or stem cell transplantation, their comparative effect on the progenitor content of the autologous hematopoietic grafts is less certain. In this study, we compared both cytokine-stimulated and control grafts collected from BM and PB. We observed that cytokine stimulation using either G-CSF or GM-CSF was more successful at mobilizing or expanding the number of more primitive stem cells (LTC-IC) in BM, but not in PB. Whereas G-CSF and GM-CSF have been shown to enhance the cell cycling fraction of CFU-GM in BM, there has been only limited study of cytokine mobilization techniques on LTC-IC expansion in BM-derived LTC-IC compared to those found in cytokine-stimulated PB.17

Our observation that cytokine stimulation produced more LTC-IC in BM compared to PB may suggest an intrinsic difference in LTC-IC subsets and their response to cytokines depending on location.13 In BM progenitors, expansion without translocation is necessary, while in PB, expansion must be accompanied by translocation through altered adhesive interaction with BM stroma. In BM, G-CSF pretreatment was more effective than GM-CSF in augmenting the final BM graft content of LTC-IC. G-CSF was more effective than GM-CSF in mobilization of progenitors into PBSC, but for this compartment, CFU-GM were most effectively mobilized. Previous study by Ho

The Spearman rank-correlation coefficients (P-value) between progenitor dose infused/kg (CFU-GM and LTC-IC) and lineage-specific hematologic recovery following autotransplantation are shown. NE = not evaluable (n < 5).
et al. showed G-CSF stimulation to be more effective than GM-CSF at mobilizing CFU-GM into PB. It is interesting that G-CSF increases the mobilization of more primitive progenitors into BM, but yields more committed progenitors in PB.

More rapid recovery of hematopoiesis can reduce mortality as well as the morbidity and cost of autologous transplantation. Current practice in graft evaluation to predict post transplant hematopoietic recovery is contingent on a sufficient CD34+ transplant dose, where a dose of $\geq 5 \times 10^8$ CD34+ cells/kg delivers consistently rapid hematopoietic recovery. Previous studies have shown that using PB autografts containing $\geq 5 \times 10^8$ CD34+ cells, neutrophil and platelet recovery within 9–12 days can be expected.

We observed modest differences in time to engraftment when comparing grafts mobilized with either G-CSF or GM-CSF. Transplants using GM-CSF-stimulated BM and G-CSF-stimulated PB showing earlier engraftment are compatible with the hypothesis, suggesting enrichment of marrow progenitors by GM-CSF and increased translocation of progenitors by G-CSF. Combination studies of cytokines along with inhibitors of progenitor adhesion could enhance this engraftment even further, although most such investigations have focused on preclinical models.

We investigated a relationship between either CFU-GM or LTC-IC dose as more accurate predictors of the time to engraftment. Although we observed that G-CSF and GM-CSF have differing capacity for LTC-IC and CFU-GM enhancement in BM or PB, the progenitor dose infused did not correlate with time to hematopoietic reconstitution. In fact, correlation coefficients across all groups did not suggest any trend supporting a biologic association with the engraftment end points. It is acknowledged that limited sample size and possible heterogeneity in prior chemotherapy and other clinical factors may limit the power of our analysis.

Sutherland et al. also found no correlation between the number of LTC-IC in PB with hematopoietic reconstitution. Previous studies have suggested a strong correlation between CFU-GM dose and hematopoietic reconstitution, although we observed neither a direct correlation nor a threshold dose of LTC-IC or CFU-GM predictive of hematopoietic reconstitution. Unavailability of CD34 graft content also compromised our study. Recently, Hogge et al. reported that 90% of patients became platelet transfusion independent by 28 days posttransplant if their grafts contained either $\geq 2 \times 10^8$ CD34+ cells/kg, $\geq 5 \times 10^5$ total colony-forming cells (CFCs)/kg, or $\geq 1000$ CFC in 5-week LTC-IC/kg. Quantitation of phenotypic (CD34+, CD34+ 38-) or clonogenic (cobblestone area-forming cells) progenitors can possibly define an inadequate graft, especially after intensive prior alkylator-based chemotherapy. Further study will be required for more reliable assessments of the quality of hematopoietic cells within a cryopreserved autograft. Recent interest in cytokine-stimulated BM allografts as well as widespread application of G-CSF-mobilized PB allografts further suggests the need for careful quantitative, as well as qualitative characterization of graft content.

INTRODUCTION

Although hematopoietic cell transplantation (HCT) has the potential to cure high-risk hematologic and nonhematologic disorders, it is a complex, resource-intensive, and costly procedure. Costs of transplantation can include charges for delivery of care (eg, physician charges), supportive care (eg, blood product transfusions), graft procurement, hospitalization, pharmacy, and laboratory and radiologic investigations. Also, despite major advances in transplant techniques and supportive care practices, HCT continues to be associated with substantial treatment-related mortality (TRM) such as infections, organ failure, and graft-versus-host disease (GVHD), and management of these complications can further increase the overall cost of posttransplant care. Studies of transplantation costs are complex and difficult to conduct because of the wide variation in transplant methods, conditioning, and GVHD prophylaxis regimens and supportive care practices. However, studies have described costs of allogeneic HCT using either myeloablative or nonmyeloablative conditioning regimens, and show that HCT in general is an
expensive procedure, and occurrence of complications after transplantation increases overall medical costs [1-10].

Introduction of unrelated umbilical cord blood (UCB) as an alternative graft source for patients without a matched related donor (MRD) is among the most significant recent breakthroughs in the field of transplantation. UCB has the advantages of rapid availability, and may be associated with lower risks of GVHD, despite the use of units with higher HLA disparity [11,12]. Our group has described the use of UCB HCT in adults, especially using 2 UCB units to optimize cell dose with outcomes comparable to that seen with other donor sources [13-15]. However, use of UCB is associated with delayed engraftment and a higher risk of graft failure. Incremental experience is rapidly leading to adoption of UCB as an alternative donor source by many transplant centers. A better understanding of the costs of UCB HCT is of importance from the health care resource utilization and health policy perspective, and can also assist in comparison of cost-effectiveness of UCB with other alternative (eg, matched unrelated donor and haploidentical) donor sources. Identification of specific factors that may be predictive for UCB transplant costs can help with the development of strategies to reduce costs while maintaining outcomes with a resultant increase in the applicability of UCB HCT.

We conducted a retrospective cohort study in a contemporary group of adult HCT recipients to evaluate the costs of myeloablative and nonmyeloablative UCB HCT, and to compare them with the costs of myeloablative and nonmyeloablative MRD HCT. We also explored various risk factors for their association with increased costs of HCT.

PATIENTS AND METHODS

Patients

The study cohort consisted of consecutive patients who received an allogeneic HCT between 2004 and 2006, and were ≥18 years of age at the time of transplantation. From the 318 eligible patients, 24 were excluded: recipients of planned autologous HCT followed by nonmyeloablative allogeneic sibling donor HCT for multiple myeloma (MM; N = 12), and recipients of matched unrelated donor grafts (N = 12). Hence, the final study cohort consisted of 294 patients. Transplant-related and outcome data were retrieved from the University of Minnesota Blood and Marrow Transplant Program Database, which prospectively collects these data on all patients transplanted at our institution. Additional data for this study were abstracted from patient medical records. Patients were treated on clinical protocols approved by our institutional review board.

Conditioning regimen intensity (myeloablative [MA] versus nonmyeloablative [NMA]) was prospectively determined by transplant protocols. Specific indications for HCT using NMA conditioning were older age (≥55 years for MRD and ≥45 years for UCB), presence of significant comorbidity (serious organ dysfunction, invasive mold infection within 3 months before transplantation or Karnofsky performance score of 50-60), or previous extensive prior therapy (>12 months of alkylator-based chemotherapy, >6 months of alkylator-based chemotherapy and extensive radiation, or history of autologous transplantation). Patients received UCB as a graft source if they had no HLA-compatible related donors. Our UCB selection criteria for adults have been previously published and allow the use of 2 UCB units to optimize cell dose, if necessary [12].

Patients were classified as having standard or high risk disease. Standard risk disease included acute leukemia in first complete remission (CR1), chronic myelogenous leukemia (CML) in first chronic phase, myelodysplastic syndrome (MDS) (refractory anemia only), and nonmalignant hematologic disorders; all other diagnoses were categorized as high-risk disease.

Conditioning Regimen and Supportive Care

MA and NMA regimens used at our institution have been described previously [13,14,16]. Briefly, patients undergoing MA MRD HCT received a regimen consisting of total-body irradiation (TBI) and cyclophosphamide (Cy), whereas recipients of MA UCB HCT received TBI, Cy, and fludarabine (Flu). NMA regimens for both MRD and UCB recipients consisted of TBI, Cy, and Flu. The TBI dose in MA regimens was 1320 cGy (165 cGy twice daily × 4 days) and in NMA regimens was 200 cGy (single fraction). Our GVHD prophylaxis and treatment regimens have also been described previously [17]. All patients received GVHD prophylaxis with cyclosporine (CaA; days −3 to at least +100), with trough levels maintained between 200 and 400 ng/mL and either methotrexate (MTX; in MA MRD recipients) or mycophenolate mofetil (MMF; in MA and NMA UCB and NMA MRD recipients; days −3 to at least +30).

Outpatient clinical evaluation to determine eligibility for transplantation was performed within 30 days prior to transplantation for all patients, and included history and physical examination, bone marrow biopsy and aspirate evaluation, assessment of organ function, determination of infectious markers, and appropriate radiologic imaging or other investigations for disease staging. Allogeneic HCT recipients were then admitted to the inpatient unit for initiating conditioning therapy and were discharged from the hospital after they had engrafted (absolute neutrophil count
[ANC] > 0.5 x 10^9/L for 3 days), had adequate oral intake, had transfusion or other infusion requirements that could be met as an outpatient, and had no complications requiring continued hospitalization. Frequency of outpatient follow-up was based on patient overall clinical condition and need for ongoing support (eg, transfusions, antibiotic infusions). All apheresis procedures for MRD peripheral blood stem cell (PBSC) collection were performed as an outpatient. All patients received antibacterial, antiviral, and antifungal prophylaxis and blood product and nutritional support per institutional guidelines. Granulocyte-colony stimulating factor (G-CSF) was administered to all patients until the ANC was >2.5 x 10^9/L for 2 days.

All patients are followed within our transplant program and institution from the time of pretransplant evaluation until at least 100 days posttransplant. Patients are required to stay within a 30-min driving distance from our transplant center, and accommodation is arranged for patients who do not live locally. All hospitalizations within the first 100 days are exclusively in a dedicated inpatient transplant unit that has resources for management of severe post-HCT complications (eg, mechanical ventilation, dialysis, pressor support). All outpatient visits within the first 100 days occur in our transplant clinic, which has infusion chairs and resources for performing minor procedures. Hence, our institutional accounting department captures all relevant medical costs for the first 100 days except costs for outpatient prescription drugs, including drugs administered through home-care services. Transplant-related care in this early posttransplant period was coordinated by our group of transplant physicians and midlevel providers who periodically rotate through both the inpatient and outpatient services and take care of all HCT recipients irrespective of their underlying diagnosis or transplant type. Therefore, individual provider practice variation did not have a major influence on costs within specific transplant types in our analysis.

Cost Data

Data regarding inpatient costs, days of hospitalization, and number of outpatient clinic visits were obtained from the institutional accounting department for all transplant-related costs prior to day 0 (from day -30) and until day 100 posttransplantation. Costs were determined by each hospital department's item and procedure specific costs and then summed from the itemized listing of each patient's hospital accounting record through day 100. Besides total cost of care (direct and indirect costs), specific categories of costs were also available. These categories included costs for "graft acquisition," "laboratory services," "radiologic investigations," "pharmacy services," "room and board," "blood components," and "other services." Examples of "other service" costs include costs for occupational therapy, physical therapy, and vascular access and operating room costs. We excluded costs for "physician services." Also, we could not account for outpatient prescription drug costs and did not include patient related nonmedical costs (eg, out-of-pocket costs, transportation, and accommodation) in our analysis.

Costs for "graft acquisition" consisted of costs for donor evaluation, apheresis procedure, and graft processing and storage for MRD HCT. For UCB recipients, this category included costs for searching the cord blood bank inventory, confirmatory HLA-typing of the cord blood unit, and shipping of the product. Median graft acquisition costs were $9566 for MRD and $68,830 for UCB transplantation. Although patients receiving matched unrelated donor HCT were excluded from this study, their median graft acquisition costs were $55,121. We excluded costs for graft acquisition from further cost analyses, as we wanted to specifically focus on the impact of posttransplant events on total costs. However, graft acquisition costs for a second graft infusion for graft failure or donor lymphocyte infusion for relapse within the first 100 days were included in cost analyses and were combined with the "other" category.

Because our data consisted of the actual dollar amount for cost incurred and given the relatively contemporary nature of our cohort, we did not adjust for inflation in our cost analyses.

Statistical Methods

The primary endpoint of this study was to compare medical costs among recipients of MA and NMA MRD and UCB transplantation. We also wanted to explore factors that were associated with increased costs of transplantation. To simplify comparison among different transplant categories, especially because of the variation in patient selection, risks for transplant-related complications and overall outcomes, costs are presented as cost per-day survived (in dollars).

Data are described as proportions or as median with range or interquartile range (lowest quartile-highest quartile). Comparison of patient, disease, and transplant characteristics was performed using chi-square, Fisher's exact, or Wilcoxon's rank sum test as appropriate. Cumulative incidence of engraftment, TRM, and GVHD was calculated by treating deaths from other causes as competing risks. The Kaplan-Meier method was used to plot curves for overall survival (OS). Multivariate Cox regression analysis was performed for OS after including the following variables: transplant type (main effect variable), age at HCT, sex, Karnofsky performance status at HCT, disease risk, previous HCT, cytomegalovirus (CMV)
status, HLA-match, acute GVHD (aGVHD) (grade iii-iv), graft failure, dialysis, mechanical ventilation, and hepatic veno-occlusive disease (VOD). Event times were measured from date of transplantation to date of death or last contact.

Analysis of variance (ANOVA) method was used to compare costs among different transplant types and was adjusted for the following variables: age at HCT, Karnofsky performance status at HCT, disease risk, previous HCT, CMV status, aGVHD (grade iii-iv), graft failure, dialysis, mechanical ventilation, hepatic VOD, duration of hospital stay (days of initial and any subsequent hospitalizations), and number of total medical encounters (days of hospitalization and outpatient clinic visits). HLA-match status correlated with transplant type and was not included as a separate variable. There were no significant interactions between transplant type and other predictor variables included in the ANOVA models.

All P-values reported are 2 sided. Analyses were performed using the SAS 9.1 software (Cary, NC).

RESULTS

Patient and Transplant Characteristics

Patient, disease, and transplant characteristics of our cohort are described in Table 1. As expected, recipients of NMA conditioning were older than those who received MA conditioning. The majority of patients who underwent UCB HCT (95%) received 2 cord blood units to optimize cell dose. MRD recipients were more likely to receive a 6/6 HLA matched graft (93% versus 9% for UCB). UCB recipients had slower neutrophil and platelet engraftment, had higher incidence of graft failure, and were more likely to have longer hospital stay compared to MRD recipients. The rates of major complications (dialysis, mechanical ventilation, or hepatic VOD) were similar among all types of allogeneic HCT.

Patient Survival and Outcomes

Probability of OS and cumulative incidences of TRM and aGVHD (grade iii-iv) in the first 100 days posttransplant were comparable among the 4 types of allogeneic HCT (Table 2). Transplant type was not predictive for OS on multivariate analysis (Table 3). Factors independently associated with increased risk of overall mortality included graft failure (relative risk [RR] 3.6, 95% confidence intervals [CI] 2.2-5.9), need for dialysis (RR 2.1, 95% CI 1.4-3.3), and need for mechanical ventilation (RR 4.4, 95% CI 3.1-6.2).

Costs of Transplantation

The median total cost of transplantation (excluding graft acquisition costs) within the first 100 days was $137,112 (interquartile range [IQR], 97,658-225,430) for MA and $84,824 (IQR, 52,247-151,906) for NMA allogeneic HCT, respectively (P < .001). The median total cost for UCB HCT was $137,564 (IQR, $81,486-$256,451) compared with $83,583 (IQR, $60,783-$123,581) for MRD HCT (P < .001). UCB HCT using either MA or NMA conditioning was associated with significantly higher costs than MRD HCT (Table 4). The median cost per day survived was $1,016 for MA and $612 for NMA MRD HCT and was $2082 for MA and $1156 for NMA UCB HCT (P < .001). For purposes of comparison, the median cost per day survived for matched unrelated donor HCT was $1586 for MA and $650 for NMA conditioning; however, these patients were excluded from further analyses because of small patient numbers.

The categories of cost for different transplant types are summarized in Figure 1. In general, the major contributors of cost for all transplant types were room and board and pharmacy services. MA and NMA UCB HCT recipients had longer hospitalizations, and as a result, had higher costs for room and board compared to recipients of MRD HCT. Pharmacy and laboratory services are more likely to be utilized during inpatient stay, and, hence, costs for these services were higher following UCB HCT. Because UCB transplant recipients also had a longer time to platelet engraftment, it was associated with higher blood component costs.

The contribution of various cost categories to total costs did not differ significantly among patients with low, intermediate, or high costs of care (Figure 2). However, the contribution of costs for blood components was relatively higher among patients whose care was the most expensive (total cost per day survived in the highest tertile, >$1805) compared with those with the least total costs (total cost per day survived in the lowest tertile, <$830).

Predictors of Cost

In multivariate analysis that adjusted for various factors that could influence costs (Table 5), MA UCB HCT was associated with higher costs than MA MRD HCT, but this difference was marginally significant (RR 1.3, 95% CI 1.1-1.5, P = .05). Interestingly, the costs of NMA MRD and NMA UCB HCT were similar to those of MA MRD HCT. More important predictors of costs were graft failure, need for dialysis, need for mechanical ventilation, and very long hospital stay. This is summarized in Table 6 and Figure 3, which highlights that patients with total costs in the highest tertile had a higher proportion of these risk factors compared to those with costs in the middle or lowest tertiles.

The median total cost per day survived for 23 patients with graft failure (MRD = 2, UCB = 21) was

MRD indicates matched related donor; UCB, umbilical cord blood; MA, myeloablative; NMA, nonmyeloablative; KPS, Karnofsky performance status; CMV, cytomegalovirus; HLA, human leukocyte antigen; ANC, absolute neutrophil count.

*Worst match for recipients of double UCB transplant.

$6976 (IQR, 5074-8698). In comparison, the median cost per day survived for patients who did not experience graft failure was $1105 (IQR, 679-2149) (P < .001). UCB HCT was associated with higher total costs even after patients with graft failure were excluded; median cost per day survived for MA and NMA MRD HCT recipients was $1005 and $612, whereas that for UCB HCT recipients was $1703 and $1115, respectively (P < .001).

Patients who received dialysis had a median total cost per day survived of $4764 (IQR, 1194-6976) compared to $1102 (IQR, 678-2209) among those who
did not receive dialysis (P < .001). Similarly, patients who received and did not receive mechanical ventilation had total cost per day survived of $5099 (IQR, 1287-7570) and $977 (IQR, 614-1508), respectively (P < .001).

**DISCUSSION**

In our contemporary cohort of adult HCT recipients, we observed the absolute costs of MA and NMA UCB transplantation to be higher than MA and NMA MRD transplantation. However, the costs of transplantation were primarily driven by severe posttransplant complications (graft failure, dialysis, and mechanical ventilation) and prolonged inpatient stay. UCB recipients have longer time to neutrophil and platelet engraftment than MRD recipients. Because 1 of the main endpoints for hospital discharge is engraftment, it is not surprising that UCB recipients had longer inpatient stay with its associated costs (room and board, pharmacy services, laboratory services, and blood components). Also, graft failure was more common following UCB HCT. Graft failure does increase the duration of hospitalization, and prolonged pancytopenia can increase the risk of infectious complications and transfusion requirements with a resultant increase in costs. The cost of a second graft infusion, especially UCB, also adds to this expense. Because the rates of severe complications (excluding graft failure) were similar among the 4 groups, the cost differences between MRD and UCB are more likely a result of prolonged hospitalization because of delayed engraftment and graft failure rather than complications. Our study did not address long-term costs of UCB transplantation. There is emerging data that UCB HCT is associated with a lower risk of chronic GVHD (cGVHD) [14,17]. Whether this would translate to lower or comparable costs versus MRD or matched unrelated donor HCT over an extended period of time needs to be investigated.

The use of less intense NMA conditioning does not necessarily translate to lower costs. In our study, the cumulative incidence of TRM was similar between all allogeneic transplant types, regardless of donor source or conditioning regimen intensity. Also, there was no difference in the rates of severe aGVHD, dialysis, mechanical ventilation, or hepatic VOD. Therefore, the older age and/or poor health status of NMA HCT recipients may offset the lesser toxicity of a reduced-intensity conditioning (RIC) regimen. We observed similar costs for MA and NMA MRD HCT. The occurrence of severe complications was a more important

driver of costs than conditioning regimen intensity. Other investigators have recently conducted cost analyses comparing MA and NMA HCT. Saito et al. [8] included 90 NMA and 185 MA HCT recipients transplanted between 2000 and 2003 in their retrospective analysis. They showed that NMA HCT costs approximately $33,030 less, and was associated with 16 fewer days of hospitalization than myeloablative HCT within the first year after transplantation. In another study, Cordonnier et al. [2] evaluated the 1-year costs of transplantation in 11 NMA and 12 MA HCT recipients with acute myelogenous leukemia (AML) who were enrolled on a prospective trial between 1998 and 2003. There was a trend toward lower costs of transplantation in the first 6 months for NMA conditioning, but the costs from 6-12 months were higher because of late complications and readmissions and there was no difference in the costs of NMA and

Graft source and HLA match correlated with transplant type and were not included in the models as separate variables.
†Excluding costs of graft acquisition.
‡Total hospital stay in first 100 days posttransplantation.

MA HCT at 1 year posttransplantation. Differences in patient population and transplant techniques (eg, conditioning regimens) could explain the discrepant results from our and these 2 published studies. Some observational studies have shown equivalent long-term survival among patients receiving MA and NMA HCT for selected diseases [16,18,19]. With similar outcomes, the transplant modality with lesser costs and lesser morbidity would be preferred. Hence, more studies to better understand cost differences between MA and NMA conditioning regimens are needed and any randomized trials comparing these 2 modalities should include economic and quality of life endpoints.

The role of complications in increasing costs of transplantation has been described previously. In a study of 315 MA allogeneic HCT recipients transplanted between 2000 and 2004, [7], showed that the mean cost of transplantation in their cohort was $779,222, but severe complications increased total costs by an average of $20,228. [5], have also shown that complications are associated with higher costs. Their study included 181 patients who received a n MA allogeneic HCT between 1994 and 1997; the median initial inpatient cost was $105,300 and occurrence of infection, hepatic VOD, aGVHD, and death were predicted to add between $15,300 and $28,100 each to the costs of transplantation. Prevention and early recognition and management of complications, where possible, can decrease the costs of transplantation. Esperou et al. [3], in a study of 85 MA allogeneic HCT recipients from 1998-2000, have also shown that predictors of higher costs (adding an average $20,000/patient) include transplant related complications, GVHD, and repeated infections.

Several limitations have to be considered in the interpretation of our analysis. There exists considerable practice variation in HCT among transplant centers, and our results may not be generalizable. Also, we captured costs within the first 100 days following transplantation and did not consider costs of long-term care or management of cGVHD and its complications. Other studies have shown that the costs of transplantation are largely concentrated within the first 100 days [7].

We selected the early posttransplant period for investigation because all medical care is conducted exclusively at our center. Nevertheless, we could not account for costs of outpatient prescription drugs and home-care services. Transplant conditioning and GVHD prophylaxis and management regimens were dictated by specific protocols, and supportive care was based on established guidelines, limiting the impact of practice variation on costs.

We excluded costs of graft acquisition in cost analyses because the characteristics of graft procurement, storage, and processing are very different for MRD and UCB. Given the resources needed for UCB collection and storage, UCB graft acquisition is much more expensive than MRD. The contribution of graft
acquisition costs to total costs cannot be ignored, especially because of its large dollar amount, and any strategies to increase the cost effectiveness of UCB HCT will also have to address these costs.

Because of the relatively small number of patients who received a matched unrelated donor HCT, we could not perform detailed analyses comparing costs between matched unrelated donor and UCB transplantation. Because UCB is primarily considered among various alternative donor options for patients without an MRD, future cost analyses comparing matched unrelated donor and UCB HCT will be important. In our unadjusted descriptive analysis, transplantation with matched unrelated donor was more expensive than MRD but less expensive than UCB for both MA and NMA conditioning regimens.

In conclusion, allogeneic HCT is a costly procedure. In the first 100 days after transplantation, the costs of MA and NMA MRD and nonmyeloablative UCB transplantation are similar, whereas MA UCB HCT is more expensive. Severe complications, graft failure, and prolonged hospitalization are the major contributors to total costs in the early posttransplant period. Increased costs of UCB HCT are primarily because of longer hospitalization for delayed engraftment and graft failure. Strategies to decrease the risk of severe complications would reduce the overall costs of transplantation in general. Methods to enhance engraftment and decrease the risk of graft failure in recipients of UCB HCT would make this procedure more cost effective.

Unrelated donor umbilical cord blood transplantation for the treatment of hematologic malignancies
Craig Sauter and Juliet N. Barker

Introduction
Allogeneic hematopoietic stem cell transplantation (HSCT) is indicated for the treatment of many high-risk hematologic malignancies. Unfortunately, application of this treatment is limited by a lack of suitable donors. Only 25% of patients have a HLA-matched sibling donor suitable for HSC donation and despite the many millions of volunteer donors registered in the unrelated donor (URD) pool, many patients do not have an adequately human leukocyte antigen (HLA)-matched URD using high-resolution donor–recipient HLA matching especially patients from racial and ethnic minorities [1]. Additionally, the procurement of an URD graft can often take months, whereas patients with hematologic malignancies frequently require urgent transplantation.

Umbilical cord blood (UCB) can reconstitute hematopoietic stem cells in adults following both myeloablative [2–8] and reduced-intensity/nonmyeloablative (NMA) [9,10,11] conditioning and has the advantage of ready availability. Importantly, in marked contrast to the transplantation of URD HSC [12], the reduced stringency of the required HLA match with UCBT translates to the potential to extend allogeneic HSCT access to patients without other suitable donors (Table 1). This factor alone, along with multiple other attributes, frequently outweighs the disadvantages of UCBT as compared with URD HSCT (summarized in Table 2), thus accounting for the rapid expansion of use of this relatively new HSC source (Fig. 1). This review will outline the current status of UCBT as compared with URD HSC transplantation as well as discussing current issues associated with the transplantation of this HSC source.

Outcome of umbilical cord blood transplantation compared with unrelated donor bone marrow transplantation
Although no randomized controlled trials have compared UCBT and URD transplantation, retrospective studies have compared single-unit UCBT with URD bone marrow transplantation (BMT) using myeloablative conditioning in adults and children. In 2004, Laughlin et al. [5] and Rocha et al. [6] reported the first comparisons between UCBT and URD transplantation in adults. The

Patients were offered UCBT if allogeneic transplant was indicated and no suitably HLA-matched-related or unrelated volunteer donor was available. Notably, 60% of patients were of non-North Western European ancestry with 50% of patients being non-European. In addition, the four patients of North-Western European ancestry had proven or potential 9/10 or 10/10 HLA-A, B, C, DRB1, DQ allele-matched-unrelated volunteer donors but received UCB due to transplant urgency (n = 1) or patient preference (n = 3). UCBT grafts were 4/6 HLA-matched at A and B antigens and DRB1 alleles. HLA, human leucocyte antigen; UCBT, umbilical cord blood transplantation.

American series found comparable survival after UCBT (n = 150) and one antigen-mismatched BMT (n = 83) [5], whereas the European reported that HLA-mismatched adult UCBT (n = 98) was associated with comparable survival to 6/6 HLA antigen-matched BMT (n = 584) [6]. In contrast, a Japanese series reported by Takahashi et al. [7] demonstrated superior transplant-related mortality (TRM) and disease-free survival (DFS) in 68 adult UCBT as compared with 45 URD BMT recipients.

More recently, Eapen et al. [13**] have analyzed the outcomes of 503 UCBT recipients of 4/6 HLA-A, B antigen and DRB1 allele-matched single-unit UCBT as compared with those of URD BMT in children below 16 years of age with leukemia. Most notably, in a subset analysis comparing UCBT outcomes with the 116 recipients of the ‘gold standard’ of 8/8 HLA allele-matched bone marrow, the 35/6/6 HLA-matched UCBT recipients had significantly higher 5-year DFS, with 201/5/6 and 267 4/6 UCBT having comparable DFS with that of 8/8 allele-matched BMT recipients and demonstrated a robust protection against relapse (Table 3).

These findings support UCBT as an alternative to URD BMT in children. Further, if engraftment after UCBT is improved, it suggests that pediatric UCBT may be a superior HSC for the treatment of leukemia. In adults, the American and European comparisons, although establishing UCBT as a potential alternative to URD BMT, have highlighted that the poor engraftment and high TRM must be addressed for this HSC to be widely adopted. At the current time, whether UCBT will be offered to a patient will be frequently determined by the relative availability of a closely HLA-matched (7–8/8 alleles) URD versus an UCBT graft of at least 4/6 HLA-A, B antigen and DRB1 allele match and adequate dose; and the experience and research bias of the transplant center.

GVHD, graft-versus-host disease; HLA, human leucocyte antigen; UCB, umbilical cord blood; URD, unrelated donor.

*Not yet examined for acute GVHD.
needed for adult UCBT recipients this approach is equally as relevant to many children given graft failure is still a devastating feature of many pediatric UCBT series and many larger children will only have access to units of relatively low cell doses that similarly challenge adult UCBT recipients.

Initial investigation with double-unit UCBT following a total-body irradiation (TBI)-based myeloablative conditioning regimen yielded a DFS of 57% [95% confidence interval (CI) 35–79] in 23 leukemia patients (median age 24 years), with a DFS of 72% if transplanted in remission [19]. Updated survival data after myeloablative double-unit UCBT in high-risk hematologic malignancies is shown in Fig. 2. Interestingly, both engraftment and survival was improved after double-unit UCBT as compared with historical single-unit controls [4] despite only one of two relatively low cell dose units being responsible for sustained donor engraftment in the vast majority of patients. This raises the possibility that the ‘losing’ unit is somehow facilitating the engraftment of the engrafting or ‘winning’ unit. However, it is important to note that the single-unit historical controls were transplanted using cyclophosphamide and TBI with antithymocyte globulin (ATG) and cyclosporine-A (CSA)/methylprednisolone as immunosuppression. In contrast, though the double-unit transplants were also performed with cyclophosphamide/TBI and CSA, the ATG and MP were substituted with low-dose fludarabine (Flu) and mycophenolate mofetil (MMF). This raises the possibility that some of the advantage of double-unit UCBT was due to changes in the preparative regimen and immune suppression independent of the graft. This question is therefore being investigated in the Bone Marrow Transplant Clinical Trials Network (BMT CTN) single versus double-unit randomized trial in children in the United States utilizing the cyclophosphamide/Flu/TBI and CSA/MMF regimen. Importantly, however, this study may not fully answer the question of the utility of double-unit UCBT in adults. A major question for the field currently is how double-unit UCBT compares with URD peripheral blood stem cell (PBSC) transplantation in adult patients and should be studied in the near future.

Survival data are reported at 5 years after transplant. DFS, disease-free survival; HSC, hematopoietic stem cell; TRM, transplant-related mortality; UCB, umbilical cord blood.
Figure 2 Survival after myeloablative double-unit umbilical cord blood transplantation (n = 83)

Patients were conditioned with cyclophosphamide 120 mg/kg, TBI 1320 cGy, fludarabine 75 mg/m² with CSA/MMF, CI confidence interval; CSF, cyclosporine-A; DFS, disease-free survival; MMF, mycophenolate mofetil; TBI, total-body irradiation. University of Minnesota data (reproduced with permission from Professor John Wagner, University of Minnesota, 2007).

The double-unit UCBT experience has raised unique questions about transplant biology especially given that preliminary University of Minnesota data have suggested that this strategy has also been associated with a reduced risk of relapse as compared with single-unit UCBT [20]. To date, no reliable factor has been able to predict which unit will predominate in engraftment after double-unit transplantation. Interestingly, Scaradavou et al. [21] have recently demonstrated an association between UCB unit CD34+ cell viability after thaw [as measured by flow cytometric 7-amino-actinomycin D (7-AAD) staining] and unit predominance. In this analysis of 26 double-unit UCBTs, although the factor determining unit predominance when both units of a double-unit graft have high viability was unclear, units with low viability did not engraft (P = 0.007). Such data suggest that the reason that double-unit UCBT is efficacious may simply be because it increases the chance that the patient will receive at least one unit of high viability and thus with engraftment potential. This introduces the concept that postthaw CD34+ cell viability could be an effective measure of unit quality and has the advantage that, unlike colony-forming assays, is available on the day of transplant. Postthaw unit quality is a relatively new variable to be considered in the field of UCBT and will be a critical area of investigation for the future. If these findings are confirmed it would suggest that double-unit UCBT may be indicated even in children given the viability of a unit that appears satisfactory from the standpoint of HLA-matched and TNC dose cannot be predicted prior to thaw.

Although the poor engraftment and high TRM associated with low-infused TNC dose in single-unit UCBT has understandably led to a focus on strategies to augment graft cell dose, unit selection is complicated by the fact that both engraftment and TRM are also influenced by HLA match. For example, in an analysis of 989 single-unit myeloablative UCBT recipients facilitated by the National Cord Blood Program of the New York Blood Center (NYBC), HLA-A, B antigen and DRB1 allele match was associated with significantly improved engraftment, a lower incidence of severe acute graft-versus-host disease (GVHD), lower TRM, and improved DFS [22]. Eurocord analyses have also found that HLA match is associated with significantly improved engraftment and lower TRM [8].

These findings lead to the question of how to 'trade-off' HLA match with TNC dose when selecting UCB units for transplantation. Although this issue is yet to be fully resolved it is intriguing that in the NYBC analysis referenced above [22] 6/6 HLA-matched UCBT recipients (any dose) had superior DFS to recipients of either 5/6 units at least 2.5 x 10⁷ TNC/kg or 4/6 units at least 5 x 10⁶ TNC/kg. Further, recipients of 5/6 at least 2.5 x 10⁷ TNC/kg units had a comparable DFS to those of 4/6 HLA-matched units with a TNC at least 5.0 x 10⁷/kg [although with less severe acute GVHD (aGVHD)]. This raises the concept of a 'sliding scale' in unit selection with HLA-matched compensating for lesser cell dose (or conversely that the greater the HLA mismatch the greater the cell dose required), and prompts a unit selection algorithm of 6/6 units followed by 5/6 units above 2.5 x 10⁷/kg, and 4/6 units above 5.0 x 10⁶/kg. However, many patients will not have access to such units, and some patients with such optimal units will still not engraft. One strategy to address this limitation that is being investigated in a Center for Bone Marrow Transplant Research (CIBMTR) sponsored study is to prioritize HLA match above a cell dose threshold of 1.5 x 10⁷/kg but to augment engraftment by the infusion of two units.

Graft-versus-host disease after umbilical cord blood transplantation

Although GVHD remains one of the leading causes of TRM in allogeneic HSCT, UCBT has consistently demonstrated a lower than expected incidence of acute and chronic GVHD (cGVHD) [2–8] especially given the considerable degree of HLA mismatch if high-resolution
typing is considered [23]. In comparison with URD BMT, Exepen et al. [13*] reported a similar incidence of grade 2–4 acute and chronic GVHD in pediatric 8/8 allele-matched BMT and 4–6/6 A, B antigen, DRB1-matched UCBT. In adult recipients, Laughlin et al. [5] found a similar incidence of grade 2–4 aGVHD and a lesser incidence of extensive cGVHD as compared with HLA-matched BMT recipients. In contrast, Rocha et al. [6] reported a lower risk of grade 2–4 aGVHD in adult UCBT as compared with HLA-matched BMT recipients with a relative risk of cGVHD of 0.64 after URD BMT although this did not reach significance (P = 0.11). Takahashi et al. [7] have reported similar findings to the Rocha et al. study [6], and more recently these investigators have even reported a significantly lower incidence of grade 3–4 aGVHD and extensive cGVHD after predominantly HLA-matched-related donor HSC transplantation and mismatched URD donor UCBT in adults [24*].

Of further interest beyond the incidence of GVHD is the nature of this disease after UCBT and its response to therapy. Although this has not yet been examined for aGVHD, Arora et al. [25*] found more frequent responses of cGVHD to therapy in 47 UCBT as compared with predominantly HLA-matched URD BMT recipients at 2 months (74 versus 48%, P = 0.005), 6 months (78 versus 49%, P = 0.001) and 1 year (72 versus 51%, P = 0.03) following cGVHD diagnosis. UCBT cGVHD was also associated with a lower TRM (11 versus 27% with URD BMT). It is likely that the findings in this study in favor of UCBT may have even been more pronounced if the URD transplant recipients had received PBSC as the HSC source rather than bone marrow, and given the wide adoption of PBSC (Fig. 1) comparisons of both aGVHD and cGVHD after UCBT to recipients of URD PBSC should be a priority for the future.

The exact reasons for the relatively low incidence of GVHD after UCBT are unknown but likely result from the functional immaturity of the infused lymphocytes including decreased cytotoxicity, an altered cytokine profile, decreased HLA expression and increased regulatory T cells. Of even more interest is to understand the biology of why UCBT is associated with a retained graft-versus-leukemia effect despite the GVHD reduction.

Infectious complications after umbilical cord blood transplantation and immune recovery
Opportunistic infections are a significant cause of TRM in HSCT regardless of graft source. However, studies have revealed varying results in the assessment of infection risk after UCBT as compared with other HSC sources. A University of Minnesota analysis revealed equal incidences of one or more serious infections in unmodified bone marrow [81% (95% CI 65–97%), T-cell depleted [83% (95% CI 60–100%)] and UCB [90% (95% CI 74–100%)] pediatric transplant recipients (P = 0.48) in the first 2 years after transplant, with no significant differences overall when taking all serious infections into account [26]. Further, more recently this group has reported a similar risk of cytomegalovirus (CMV) infection in recipients of UCB, bone marrow and PBSC grafts [27]. Another study [28] has reported increased incidences of severe infection in 48 adult UCBT (85% risk) as compared with 144 adults URD HSC transplant (69% risk) recipients, although day 100 and 3-year infection-related mortality did not differ between HSC sources.

Regardless of the specifics of such comparisons infection is a major challenge in UCBT and at many centers infection-related mortality is now the most frequent cause of death in UCBT with the majority of deaths occurring within the first 3–4 months [29*]. Although improved engraftment with new preparative regimens and double-unit grafts, and aggressive supportive care to abrogate neutropenic sepsis and prevent fungal infections by the use of extended spectrum azoles have led to decreased infection-related TRM, viral infections remain a critical challenge in the early posttransplantation period. For example, Duke University analyzed 330 pediatric patients undergoing UCBT and reported most deaths within the first 6 months after transplant being attributable to opportunistic infection, of which more than half were secondary to CMV or adenoovirus [29*].

Important in interpreting the infectious complications and immune recovery seen after UCBT is not only considering patient and unit characteristics but also what preparative regimen and immune suppression was used. The use of ATG [30,31], corticosteroids, or both for GVHD prophylaxis, for example, appears to be associated with impaired immune recovery and increased risk of severe infection. How to augment immune reconstitution is a major question in the field of UCBT today and assume even greater importance with the recognition that improved immune recovery has also been associated with protection against leukemic relapse [32]. Cellular therapy approaches, although clearly challenging given the naïve neonatal immune system, may yet show promise in the future. In the interim, improved preparative regimen/immune suppression and aggressive supportive care including surveillance for viral reactivation is mandatory in the care of UCBT patients in the early posttransplant period.

Reduced-intensity or nonmyeloablative conditioning
Reduced-intensity conditioning (RIC) or NMA HSCT has been investigated as a method to offer the potential benefit
of a graft-versus-malignancy effect to older, more heavily pretreated, more infirm patients, or all with less toxicity. Early series from the University of Minnesota demonstrated that UCBT after NMA conditioning was feasible [9]. However, it was observed that there was a strong association between recent exposure to combination chemotherapy or a prior autologous transplant and the likelihood of sustained donor engraftment (Fig. 3) [33]. This group has recently updated their NMA UCBT experience [10*]. One-hundred and ten patients (median age 51 years) with high-risk or advanced leukemias, myelodysplasia and Hodgkin's or non-Hodgkin's lymphoma unsuitable for myeloablative conditioning received cyclophosphamide 50 mg/kg, Flu 200 mg/m², and TBI 200 cGy with immune suppression of CSA/MMF. Eighty-five percentage of patients received double-unit grafts to attain a target TNC dose of at least 3.0 × 10⁶/kg. In this high-risk patient group, TRM was 26% (95% CI 18–34) at 3 years with an

BMDW, bone marrow donors worldwide; NMDP, National Marrow Donor Program. Reproduced with permission from Mary Halet, NMDP, April 2008.
overall survival of 45% (95% CI 34–56) and progression-free survival (PFS) of 38% (95% CI 28–48) at 3 years. Interestingly, the PFS was significantly higher in recipients of double-unit [39% (95% CI 27–51)] as compared with single-unit [24% (95% CI 4–44)] grafts. Further to these findings, the Minnesota group has also reported comparable PFS after RIC allograft in recipients older than 55 years of matched-related donor (n = 47) or UCB (n = 43) grafts with 3-year PFS of 30% (95% CI 16–44) and 34% (95% CI 19–48), respectively [34].

Ballen et al. [11] have also investigated double-unit UCBT utilizing a RIC regimen of Flu 180 mg/m² with melphalan 100 mg/m², rabbit ATG, and CSA/MMF in advanced hematologic malignancies or severe aplastic anemia reporting a 100-day TRM of 14% and a promising 1-year DFS of 67% in 21 patients. The outcomes from these series appear comparable to previously published series of RIC/NMA transplantation using volunteer donors but this will need to be studied formerly in randomized studies in the future. For the meantime, major questions in the field of RIC/NMA UCBT are: how to ensure engraftment in patients (such as those with myelodysplasia, myelofibrosis and acute myelogenous leukemia who have received a single induction) without intensive prechemotherapy (especially given the addition of ATG to the NMA preparative regimen) as a strategy to augment engraftment is associated with a high incidence of Epstein-Barr virus posttransplant lymphoproliferative disease [30]; and what is the efficacy of RIC/NMA UCBT in specific disease entities.

Umbilical cord blood banking
As a counterpart to the increased adoption of UCB as an alternative HSC source, the number of units banked worldwide continues to increase with at least 250,000 units for unrelated recipient use banked to date. However, the UCB search continues to be a challenge with no centralized search mechanism to access all units in the global inventory (Fig. 4) and no international regulation to ensure uniform standards from bank to bank. Notably, it is not known how many units would be needed to ensure, for example, a 5/6 HLA-A, B antigen and DRB1 allele-matched unit for the majority of patients of any race or ethnicity. Such projections, although complicated, are important in the consideration of the future funding needed for public UCB banks. A further issue is that of unit quality including: whether the critical determinants of a quality product; and how this should be regulated. McCullough et al. [35] investigated the quality of 268 units from banks in the United States and Europe and discovered that quality issues existed in 56% of units, with 10% likely and 35% potentially associated with patient risk. The major issues associated with UCB banking are discussed by Atlas [36] and Rubinstein [37].

Conclusion
UCB is a promising alternative HSC source although reaching its full potential will likely require a significant increase in the size of the global UCB inventory. If that can be achieved, this combined with measures such as improved preparative regimens, double-unit grafts, improved supportive care, measures to augment immune recovery will likely improve TRM and thus extend the adoption of UCBT to treat patients with high-risk hematologic malignancies.

References and recommended reading
Papers of particular interest, published within the annual period of review, have been highlighted as:

Additional references related to this topic can also be found in the Current World Literature section in this issue (p. 640).

11. This study represents the largest series of UCBT using NMA conditioning.
15. This is a landmark study demonstrating that UCB is an acceptable alternative HSC source for the transplantation of children with leukemia with comparable survival after 4–6/6 HLA-matched UCBT as compared with the gold standard of 8/8 allele-matched BM and superior survival after 6/6-matched UCBT.

This study is an excellent comprehensive review of the unique characteristics of immune reconstitution in UCBT and highlights the challenge of infectious complications in UCBT especially in the postengraftment period.

Factors associated with parameters of engraftment potential of umbilical cord blood

Thomas J. George, Michele W. Sugrue, Sarah N. George, and John R. Wingard

BACKGROUND: Umbilical cord blood (UCB) is an acceptable source of hematopoietic cells for transplantation with success being associated with the nucleated cell count (NCC), CD34+ cells, and colony-forming unit-granulocyte-macrophage (CFU-GM) content infused. A total of 1093 UCB samples with neonatal and parental characteristics that might influence hematopoietic content were examined.

STUDY DESIGN AND METHODS: UCB samples were screened, processed, and reevaluated for the above cell counts. These parameters of engraftment potential were analyzed for associations with neonatal and parental characteristics.

RESULTS: Postprocessed NCCs (median, 6.53 × 10^6 ± 2.80 × 10^6 SD; mean 7.30 × 10^6), CD34+ counts (median, 2.02 × 10^6 ± 2.20 × 10^6 SD; mean 2.65 × 10^6; r = 0.66; p < 0.001), and CFU-GM content (median, 2.85 × 10^3 ± 3.16 × 10^3 SD; mean, 3.54 × 10^3; r = 0.61; p < 0.001) all were strongly interrelated. Both initial volume (median, 77.6 ± 26.2 mL; SD, 81.9 mL) and initial NCC (median, 97.5 × 10^3 ± 4.90 × 10^3 SD; mean, 10.9 × 10^3) correlated well with postprocessed NCC (r = 0.80; r = 0.80; p < 0.01), CD34+ count (r = 0.40; r = 0.63; p < 0.01), and CFU-GM content (r = 0.38; r = 0.59; p < 0.01), with a stronger relationship seen with initial NCC. Infant birth weight (specifically, >5000 g), but not sex, gestational age, or cytomegalovirus status correlated strongly with collection volume and UCB cell counts. Units from minority volunteers contained relatively smaller volumes and hematopoietic content.

CONCLUSION: UCB banks should emphasize selecting the heaviest infants and processing large-volume units with high NCCs to optimize hematopoietic potential. Minority recruitment should be encouraged with consideration given to inherent racial differences in cell counts. There does not appear to be a significant relationship between other neonatal and parental characteristics and that of engraftment potential.

In recent years, partially matched umbilical cord blood (UCB) has been determined to be a suitable graft source for hematopoietic cell transplantation. Engraftment success, defined as the pace of neutrophil and platelet recovery and risk for transplant-related events, as well as overall transplant success, has been influenced by several variables including the underlying diagnosis, stage of the disease, and degree of donor-recipient HLA-match. The total nucleated cell count (NCC) infused, reported as cells per kg of recipient body weight, has been a reliable and reproducible indicator of outcome. The number of CD34+ cells and the number of colony-forming units-granulocyte-macrophages (CFU-GM) are also parameters used to assess hematopoietic potential of UCB units. Although the latter two parameters help to refine the hematopoietic potential of a graft, decisions as to processing and cryopreservation of freshly collected UCB units are generally made based on initial NCC and volume of cord blood because of the rapid availability of these parameters. Transplanted UCB grafts have been considered acceptable if they contain at least 1 × 10^6 to 3 × 10^6 NCCs per kg, with higher doses of cells infused correlating with shorter time to engraftment.

Although UCB is a rich source of hematopoietic stem and progenitor cells, UCB grafts contain much less volume, providing transplant recipients approximately 1/10th as many CD34+ cells compared to those receiving

ABBREVIATIONS: NCC(s) = nucleated cell count(s); UCB = umbilical cord blood.

TRANSFUSION 2006;46:1803-1812.
allogeneic marrow resulting in delayed hematopoietic recovery in recipients of UCB after transplantation. A high postthawing CD34+ content in UCB grafts has been shown to correlate with improved event-free survival in adult transplant recipients and may correlate with positive outcomes in the pediatric population. Unfortunately, the CD34+ content of thawed grafts is not consistently available at the time of transplant graft selection and is subject to reporting variability between cord banks.

Direct assessment of hematopoietic progenitor cells as determined in semisolid medium culture assays is helpful to predict graft hematopoietic potential as well as verifying viability of the cells after processing or cryopreservation. Recently, the dose of CFU-GM infused was found to better correlate with engraftment speed and risk for transplant-related events more accurately than NCC. Unfortunately, the use of these assays are limited by inconsistent growth and scoring between labs, which are potentially subject to technician experience and may take up to 14 days and therefore cannot be consistently used to determine graft adequacy before transplantation.

UCB banking has become established worldwide with funding provided by both public and private organizations. Limited resources require that UCB banks select, process, and store specimens with the greatest hematopoietic potential while maintaining a HLA-diverse population. Standardization in collection, processing, and storage between banks has been sought, particularly given it is given notable discrepancies between UCB banks and transplant centers.

We examined the characteristics of 1033 UCB samples collected at a single institution over a 2-year period. Our goal was to identify associations between the parameters of engraftment potential and a variety of neonatal and parental variables in an attempt to maximize future UCB specimen success.

**MATERIALS AND METHODS**

**Inclusion criteria**

Maternal donors were prospectively evaluated during their pregnancy, and appropriate medical information was voluntarily obtained after informed consent with institutional review board approval. Maternal serum was screened for infectious diseases including human immunodeficiency virus (HIV)-1 and -2, HIV-1 p24 antigen, hepatitis C antibody, hepatitis B core antibody, hepatitis B surface antigen, human T-lymphotropic virus-1 and -2, and cytomegalovirus (CMV). All positive test results except for CMV excluded the donor before collection. Gestational age of the infant at the time of delivery and UCB procurement was required to be at least 36 weeks.

**UCB collection**

Collection personnel with experience in venipuncture, infection control, and handling of biohazard material received training sufficient to perform the procedure. Immediately after either spontaneous vaginal or cesarean delivery, the umbilical cord was isolated and prepared in sterile fashion. UCB product collection was performed in the same manner for ex utero and in utero placental deliveries. Umbilical cords were clamped and the distal portion prepared for phlebotomy with a PVP iodophor scrub. Blood was aspirated into a 50-ml syringe containing 6 ml of citrate-phosphate-dextrose (Baxter Healthcare Corp., Deerfield, IL) via the umbilical vein. Once the syringe was filled, a new site was prepared and the process was repeated until no additional blood could be collected. Finally, all syringes were expressed into a 250-ml transfer pack. Participating facilities included Shands at the University of Florida, Gainesville, Florida; Shands at Alachua General Hospital, Gainesville, Florida; North Florida Regional Medical Center, Gainesville, Florida; Shands at Lake City, Lake City, Florida; and Baptist Health, Montgomery, Alabama.

**UCB processing and cryopreservation**

Collected UCB products were initially assessed for ABO/Rh, volume, and NCC. Products were considered ineligible for further manipulation if they contained fewer than $8 \times 10^9$ NCCs or less than 40 ml. Products containing $6 \times 10^9$ to $8 \times 10^9$ NCCs were processed and cryopreserved in toto. For products whose content exceeded $8 \times 10^9$ NCCs, HLA typing, sterility, and red cell (RBC) reduction procedures were performed. Briefly, 20 percent volume for volume hetastarch (Novaplus, Abbott Laboratories, North Chicago, IL) was added followed by centrifugation (5 min, 33 g). Cellular-rich supernatants were expressed into a 150-ml transfer pack (Baxter Healthcare Corp.) and recentrifuged (10 min, 226 g). Finally, the cellular-poor supernatant was expressed and the remaining pellet transferred to a cryopreservation container (Baxter Healthcare Corp.). Samples were taken for postprocessing analysis and the product was chilled in an ice bath. Cryoprotective solution containing 20 percent dimethyl sulfoxide (DMSO; Research Industries Corp., Salt Lake City, UT), 20 percent human serum albumin (Baxter Healthcare Corp.) in solution (Plasmalyte-A, Baxter Healthcare Corp.) was prepared to a volume equaling the RBC-reduced UCB product and chilled in an ice bath. Cryoprotective solution was slowly added to the cellular pellet, and containers were placed in aluminum cassettes. Freezing took place in a controlled-rate freezer according to standard protocol before storage in the vapor phase of liquid nitrogen.
Evaluation of the UCB products

Cell counts. NCCs were performed on the products before and after the processing procedure as detailed above. Counts were performed with a volume impedance cell counter (Sysmex F-800, Baxter Healthcare Corp.) employing lysing solution (Quicklyte, TOA Medical Electronics, Kobe, Japan) to lye RBCs as recommended by the manufacturer. All CD34+ and CFU-GM counts were analyzed after processing.

CD34+ cell content and viability. Modified flow cytometric analysis of samples was performed utilizing phycoerythrin–labeled anti-CD34 (Becton Dickinson Immunocytometry Systems, San Jose, CA) and peridinin chlorophyll protein–labeled anti-CD45 in bead-containing tubes (TruCount, Becton Dickinson). After RBC lysis with a fixative-free reagent, the impartant nucleic acid dye YO–PRO-1 (Molecular Probes, Eugene, OR) was added, and samples were analyzed with a four-color analysis (two lasers; FACSCalibur, Becton Dickinson). The main advantages of our CD34+ enumeration procedure are that it excludes nucleated RBCs and dead white blood cells (WBCs). It also directly enumerates CD34+ cells per μL, as opposed to providing a percentage of WBC that are CD34+. This procedure has previously been reported in detail for both CD34+ cell count enumeration and quantification of graft viability. NCC viability was estimated before banking by the trypan blue exclusion method (Gibco Laboratories, Grand Island, NY). A total of 100 nucleated cells were counted and a percentage of viable cells was determined.

Clonogenic assays. Clonogenic assays were performed on all processed UCB products. A total of 10^6 NCCs per 1-ml aliquot of methylcellulose with phytohemagglutinin–WBC-conditioned medium (StemCell Technologies, Inc., Vancouver, BC, Canada) were seeded in 35-mm petri dishes and incubated for 12 to 14 days at 37°C in a fully humidified atmosphere containing 5 percent CO2. Aggregates of at least 50 cells were scored for CFU-GM, CFU-granulocyte-erythrocyte-megakaryocyte-megakaryocytic (GEMM), or burst-forming units–erythroid with an inverted microscope. The total number of colonies for each product was then calculated based on the total NCC.

Data collection

Characteristics of the collected UCB were recorded in computer spreadsheet format (Microsoft Excel, Microsoft Corp., Seattle, WA). Specifically, data entry was performed on the following variables: initial volume of UCB collected, total initial NCC before processing, postprocessing volume before cryopreservation with or without RBC depletion, postprocessed NCC, CD34+, CFU-GM, and viability count. Gestational age, birth weight, infant sex, and maternal CMV status were obtained from the medical record at the time of the delivery. Voluntary self-reporting via survey completion of maternal and paternal race was provided before UCB harvest.

Statistical analysis

Data were analyzed with computer software (MINITAB 14, Minitab, Inc., State College, PA). Medians, standard deviations (SDs), and means were generated based on single variables as well as grouped by RBC manipulation, maternal race, paternal race, infant sex, and maternal CMV status. The Kruskal-Wallis test was used to detect differences between medians. Pearson correlation coefficients (r) were calculated with differences between coefficients determined by z-test or confidence intervals along with Fisher's r-to-z transformation. Two-by-two variables (CMV vs. race) were assessed with the Pearson chi-square test. Multivariate analysis calculations were performed with multivariate analysis of variance. All comparative tests were analyzed for significance at the 5 percent level of significance (i.e., p < 0.05).

Results

General characteristics of the 1035 UCB units are detailed in Table 1. CD34+ quantification and CFU-GM analysis were prospectively performed on all samples after processing. However, inconclusive results, contaminated samples, or technical difficulties resulted in reportable data in 965 (93%) and 1019 (99%) samples, respectively. RBC depletion was performed on 69 percent of samples. Maternal CMV status was available in 857 (87%) cases. Self-reporting of maternal and paternal race (n = 918 [89%] for both) revealed a predominance of Caucasian donors as volunteers. Infant sex was reported in 857 (83%) cases with a nearly equal distribution of sexes. Data were available on 580 (56%) and 556 (57%) samples regarding infant gestational age and birth weight, respectively.

Processing and RBC depletion

The initial NCC was reduced by approximately 33 percent after processing (Table 1). Of the initial samples collected, 68 percent contained enough NCC to undergo RBC depletion per protocol. Those samples contained a higher concentration of initial NCC, postprocessed NCC, CD34+, and CFU-GM content than those that did not undergo RBC depletion (p < 0.001 for each; Table 2). The process of RBC depletion resulted in a greater loss of NCC compared to those undergoing the standard processing procedure (37% reduction vs. 15%; p < 0.001, data not shown). The depleted samples retained an absolute larger concentration of hematopoietic precursors despite the added procedure of RBC depletion. Samples undergoing RBC depletion came from heavier infants (3624 ± 3462 g; p < 0.001). Otherwise, there was no dif-
difference between the need for RBC depletion and gestational age (p = 0.2) or CMV status (p = 0.7; data not shown).

Assessment of hematopoietic potential

The postprocessed NCC (median, 6.53 x 10^7 ± 2.80 x 10^6 SD; mean, 7.30 x 10^7) correlated strongly with CD34+ count (median, 2.02 x 10^6 ± 2.20 x 10^6 SD; mean, 2.85 x 10^6; r = 0.66; p < 0.001) and CFU-GM content (median, 2.05 x 10^3 ± 3.16 x 10^2 SD; mean, 3.54 x 10^3; r = 0.61; p < 0.001; Table 3). Likewise, a very strong correlation was seen between CD34+ and CFU-GM content (r = 0.69; p < 0.001). There was excellent internal correlation between the postprocessed NCC and the initial NCC collected (median, 9.75 x 10^7 ± 4.38 x 10^6 SD; mean, 10.9 x 10^7; r = 0.80; p < 0.001; Fig. 1). Both initial volume (median, 77.5 mL ± 26.2 mL SD; mean, 81.8 mL) and initial NCC correlated well with postprocessed NCC (r = 0.60; p = 0.001), CD34+ count (r = 0.40; p = 0.63; p = 0.01), and CFU-GM content (r = 0.38; p = 0.59; p = 0.01), with a stronger relationship seen with initial NCC.

Associations of neonatal and parental characteristics and preprocesing factors with engraftment potential parameters

Male infants were heavier by an average of 141 g (3852 g vs. 3511 g; p = 0.01) and had a higher content of CD34+ cells collected (2.25 x 10^8 vs. 1.96 x 10^8; p = 0.02).

* Data are reported as Pearson correlation coefficients (r); associated p value.
Fig. 1. Scatterplots of NCC correlations.

These cell count differences appeared to be dependent only on male sex, however, and not birth weight, upon multivariate analysis (p < 0.012; data not shown). Otherwise, infant sex did not influence volume collected, NCC, CFU-GM content, or gestational age.

Table 4 shows the relationship between gestational age and UCB characteristics. Gestational age (median, 39 ± 1.1 weeks SD; mean, 39.2 weeks; range, 38-42 weeks) did not correlate with volume or cell counts, except for a slight correlation between increased gestational age and lower CD34+ counts (r = -0.13; p = 0.002). As gestational age and birth weight appeared related (r = 0.24; p < 0.001), data were separated into one of three gestational age categories (<38, 38-40, and >40 weeks). There were significant differences in birth weight between young (<38 weeks) and average (38-40 weeks; 3199 g vs. 3596 g; p < 0.001) and young and older (>40 weeks) infants (3199 g vs. 3709 g; p < 0.001). Based on these age groups, however, there were no significant differences noted between volume collected, initial or postprocessed NCC, CD34+ cells, or CFU-GM content of the collected UCB.

Table 4 also shows the relationship between birth weight (median, 3596 g ± 427 g SD; mean, 3578 g; range, 2245-4898 g) and UCB characteristics. Small, but significant positive correlations were identified between birth weight and volume (r = 0.25; p < 0.001), initial NCC (r = 0.29; p < 0.001), postprocessed NCC (r = 0.17; p < 0.001), CD34+ count (r = 0.14; p < 0.001), and CFU-GM content (r = 0.18; p < 0.001). Data again were separated into one of three birth weight categories (<3000, 3000-4000, and >4000 g). Based on these groups, there were differences noted in initial volume, initial and postprocessed NCC, CD34+ cells, CFU-GM content, and gestational age. Specifically, the pattern was one of increased volume, cell count, and age per increase in birth weight category. The majority of these differences were significant, particularly as birth weight exceeded 3000 g (see Table 4 for details).

The characteristics of UCB samples examined by maternal and paternal race are shown in Table 5. Correlation coefficients between initial NCC, postprocessed NCC, CD34+, and CFU-GM content were similar for UCB collected from Caucasian or non-Caucasian parents (data not shown). There was a trend toward increased CD34+ cell content in UCB from Caucasian mothers (p = 0.06). Initial NCC and CFU-GM content were both significantly higher in samples obtained from Caucasian mothers compared to non-Caucasian mothers with no difference in

* Medians are reported unless otherwise specified.

Initial volume, gestational age, or birth weight. The difference noted in NCC was lost after processing (p = 0.06), however, thereby showing no significant difference between postprocessed NCC and maternal race.

Initial NCC and CFU-GM content were higher in samples obtained from Caucasian fathers compared to non-Caucasian fathers. There was also a significantly higher number of CD34+ cells in samples from Caucasian fathers (p = 0.03) as well as a larger initial volume (p = 0.01). Unlike in the maternal set, there remained persistent differences in NCC after processing (p = 0.01). There were no differences in gestational age, but infants from Caucasian fathers were heavier (3596 vs. 3497 g; p = 0.03).

CMV status and race were both determined in 826 samples (86%). There were significant differences between CMV status and maternal and paternal race. Specifically, 52 percent of Caucasian versus 65 percent of non-Caucasian mothers were CMV-positive (χ^2 = 5.0; p = 0.03), whereas 52 percent of Caucasian versus 68 percent of non-Caucasian fathers were CMV-positive (χ^2 = 9.6; p = 0.002). Regardless, CMV status did not impact volume, NCC, CD34+ cells, CFU-GM content, gestational age, or birth weight.

**DISCUSSION**

This analysis of data from our cord blood bank represents one of the largest regional databases reported in the literature with inclusion of laboratory, neonatal, parental, and racial data. Descriptive characteristics including volume and cell counts for this and other reported domestic and international registries are displayed in Table 6. Such a comparison is limited by a lack of standard collection and management policies between cord blood banks. Regardless, our data are consistent with other reported experiences in all categories, except CFU-GM content. Importantly, we note equivalent volumes collected, initial and postprocessed NCC, and CD34+ content. Progenitor cell viability in our unit was verified through the flow cytometric analysis of CD34+ cells as previously reported. Variability in CFU-determini

1808 TRANSFUSION Volume 45, October 2008
nation has been previously reported, and our CFU-GM assays utilize techniques that differ from that reported by others. Specifically, our assays are read at 12 days (instead of 14 days), are not routinely RBC lysed for ease of viewing, and do not use recombinant growth factors in synthetic media. Taken together, these differences have the potential to underestimate our UCB CFU-GM content. As a result, our laboratory has changed CFU-GM assays in an attempt to become more consistent with other facilities; however, significant interinstitutional variability remains.

Both initial volume and initial NCC correlated well with postprocessed NCC (r = 0.69; r = 0.90; p < 0.01), CD34+ count (r = 0.40; r = 0.65; p < 0.01), and CFU-GM content (r = 0.38; r = 0.59; p < 0.01), with a stronger relationship seen with initial NCC. Others have reported initial volume collected to be an accurate and reliable measure of CD34+ count. Our data suggest that initial NCC is a better surrogate marker than volume for UCB hematopoietic potential. Strong correlations were also identified between postprocessed NCC and CD34+ (r = 0.56) and with CFU-GM content (r = 0.61). Both were highly significant and consistent with correlations previously published (NCC/CD34+ range, 0.59-0.87). NCC/CFU-GM range, 0.49-0.89). CD34+ and CFU-GM content also had a strong direct correlation (r = 0.68), suggesting that CD34+ content may predict CFU-GM content better than total NCC, consistent with the reporting of others.

As a measure of internal control, there was a very strong correlation between postprocessed and initial NCC (r = 0.9; p < 0.001) despite the degree of RBC depletion and processing required. Indeed, the procedure of UCB processing results in the loss of approximately one-third of NCC, consistent with that previously reported (35%). The majority of this loss occurs in those samples that undergo RBC depletion (37% vs. 15%; p < 0.001), which represents the majority (88%) of our samples. Despite this increased loss, however, those samples with higher initial NCC (which subsequently undergo RBC depletion) retain an adequate postprocessed NCC. RBC depletion of UCB limits the volume of specimens required for storage and DMSO concentration, allows uniform and rapid freezing and thawing, lessens the potential exposure of mismatched RBC antigens to transplant recipients, and minimizes free hemoglobin infused. Although not internationally standardized, our UCB bank required a minimum NCC of 6 x 10^6 before processing and storage, but has recently increased this number to 8 x 10^6. It would appear that our threshold of performing RBC depletion based on initial NCC of greater than 8 x 10^6 is justified. Our units were not assessed for the nucleated RBC content of the NCC, however. It has been suggested that nucleated RBCs can comprise a significant proportion of the NCC in a graft and lyse more easily during processing and thawing. It is possible that such loss of NCC and nucleated RBCs in processing could adversely affect the speed of myeloid engraftment after transplantation.

As should be expected, there was no significant relationship between infant sex and most UCB characteristics. Male infants in our registry were heavier than their female counterparts, with a clear relationship established between increased birth weight and UCB cell content as a possible explanation (see Table 4 and text below). Male sex alone, however, appeared to be the major influence on these differences, as suggested upon multivariate analysis. Although only 57 percent of our data set contained birth weight information, our findings are consistent with those of others who reported an independent association between increased cells counts and male sex, particularly with regard to the CD34+/CD61 subset. Perhaps there may be an underlying effect of in utero sex-specific hormones on neonatal circulation and hematopoiesis.

All infants were of gestational age between 36 and 42 weeks. Newborns of increasing gestational age were bigger, as expected, but had no significant differences as related to cell counts, although a negative correlation was identified with CD34+ counts. Inverse relationships
ACKNOWLEDGMENTS
The authors thank the volunteers and donors of UCB at each of the locations previously specified whose selfless contributions are truly deserving. Additionally, we are indebted to J.A. Iturraspe and G.A. Martinez of Life South Community Blood Centers for their acquisition and processing of samples as well as D.D. Fisk, C.E. Hutchison, T.D. Peña, E.H. Rosenau, and C.C. Roberts at Shands Hospital, who all provided additional processing of samples, cell counting, and data collection. Finally, we thank J.C. Hopkins for data entry and database management.

ABSTRACT

Purpose
To determine risk factors of umbilical cord blood transplantation (UCBT) for patients with lymphoid malignancies.

Patients and Methods
We evaluated 104 adult patients (median age, 41 years) who underwent unrelated donor UCBT for lymphoid malignancies. UCB grafts were two-antigen human leukocyte antigen–mismatched in 68%, and were composed of one (n = 78) or two (n = 26) units. Diagnoses were non-Hodgkin’s lymphoma (NHL, n = 61), Hodgkin’s lymphoma (HL, n = 29), and chronic lymphocytic leukemia (CLL, n = 14), with 87% having advanced disease and 60% having experienced failure with a prior autologous transplant. Sixty-four percent of patients received a reduced-intensity conditioning regimen and 46% low-dose total-body irradiation (TBI). Median follow-up was 18 months.

Results
Cumulative incidence of neutrophil engraftment was 84% by day 60, with greater engraftment in recipients of higher CD34⁺ kg/cell dose (P = .0004). CI of non-relapse-related mortality (NRM) was 28% at 1 year, with a lower risk in patients treated with low-dose total-body irradiation (TBI); P = .03. Cumulative incidence of relapse or progression was 31% at 1 year, with a lower risk in recipients of double-unit UCBT (P = .03). The probability of progression-free survival (PFS) was 40% at 1 year, with improved survival in those with chemosensitive disease (49% vs 34%; P = .03), who received conditioning regimens containing low-dose TBI (60% vs 23%; P = .001), and higher nucleated cell dose (49% vs 21%; P = .009).

Conclusion
UCBT is a viable treatment for adults with advanced lymphoid malignancies. Chemosensitive disease, use of low-dose TBI, and higher cell dose were factors associated with significantly better outcome.

J Clin Oncol 27:256–263. © 2008 by American Society of Clinical Oncology

Allogeneic hematopoietic stem-cell transplantation (HSCT) is a curative approach for patients with advanced, relapsed, or refractory non-Hodgkin’s lymphoma (NHL), Hodgkin’s lymphoma (HL), and chronic lymphocytic leukemia (CLL). Comparative studies have reported lower relapse rates after allogeneic transplant relative to autologous transplant. However, conventional allogeneic HSCT is associated with high non-relapse-related mortality (NRM), which offsets the potential survival benefit of this procedure. Reduced-intensity conditioning (RIC) regimens have been used with increasing frequency in such high-risk populations. Low relapse rates after RIC transplant suggest that the graft-versus-lymphoma (GVL) effect of donor T cells is retained. Umbilical cord blood (UCB) is an alternative source of hematopoietic stem cells for the treatment of hematologic malignancies in patients lacking a
human leukocyte antigen (HLA)-matched donor. Advantages of UCB include prompt availability and decreased risk of graft-versus-host disease (GVHD) despite HLA mismatch. These attributes make UCB applicable to nearly all patients, particularly those with less common tissue types, such as those in ethnic and racial minorities. However, the low number of progenitor cells has been associated with delayed engraftment and increased risk of NRM. Strategies to overcome this barrier include the use of two partially HLA-matched UCB units (double UCBT). There have been a few isolated reports for refractory NHL and malignant lymphoma treated by RIC-UCBT. This larger analysis has allowed us to report the general experience of unrelated UCBT in the treatment of advanced lymphoid malignancies in adults, and to identify treatment- and disease-based factors associated with better or poorer outcomes.

**Data Collection**

Euroword is a registry of related and unrelated UCBT that works in collaboration with the European Group of Blood and Marrow Transplantation (EBMT), and Netcord banks. Netcord is an international organization that encompasses cord blood banks all over the world, mostly in Europe (the Appendix, online only, contains a listing of banks). Netcord and EBMT databases provided data on UCBT. Centers not associated with EBMT were asked to complete reports if UCB units were obtained from Netcord banks. All data were verified and updated by the institution’s physicians and data managers. All patients or legal guardians provided informed consent for the UCBT according to the Declaration of Helsinki.

**Inclusion Criteria**

The study included patients with malignant lymphoma (both HL and NHL) or CLL (1) who received an unrelated and unmanipulated single-unit or double-unit UCBT; (2) who were older than 15 years at the time of transplantation; and (3) for whom there were adequate and sufficient data to perform the analysis. Twelve patients included in this study were previously reported.

**End Point Definitions**

The primary end point was progression-free survival (PFS) at 1 year, defined as the time from transplantation to relapse, disease progression, or death. Other end points included incidence of neutrophil recovery, defined as first of 3 consecutive days with a neutrophil count of at least 0.5 x 10^9/L, and the incidence of platelet recovery as the first of 7 consecutive days of an unsupported platelet count of at least 20 x 10^9/L; graft failure was defined as no sign of neutrophil recovery, as well as transient engraftment of donor cells 60 days after transplantation; acute GVHD at day 100 and chronic GVHD at 1 year, diagnosed and graded according to published criteria, with histopathologic confirmation when possible; relapse or progression at 1 year, as defined by the criteria on the basis of clinical, imaging, or laboratory evidence; and NRM at 6 months and at 1 year, defined as deaths related to transplantation and not to relapse. Chimerism data was evaluated in the first 3 months after UCBT. Full donor chimerism was defined as the presence of more than 95% of the cells of donor origin, mixed chimerism if more than 5% and less than 95% of donor cells, and autologous recovery if less than 5% of donor cells. Data on the method of chimerism detection were not collected.

**Statistical Analysis**

Data were analyzed through March 2007. Cumulative incidence function (CIF) using death as a competing event was used to estimate neutrophil and platelet engraftment, acute and chronic GVHD, NRM, and relapse. The Kaplan-Meier method was used to estimate overall survival (OS) and PFS. For continuous variables, the median was used as the cutoff point. For assessment of prognostic factors using CIF, univariate and multivariate analyses were performed using the Gray’s test and the proportional subdistribution hazard regression model of Fine and Gray. For OS and PFS, log-rank tests and Cox proportional-hazards model in univariate and multivariate analyses were used. Acute and chronic GVHD were assessed as time-dependent covariates for PFS. Each potential risk factor was tested independently. All factors that reached P ≤ .05 in the univariate analysis were included in the multivariate model. All models were built using a forward stepwise method. Only factors that reached a P ≤ .05 were held in the final model. Of note, the factors "lymphoma subtype" and "use of TBI" were initially classified into multiple categories. However, in an effort to minimize multiple comparisons, and as there were no statistical differences between the categories "no TBI" and "high-dose TBI" (Appendix Table A1, online only), these categories were collapsed and the variable "use of TBI" was analyzed as "low-dose TBI versus others." The variable "lymphoma subtype" was not included in the final multivariate analysis because the group of patients with mantle-cell lymphoma was too small, and clinically different from indolent lymphoma. The use of antithymocyte or antithymocyte globulin (ATG/ALG) was also not included in the final model because of a strong correlation with myeloablative conditioning regimen (Appendix Table A3, online only). Statistical analyses were performed using the statistical software package SPSS.
performed with SPSS (SPSS Inc, Chicago, IL), and S-Plus (Insightful Corp, Seattle, WA) software packages.

**Patient and Disease Characteristics**

A total of 104 patients from 34 EBMT transplant centers and 14 non-EBMT centers, who underwent transplantation between January 1996 and June 2007, met the inclusion criteria: 15 patients received transplants from 1996 to 2001, 30 from 2002 to 2004, and 59 from 2005 to 2007. Sixty-one patients had NHL, 29 had HL, and 14 CLL. Patient and disease characteristics are summarized in Table 1. Forty-two patients with a response to the last therapy before the transplant (complete or partial remission) were considered chemosensitive, and 62 patients with primary refractory disease or refractory relapse before transplant were considered chemoresistant.

**Graft and Transplant Characteristics**

Graft and conditioning regimen characteristics are summarized in Table 2. A total of 78 patients received a single UCBT, and 26 received a double UCBT.

*One unit, antigen-level HLA-A and B and allele-level HLA-DRB1 typing.
†Two units, antigen-level HLA-A and B and allele-level HLA-DRB1 typing.
Conditioning regimen varied according to the transplant center. A total of 64 patients received an RIC regimen, and 36 received a myeloablative conditioning regimen. For four patients, detailed data on the conditioning regimen were not available. Median follow-up time for survivors was 18 months (range, 3 to 74 months).

**Engraftment and Chimerism Studies**

The cumulative incidence of neutrophil recovery was 84% by day 60. Neutrophil recovery occurred in 86% of patients at a median of 17 days (range, 3 to 54 days) for patients who received RIC and in 83% at a median of 22 days (range, 11 to 48 days) for patients who received myeloablative regimens. Eight patients died before day +30 without achieving neutrophil engraftment. Primary graft failure occurred in nine patients: five patients had autologous reconstitution and four engrafted after a second transplant (two patients received an autograft; one a UCET and one a peripheral blood-stem-cell transplant).

In a univariate analysis, the following variables were associated with a higher incidence of neutrophil engraftment (Table 3): use of low-dose TBI in the conditioning regimen (92% v 73% for patients not receiving TBI and 87% for patients receiving high-dose TBI; \( P = .0007 \), regimens not incorporating ATG/ALG (91% v 76%,

**NOTE.** Superscripted parentheses refer to the \( P \) value for pairwise tests: (1) \( v < 2 \); (2) \( v < 4 \); (3) \( v < 4 \); (4) \( v > 4 \). (1) and (2) \( v < 3 \) and (4) is .002; (1) \( v > 3 \) is .30; (2) \( v \) (1 and 3) is < .0001. Abbreviations: NS, not significant; NHL, non-Hodgkin’s lymphoma; UCB, umbilical cord blood; RIC, reduced-intensity conditioning; MAC, myeloablative conditioning; TBI, total-body irradiation; ATG, antithymocyte globulin; ALG, antilymphocyte globulin; TNC, total nucleated cells; NS, not significant. *\( P \) of.
P = .004), and infused CD34+ cell dose greater than 1.0 × 10^6/kg (96% vs 77%; P < .0001). In a multivariate analysis, the use of low-dose TBI (P = .04; Table 4), and a higher CD34+ cell dose (P = .0004) remained favorably associated with engraftment. Number of HLA mismatches was not identified as a factor associated with neutrophil engraftment.

The cumulative incidence of platelet engraftment was 65% by day 180. In a univariate analysis, factors associated with higher incidence of platelet engraftment were use of low-dose TBI (89% vs 53% in patients not receiving TBI and 47% in those receiving high-dose TBI; P < .0001), regimens not incorporating ATG/ALG (71% vs 57%; P = .04), and infused CD34 cell dose greater than 1.0 × 10^6/kg (85% vs 58%; P = .002). In a multivariate analysis, only low-dose TBI remained associated with platelet engraftment (P = .003).

In recipients of single UCBT, chimera studies were available for 54 of 62 assessable patients. Forty patients (74%) had complete chimera, and eight patients (15%) had mixed chimera at first testing (before day +100). Of these, four patients became complete chimeras at the second or third evaluation.

In recipients of double UCBT, chimera data were available in 17 out of 21 assessable patients. Sixteen patients (94%) had complete chimera and one patient (6%) had a mixed chimera. In 16 cases, engraftment was derived from one unit and in two cases, from both units.

NRM

Twenty-nine patients died as a result of non-relapse-related causes. The principal causes of NRM were infection (69%): bacterial (n = 9), viral (n = 6), or fungal (n = 5). Cumulative incidence of NRM was 24% at 6 months and 28% at 1 year. Factors associated with a lower NRM were age at least 41 years (19% vs 38%; P = .04), use of low-dose TBI (13% vs 50% in patients not receiving TBI and 20% in those receiving high-dose TBI; P = .0006), regimens not incorporating ATG/ALG (18% vs 38%; P = .04), and total nucleated cell (TNC) dose higher than 2 × 10^7/kg (22% vs 41%; P = .02). In a multivariate analysis, the use of low-dose TBI (P = .03), and a TNC dose higher than 2 × 10^7/kg (P = .045) were associated with lower NRM. Although patients who received RIC also tended to have lower NRM compared with those receiving myeloablative regimens (20% vs 38%), this beneficial effect was driven only by RIC regimens incorporating low-dose TBI, and not by the others.

GVHD

The cumulative incidence of acute GVHD grades 2 to 4 and 3 to 4 was 24% and 8%, respectively. Factors associated with a higher risk of acute GVHD were age 41 years or older (38% vs 12%; P = .002), use of low-dose TBI (39% vs 11% in patients not receiving and 13% in those receiving high-dose TBI; P = .003), regimens not incorporating ATG/ALG (33% vs 14%; P = .02), and RIC-UCBT (32% vs 14%; P = .04). In a multivariate analysis, only older age remained significantly associated with the risk of acute GVHD (P = .02).

Fifty-two patients were assessable for chronic GVHD; the cumulative incidence at 1 year was 18%. Eight patients (15%) developed limited and 10 (19%) extensive chronic GVHD.

Relapse or Progression

The cumulative incidence of relapse or progression was 31% at 1 year and 35% at 2 years. Overall, 35 patients (33%) relapsed or progressed after the UCBBT, with a median time to relapse or progression of 5 months (range, 1 to 33 months). Of these 35 patients, 29 (83%) were transplanted in relapse, partial remission, or had refractory disease at transplant.

Factors associated with lower relapse or progression rates were chemoresensitive disease (22% vs 38%; P = .05) and use of double UCBBT (13% vs 38%; P = .009). In a multivariate analysis, only the use of double UCBBT (P = .02) remained associated with lower relapse risk.

PFS and OS

The probability of PFS was 40% at 1 year and 36% at 2 years. Factors associated with PFS were age at least 41 years (54% vs 28%; P = .02), presence of chemoresistant disease (49% vs 34%; P = .04), histologic subtype (60% in indolent NHL, 75% in mantle cell NHL, 29% in aggressive NHL, and 30% in HL; P = .02; Fig 2), use of low-dose TBI (59% vs 20% in patients not receiving TBI and 33% in those receiving high-dose TBI; P < .0001), use of regimens not incorporating ATG/ALG (56% vs 23%; P = .001; Fig 3), and a TNC dose higher than 2 × 10^7/kg (49% vs 21%; P < .0001). In a multivariate analysis, use of low-dose TBI (P = .001), chemoresistant disease (P = .03), and a TNC dose higher than 2 × 10^7/kg (P = .009) remained factors associated with a better PFS.

Acute or chronic GVHD, analyzed as time dependent covariates, were not statistically associated with PFS (for acute GVHD, relative risk [RR] = 0.56; 95% CI, 0.56 to 1.11; P = .10; for chronic GVHD, RR = 0.39; 95% CI, 0.09 to 1.73; P = .22).

OS at 1 year was 48%. Factors associated with OS were similar to those for PFS: older age (62% vs 35%; P = .02), use of low-dose TBI (74% vs 20% in patients not receiving TBI and 39% in those receiving high-dose TBI; P < .0001), use of regimens not incorporating ATG/ALG (68% vs 26%; P < .0001), and higher UCBBT graft TNC dose greater than 2 × 10^7/kg (61% vs 22%; P < .0001). In multivariate analysis, use of low-dose TBI (P < .0001), and TNC dose higher than 2 × 10^7/kg (P = .01) remained associated with better OS. In the subgroup of patients with indolent lymphoid disease, PFS was 75% in patients with follicular lymphoma and 43% in those with CLL.

</table>

Abbreviations: NRM, non-relapse-related mortality; PFS, progression-free survival; OS, overall survival; TBI, total-body irradiation; TNC, total nucleated cell; GVHD, graft-versus-host disease; UCB, umbilical cord blood.
In the subgroup of patients who were not in complete remission at transplant (n = 80), 30 (38%) remain in remission after UCBT with a median follow-up of 18 months (range, 4 to 57 months). PFS and OS at 1 year were 45% and 48%, respectively. PFS was 69% for patients who received low-dose TBI versus only 9% in those not receiving TBI and 36% in those who received high-dose TBI (P < .0001).

In the present study, we demonstrated that UCBT is a viable option for patients with lymphoma and CLL. Despite the fact that most patients received transplants in an advanced phase of their disease, relatively low NRM and good survival rates were observed. Especially favorable characteristics were chemosensitive disease, use of low-dose TBI, and higher cell doses.

To date, there have been only a few isolated reports on the use of UCBT in patients with advanced lymphoid malignancy.26-49 The use of conventional allogeneic HSCT in patients with lymphoma and CLL is still limited.29 The reported studies are heterogeneous in terms of patient, transplant, and disease features, which make comparisons difficult.

Our results, using unrelated donor UCBT, are comparable to those using HLA-matched donors.22,25,44-47 We observed an NRM incidence of 28% and PFS and OS rates of 40% and 48% at 1 year, respectively. Branon et al29 observed 20% of NRM of and a PFS of 59% at 14 months (median follow-up time) in 38 patients with advanced lymphoma who received an RIC HLA-matched sibling donor transplant. The Lymphoma Working Party of the EBMT reported a NRM of 26% and a PFS of 46% at 1 year with a median follow-up of 7 months, in 183 patients with lymphoma who received an RIC-HSCT.22 Survival was significantly better in those with chemosensitive disease, HL, and indolent NHL.

In the present study, chemosensitivity also favorably influenced PFS (49% vs 34%), and OS (54% vs 44%). Besides, we also observed that patients with indolent NHL presented a significantly better outcome: NRM, PFS, and OS rates were 20%, 60%, and 68%, respectively. A better response rate in indolent disease is expected in this group of patients in which RIC regimens were the most frequently used. Besides, the observed worse prognosis of UCBT for both HL and aggressive NHL might also be related to the high toxicity of the conditioning regimen, yielding a high NRM rate, and a high relapse risk in a group of patients with advanced phases of disease because UCBT is usually the last possibility of treatment and is still considered experimental by many transplant centers.

To our knowledge, this is the first study to report patients with CLL who received a UCBT. We observed a 1-year PFS and OS of 43% and 51%, respectively. These results are comparable with those of allogeneic HSCT in the RIC setting, with PFS rates ranging from 34% to 52% and OS from 51% to 69%.46-50

We observed a significantly lower NRM and better PFS and OS rates in patients who received low-dose TBI. The assumption is that this regimen provides sufficient immunosuppression with lower risk of regimen-related toxicity, thus accounting for its overall beneficial effect. RIC regimens not incorporating low-dose TBI resulted in outcomes comparable to that of myeloablative therapies. The GVL effect appears to be sufficient after low-dose TBI, on the basis of the observed risks of relapse and progression in this series.

Immunosuppression with ATG/ALG was associated with poor outcomes in a univariate analysis. However, because of the correlation with myeloablative conditioning regimens in the majority of cases in our series, the role of ATG/ALG was not appropriately addressed and should be further evaluated in a more homogenous population.

In this multicentric based-registry analysis, we were not able to analyze the association of center effect with outcomes because of the small number of patients included per center and the changes over time of the conditioning regimens, even in a same center.

One of the intriguing findings of this study is the possible enhanced GVL effect associated with double UCBT. Such a finding also has been observed in adults with various hematologic malignancies.51,52 Whether this apparent enhancement of GVL is simply the result of a greater state of alloimmune immune cell activation or the greater use of more HLA-disparate UC B units has yet to be determined.

Incidence of acute GVHD was higher in patients older than 41 years, but age was not associated with PFS. One could argue that this observation could be related to a stronger GVL effect. However, there was no statistical association between GVHD and PFS, despite a trend of improved PFS in patients presenting GVHD. The GVL effect after UCBT in patients with lymphoma needs to be analyzed in a larger series of patients and with a longer follow-up.

In conclusion, UCBT is a viable alternative in adult patients with advanced lymphoma and CLL who lack an HLA-matched donor, with particularly encouraging results for patients with chemosensitive disease receiving low-dose TBI-based conditioning regimens and adequate cell doses. On the basis of our findings, several important strategies should be considered: (1) greater use of less toxic RIC regimens, such as those containing low-dose TBI, (2) better selection of UC B units, and (3) broader use of double UC BT.

Unrelated cord blood transplants in adults with hematologic malignancies

Background and Objectives. We analyzed outcomes and risk factors after unrelated cord blood transplantation (CBT) in adults with hematologic malignancies.

Design and Methods. One hundred and seventy-one patients were transplanted after 1997. Their median age was 29 years (15-55), and the median follow-up time was 18 months (2-71). Most patients had acute or chronic leukemia (n=142, 83%), 91 (53%) were transplanted in advanced phase and an autologous transplant had failed in 32 (19%). Most patients (87%) received an HLA-mismatched cord blood unit with 1-2 HLA disparities. At infusion, the median number of nucleated cells and CD34+ cells was 2.1x10^6/kg and 1x10^5/kg, respectively.

Results. The cumulative incidence of neutrophil recovery at day 60 was 72±3% with a median of 28 days (11-57). A higher neutrophil count and use of hematopoietic growth factors were independently associated with faster neutrophil recovery. The cumulative incidence of grade III-IV acute graft-versus-host disease was 32±4% and this complication was not associated with the number of HLA mismatches. The 2-year cumulative incidence of chronic graft-versus-host disease, transplant related mortality and relapse were 36±10%, 51±4% and 22±4%, respectively. At 2-years, disease-free survival for patients transplanted in early, intermediate and advanced phases of disease was 41±9%, 34±10% and 18±4%, respectively. In multivariate analyses, advanced disease status was an adverse factor for relapse and disease-free survival.

Interpretation and Conclusions. Unrelated CBT is a clear alternative for adults with hematological malignancies lacking an HLA-matched related or unrelated donor. The choice of units containing a higher neutrophil count and a policy of earlier transplantation are likely to provide better results.

Key words: unrelated cord blood transplants, adults, hematologic malignancies.

Haematologica 2006; 91:223-230

©2006 Ferrata Storti Foundation

Umbilical cord blood from unrelated donors represents a clear alternative source of hematopoietic progenitor cells to bone marrow for children lacking an HLA identical sibling. The lower risk of graft-versus-host disease (GVHD) in the cord blood transplant setting than in bone marrow transplants permits less stringent criteria for donor-recipient HLA matching. Moreover, cord blood units are acquired faster than bone marrow from unrelated donors, which is particularly relevant for patients who require an urgent transplant. However, despite the high proliferative potential of cord blood hematopoietic progenitors, the lack of nucleated and CD34+ cells in a single cord blood unit has represented the major limitation to the use of unrelated cord blood transplantation (CBT) in adults, due to concern about the risk of graft failure and delayed engraftment. However, pilot studies, including small series of adults transplanted from unrelated, mostly HLA mismatched, cord blood donors, reported encouraging results in terms of engraftment, incidence of GVHD, risk of relapse and event-free survival. As CBT has been increasingly used for adults, two independent studies have recently compared the results of unrelated CBT and bone marrow transplantation in adult patients with acute leukemia. Despite some differences between the two analyses, in both studies the main outcomes (relapse, transplant-related mortality, leukemia-free survival) were similar in the patients receiving the two different types of transplants.

Herein, we report a retrospective analysis of results and risk factors for different outcomes in 171 unrelated cord blood transplants performed between January 1998 and January 2005 in adults with hematologic malignancies and reported by 69 centers to the Eurocord, a European co-operative clinical-trial group for CBT of the European Blood and Marrow Transplantation (EBMT). Out of 171 patients, 45 with acute myeloblastic leukemia and 53 with acute lymphoblastic leukemia were included in a previously published study produced by Eurocord.

Design and Methods

Data collection and selection of patients

Eurocord is an international registry operating on behalf of the EBMT. Participation is open to both European and non-European centers conducting CBT. Eurocord works in...
close collaboration with Netcord banks. This retrospective analysis is based on data reported to the Eurocord Registry from European and non-European centers through a standardized questionnaire concerning the characteristics of patients, donors, diseases and grafts as well as transplant outcomes, reviewed by two physicians and checked for computerized errors to ensure data quality. The study included patients undergoing unrelated CBT between January 1996 and January 2003 who met the following criteria: (i) age ≥15 years old, (ii) diagnosis of a hematologic malignancy, (iii) conditioning with a myeloablative regimen, (iv) transplant with a single, non excess expanded cord blood unit and (v) not having received a previous allogeneic transplant. All patients gave informed consent for CBT according to the Declaration of Helsinki. The present study was approved by the Eurocord institutional review board.

**Patient, donor and transplant characteristics.**

The main patient, disease, transplant characteristics are reported in Table 1. A total of 171 patients reported from 63 centers in 13 countries (see Appendix) met the selection criteria. At the time of CBT, 82 patients (19%) with acute leukemia [ALL]; 3 with chronic myeloid leukemia [CML]; 7 with non-Hodgkin's lymphoma [NHL]; and 3 with myelodysplastic syndrome [MDS] had previously undergone an autologous transplant. Ninety-one patients (53%) were transplanted in an advanced phase of the disease (defined as AL in third or subsequent complete remission or refractory AL in [n=65], MDS [n=16], CML in blast crisis [n=6], or lymphoma in partial remission or in resistant relapse [n=9]). The median time from diagnosis to CBT was 13.4 months (range, 2.6-247), and median time from attainment of last complete remission to CBT in patients with AL transplanted in remission (n=75) was 129 days (range, 7-901). The median follow-up for survivors after transplant was 18.1 months (range, 1.5-70.7).

Donor-recipient compatibility for HLA-A and -B antigens was defined by serology, whereas the HLA-DRB1 match was defined at the antigen level by low-resolution DNA techniques and at the allelic level by high-resolution DNA techniques. HLA-DRB1 high resolution data were missing for only four (2.3%) donor-recipient pairs. The degree of matching was classified by the number (0, 1, 2 or 3) of HLA antigens or allelic disparities (Table 1). The HLA incompatibility involved antigens of class I in 65 pairs, class II antigens in 29 and both class I and class II antigens in 55 donor-recipient pairs. Most cord blood units (n=157, 92%) came from Netcord banks which followed the FACT-Netcord standards for collecting, freezing and storing cord blood units; the procedures for thawing and washing cryopreserved cord blood units followed the method described by Rubinstein et al.29

The median number of nucleated cells counted at the time of cord blood collection or freezing and infused are reported in Table 1. After thawing, there was a median loss of 24% (range: 4-52) of the nucleated cells CD34+ cell quantification at the time of infusion, calculated through non-standardized methods among centers and reported for only 124 cord blood units, was 1.0±0.1 cells (range: 0.02-15). Conditioning regimens differed according to centers, type of disease and disease status. An irradiation-based regimen with total body irradiation or total lymphoid irradiation was administered to 110 (64%) patients, while 61 patients were conditioned with combined chemotherapy only. In 129 (75%) cases the preparative regimen included an anti-thymocyte or anti-thymocyte globulin or a monoclonal anti-T-cell antibody. Most patients (n=117, 68%)

received cyclosporine combined with steroids as prophylaxis against GVHD (Table 1).

Definitions of endpoints

Neutrophil engraftment. Myeloid engraftment was defined as a recovery of an absolute neutrophil count of at least 500/mm³ on 3 consecutive days. Platelet recovery was defined as the time needed to reach a sustained platelet count of at least 20,000/mm³ without transfusion support for 7 consecutive days. Absence of hematopoietic recovery at day 60, second transplantation or autologous hematopoietic reconstitution was considered as failure of engraftment.

Graft-versus-host disease. Starting on day 1, acute GVHD was scored according to the standard criteria² and counted only for grades II-IV. Patients surviving more than 100 days after transplant with sustained donor hematopoiesis were considered at risk for the development of chronic GVHD.²⁴

Relapse. Time to relapse was measured from the date of CBT to the date of disease recurrence as defined by morphological evidence of the neoplastic clone in either the bone marrow or in any extramedullary site. Patients who died in complete remission were censored at the date of death.

Transplant-related mortality. This was defined as all causes of death occurring at any time after CBT and not related to the underlying malignant disease.

Overall survival. Overall survival was measured as the time interval between the date of CBT and the date of death of any cause or the date of the last follow-up for survivors.

Disease-free survival. This was defined as the time interval between the date of CBT and the date of relapse or death in complete remission, whichever occurred first.

Statistical analysis

Variables related to the patients and donors (age, sex, sex match, cytomegalovirus serology, ABO compatibility, number of HLA disparities, disease- (acute and chronic leukemia versus other diseases, status at transplant, previous autologous transplant), and transplant (n. of nucleated cells at freezing and infused per kg, conditioning regimen, GVHD prevention) variables were analyzed for their potential prognostic value on each of the aforementioned endpoints. Univariate and multivariate proportional hazards

Risk factors for acute GVHD and platelets were not selected in the Cox model. CML, chronic myeloid leukemia; GVHD, graft-versus-host disease.

regression models were used to identify independent risk factors for death and disease-free survival by means of log-rank tests and Cox proportional hazards models.2× For assessment of factors predicting neutrophil and platelet recovery, acute GVHD (grade II-IV), chronic GVHD, relapse and transplant-related mortality, a similar methodology was used in a competing risks setting, death being treated as a competing event.2× Univariate and multivariate analyses were then performed using Gray’s test and the proportional subdistribution hazard regression model of Fine and Gray.2× A stepwise backward procedure was used to construct a set of independent predictors for each end-point. All predictors with a p-value below 0.10 were considered, and sequentially removed if the p-value in the multiple model was above 0.05. All tests were two-sided. The type 1 error rate was fixed at 0.05 for factors potentially associated with time-to-event outcomes. Since we found that the sex of the recipient was selected as a prognostic factor for transplant-related mortality and survival in a multivariate analysis without a clinical explanation, we also performed an analysis comparing recipient, donor, disease- and transplant-related factors according to recipient’s gender. All analyses were carried out using the cmprsk package (developed by Gray, June 2001) on Splus 2000 software and SPSS software.

Results

Neutrophil and platelet recovery

The cumulative incidence of neutrophil recovery at day 60 was 72±3% and the median time to reach an absolute neutrophil count of at least 500/mm³ was 28 days (range, 11-57) (Figure 1A). Of the 13 patients who did not recover neutrophil counts at day 60, four engrafted later between day 66 and 80 after transplant, five underwent a second transplant, three experienced autologous hematopoietic reconstitution, and one died in aplasia.

Twenty-six patients died early after transplant and before the median date of engraftment in the overall series (between days 4 and 28), thus the graft failure rate was 9% (18 out of 145 evaluable cases). In univariate analysis, a number of nucleated cells greater than 2.7×10^9/kg (81±5% vs 65±5%; p=0.02) at the time of freezing and early status of disease at transplant (89±5% for early vs 62±7% for intermediate vs 70±5% for advanced; p=0.05) were the two factors favorably affecting the probability of neutrophil recovery. In multivariate analysis, factors found to be significantly associated with neutrophil recovery were the number of nucleated cells at collection or freezing (relative risk [RR] 2.02, 95% confidence interval [95% CI]: 1.50 to 5.15; p=0.002) and the use of hematopoietic growth factors within one week after transplant (RR: 2.15, 95% CI: 1.81 to 3.47, p=0.002) (Table 2). The cumulative incidence of platelet recovery at day 180 was 46±4% and the median time to reach a platelet count of at least 20,000/mm³ was 84 days (range, 22-176) (Figure 1B). None of the analyzed factors was associated with the probability of platelet recovery in either univariate or multivariate analysis.

Acute and chronic graft versus host disease

Acute GVHD was counted as absent or grade 1 in 36 (21%) patients, grade II in 27 (16%), grade III in 15 (9%) and grade IV in 15 (7%). The cumulative incidence of acute GVHD at 100 days after CBT was 32±4% (Figure 1C). In univariate analysis, acute GVHD greater or equal to grade II was found to be more frequently associated with a diagnosis of CML than with AL or other malignant diseases (respectively, 50±8% vs 25±2% vs 36±7%, p=0.015). No other variables, including number and class distribution of the HLA disparities, were statistically associated with the incidence or severity of acute GVHD. In multivariate analysis, no factor was found to significantly influence the development or severity of acute GVHD. Chronic GVHD was observed in 34 of 92 patients at risk (limited in 18 and extensive in 16) with a cumulative incidence of chronic GVHD at 2 years of 36±10% (Figure 1D). In multivariate analysis, no factor showed a significant association with the occurrence of chronic GVHD.

Relapse

The cumulative incidence of relapse at 2 years was 22±4% for all patients (Figure 1E). It was 24±5% for patients with AL, 5±5 % for those with CML, and 31±12% for those with MDS. Three out of 13 patients transplanted for lymphomas relapsed. According to the disease status at transplant, the cumulative incidence of relapse at 2 years was 16±7% for patients transplanted in an early phase of the disease, 22±12% for those transplanted in intermediate status and 25±5% for those transplanted in advanced phase disease. In the Cox model, only two factors were significantly associated with an increased risk of relapse: diagnosis other than CML (RR 0.01, 95% CI: 0.01 to 0.69; p=0.02) and advanced disease status at the time of unrelated CBT (RR: 1.47, 95% CI: 1.00
to 2.1; p=0.04).

**Transplant-related mortality and causes of death**

The 2-year cumulative incidence of transplant-related death was 51±4% (Figure 1F). In univariate analysis, the incidence of transplant-related mortality was significantly higher in patients older than 29 years (59±5% vs 43±6%, p=0.02), in females (60±5% vs 45±6%; p=0.01), in patients transplanted in advanced phase (57±5% vs 45±6%; p=0.04) and in those with CML compared to those with AML or with other malignant diseases (76±5% vs 44±2% vs 49±7%, respectively; p=0.006). Furthermore, there was a trend for reduced transplant-related mortality in patients receiving cord-blood units containing a higher number of nucleated cells at collection or freezing (>2.6×10^7/kg), as compared to patients receiving a lower cell dose (45±6% versus 56±5%, p=0.06). In multivariate analysis, only two factors remained significantly associated with an increased risk of transplant-related death: age >29 years (RR 1.74, 95% CI: 1.05 to 2.89, p=0.02) and female gender (RR 1.78, 95% CI: 1.13 to 2.79; p=0.01) (Table 2).

**Causes of death.** Of 171 patients, 110 (64%) died and 61 are alive. Of the 110 deaths, 85 (77%) were due to transplant-related causes and most of them (n=68) occurred within 100 days after transplantation. The primary causes of death were disease relapse (n=25; 28%), infection (n=40; 36%), GVHD (n=12; 11%), acute respiratory distress syndrome or interstitial pneumonitis (n=7; 6%), hemorrhage (n=5; 5%) veno-occlusive disease (n=4; 4%); cardiac toxicity (n=3; 3%) multi-organ failure (n=8; 7%) and other causes (n=6; 5%).

**Overall survival and disease-free survival**

For all 171 patients, the 2-year probability of overall survival and disease-free survival was 38±4% and 27±4%, respectively. The probability of being alive without disease at 2 years was 41±3% and 34±10% for patients transplanted in an early and intermediate phase of disease, respectively (38±7 for early and intermediate phases of the disease) and 18±4% for patients transplanted in advanced phase (p=0.001, Figure 2). Table 3 shows the results of univariate analysis for disease-free survival. In multivariate analysis, advanced disease status at the time of CBT (RR 1.69; 95% CI: 1.1 to 2.5; p=0.015), female gender (RR 1.47; 95% CI: 1.01 to 2.17; p=0.05) and ABO major incompatibility (RR 1.55; 95% CI: 1.05 to 2.29; p=0.03) were identified as significant factors unfavorably affecting disease-free survival (Table 2). The relevance of patients’ gender in influencing the outcomes led us to analyze the frequency of all other variables according to the patients’ sex. No variables, including patient-, donor-, disease- and transplant-related factors or causes of death were found to be statistically different when analyzed according to patients’ gender (data not shown).

**Discussion**

This registry-based study confirms that cord blood represents a source of hematopoietic stem cells that can be successfully used for unrelated transplant not only in children but also in adults. Furthermore, the study provides information on outcomes and prognostic factors that should be taken into account when an unrelated cord blood graft is available for an adult patient. The reported experience on CBT in adults supports the feasibility of this strategy and very encouraging results have been obtained in single institutions.14,15 Moreover, two recent, registry-based studies showed similar outcomes for patients with acute leukemia transplanted with cord blood or bone marrow from unrelated donors.3,4 In the present analysis, the Eurocord Group extended the study to a large series of adult patients with different hematologic malignancies transplanted in 63 centers after 1997. In a previous study of 550 CBT recipients with malignant hematopoietic disorders, we showed that transplant-related mortality has been decreasing since 1998, due to better selection of cord blood units based on cell dose and number of HLA disparities.17 To avoid possible biases due to the study period we decided to include only those patients transplanted after 1998 in the present analysis.

In this study the time to hematopoietic engraftment was longer after CBT than that usually reported for HLA matched unrelated bone marrow transplants, in which the median number of nucleated cells infused is about ten times higher. However, the kinetics of engraftment in adults was similar to that reported for children undergoing CBT,18-20 in whom the cell dose infused is about 10-fold higher, due to their smaller size. Encouraging outcomes have been reported for adults with acute myeloblastic leukemia or MDS receiving CBT at a single center in Japan.21 The lower genetic diversity and the smaller size of the Japanese population may account in part for these results. The best results were achieved in patients grafted with ≥2×10^8 nucleated cells/kg of recipient’s body weight. This threshold of nucleated cord blood cells at infusion is recommended by Eurocord.23 Although the number of CD34+ cells and the number of colony-forming cells have been recognized to affect engraftment and patients’ outcomes significantly in children and adults, in this retrospective multicenter study, the low number of evaluable patients and the absence of standardized laboratory methods prevented us from assessing the possible impact of...

OPEN FORUM

Ethical and legal aspects of placental/cord blood banking and transplant

E Gluckman* for Eurocord Netcord Organisation

*Project leader of Eurocord; Head, Bone Marrow Transplant Unit; Hôpital Saint Louis, Paris, France

Introduction

As more than 1000 unrelated cord blood transplants (CBT) have been performed worldwide, the number of cord blood banks (CBB) has been increasing with more than 25,000 units collected and available for unrelated donor haematopoietic stem cell transplant searches. The main advantages of CBT are the large donor pool, the low incidence of viral infection at birth, the low incidence of graft versus host disease (GVHD) due to the immune immaturity of the new-born and the increased speed of search as the units are readily available, having been previously tested and cryopreserved. Since placental/umbilical cord blood banking for unrelated transplantation is a relatively new field, it is very important to set up minimum standards and to reach an international agreement on aspects essential for the safety of the donor and the mother and the opportunity to offer the best possible chance for the recipient. For this purpose, Netcord was founded in 1998. It currently includes experienced placental/cord blood banks (Barcelona Spain, Denver USA, Duesseldorf Germany, Leiden Netherlands, London UK, Milan Italy, New York, NY, USA, Paris France, St Louis USA and Tokyo Japan). The joint inventory available on a single research file currently contains 28,650 validated units; 1017 have been transplanted to paediatric and 272 to adult patients. The Board of directors of Netcord has developed a detailed set of standards for cord blood banking. Eurocord is closely linked to Netcord: it is an international Registry of CBT which has already collected and analysed more than 500 CBT and performs analysis of the clinical results and implements clinical studies in order to evaluate the efficacy of CBT.

Since the first cord blood transplant was performed in 1998, several ethical issues have been raised concerning the status of cord blood haematopoietic stem cells, the issue of consent and ownership and the problems of privacy and commercialism.1-9

Status of umbilical cord blood cells

In contrast with other sources of haematopoietic stem cells which are collected for allogeneic transplant on a living consenting donor, cord blood is considered as a discarded product at the completion of pregnancy. According to different laws, cord blood cells can be considered as a blood product, a tissue or an organ transplant. Because of this difference, some might argue that the collection of cord blood cells should be governed by rules which do not require that an individual gives permission for the use of discarded tissues. In fact, because of the necessity to collect information on the medical status of the mother and the infant, to perform tests for infectious or genetic diseases and because the cells are used for a medical purposes on an anonymous patient, all agreed upon the necessity of requiring an informed consent before the delivery which is accepted and signed by the mother and if possible by both parents. Usually, the rules are those observed for unrelated bone marrow donors which stipulate that the gift is anonymous and that there will not be any financial compensation.

Consent, safety and privacy

According to Netcord standards, the following procedure must be followed for consent and ensuring the safety of the products delivered to the patients:

- Information about the program should be made available to the mother during the antenatal period.
- Informed written consent from the mother is required before, or less than 48 h after, collection.

The mother’s informed written consent must authorise the following:

- Storage of her CB for use by any patient who requires it.
- The disposal by the bank of units not meeting the criteria for banking after removing the link to the individual mother.
• The sample may be used for testing, research or for other valid purposes.
• The collection of a sample of her blood for testing for infectious diseases such as HIV and reporting back to her the results of this testing and that of the baby's blood through a physician of the mother's choice. This sample shall be obtained no more than 3 days preceding the delivery or 30 days following it. Similar tests shall be done on an aliquot of the baby donor's CB serum or plasma.
• The collection of data regarding her personal and family histories with focus on the existence of risk factors or a possible exposure to infectious and genetic diseases of potential importance in the context of stem cell allotransplantation.
• A review of the mother's hospital chart and that of the baby for further antecedents suggestive of risk factors and to record the diagnoses made prior to discharge.
• The transfer of data relating to the cord blood donation anonymously to transplant centers or registries world-wide either on paper or electronically.
• The storage of appropriate samples including cells and DNA for future testing.
• The collection of cord blood during the 3rd stage of labour when that is the strategy chosen for collection.
• The collection of a swab sample of baby saliva for CMV culture if this is the program method for neonatal screening.

Minimum tests for infectious diseases screening include bacteriological screening for aerobes and anaerobes in each unit collected before freezing. The following tests are mandatory on the mother: HbsAg, anti HCV, anti HIV 1/2, anti CMV-IGM, syphilis. In addition, national recommendations to test for HIV PCR or for antibodies against infectious diseases of regional relevance such as anti CMV IgG, HTLV 1/2, toxoplasma, EBV and parvovirus B 19 will be performed under the respective SOP of Netcord banks. The same testing shall be performed on the CB unit itself prior to release.

Information to the patients (from Eurocord protocol)

Why use cord blood?

It was demonstrated, several years ago, that the blood present in the placenta at birth is enriched in haematopoietic stem cells. The number of haematopoietic stem cells present in cord placental blood is equivalent to the amount given in a bone marrow transplant.

These cells also have the advantage of being less immunologically reactive; they are expected to give less graft versus host disease than adult cells. For this reason a complete HLA identity is not an absolute prerequisite for indication of a cord blood transplant.

How is cord blood collected?

After birth, the cord is clamped and resected. Blood is immediately collected in the umbilical vein. After collection, cord blood is transported in a bank where it is frozen in liquid nitrogen after a sample has been taken for testing.

What are the tests performed?

The mother signs an informed consent for the donation of cord blood cells. It is explained that cord blood donation is anonymous and that the mother cannot receive any payment for her donation. If a haematopoietic stem cell transplant is needed in her family, she cannot claim any ownership of her cord blood. A questionnaire is given to enquire about family history in order to detect any criteria for exclusion of the donation including genetic or infectious diseases. In addition, the mother is tested for infectious diseases before and after donation. After collection, the cord blood is tested for HLA typing, number of cells and infection. The results of HLA typing are sent to a Registry for utilisation. When cord blood is selected for a patient, HLA typing and infectious disease markers are repeated on a sample which is kept separately at the collection for further testing. All efforts are made to avoid any risk of transmission of genetic or infectious disease transmission with the transplant, in agreement with current regulations.

Why a cord blood transplant?

In your case, your physician thinks that an haematopoietic stem cell transplant is the best treatment of your disease. An HLA compatible donor was not found in your family nor in international registries of unrelated bone marrow donors. For this reason, we have selected a cord blood as closely matched as possible.

Modalities of transplantation

Utilisation of cord blood cells does not modify the usual technique of haematopoietic stem cell transplant which involves conditioning, graft versus host disease (GVHD) and infectious disease prevention. Placental blood is thawed in a water bath and infused immediately through a central venous catheter.

The main risks are rejection, GVHD and infectious complications. On long-term follow-up, other complications can occur, including relapse or chronic GVHD. These complications can also occur after a standard bone marrow transplantation.

This is a research protocol. More than 1200 patients have been transplanted with familial or unrelated cord blood world-wide; the first cord blood transplant was performed in 1988. Preliminary results are very
encouraging but more cases and more follow-up are needed for an analysis of long-term results.

Information concerning your case will be sent to a central Registry for analysis of the results. Your name will not appear and the information will be kept confidential.

Commercialism

Eurocord has been very active in opposing a patent on cord blood cells. This patent covered "haematopoietic stem and progenitor cells of neonatal and fetal blood and the therapeutic uses of such cells upon thawing." The patent has been successfully opposed by Eurocord because of lack of novelty, lack of an inventive step and lack of enabling disclosure (decision of the European Patent Office in Munich, 8 June 1999). The patent office was convinced by several papers describing similar techniques that predated the patent. The patent has already been rejected in the USA and in Japan. This result has been obtained on legal grounds but it is also an ethical victory as it overturns a patent on human tissues.

Reports of successful CBT captured the interest of parents who expressed an interest in preserving a cord blood unit (CBU) in the event that either the newborn or a sibling might one day require a transplant. Occasionally, parents even plan pregnancy as a means to develop access to a transplant and intend to use the CBU almost immediately. Otherwise, since transplant is used to treat mostly rare diseases, the enthusiasm to maintain storage of a self or family-directed CBU is often diminished over time due to cost considerations.

Mostly commercially motivated CBT banks have sought participation from expectant mothers who agree to pay for storage of a CBU from their newborn infant. The infrequent utilisation of a related CBU does minimise its utility. The probability that the cord blood will be of use in a family with no history of blood disease approaches zero, moreover, one's own stem cells may be less effective in treatment than those of an unrelated donor. In addition, it has been shown recently that leukemic cells were found at birth in children diagnosed with acute leukemia for periods as long as 5–10 years. This demonstrates the latency of the disease and indicates that some leukemias can be acquired in utero. Furthermore, mounting costs have cast a doubt on the viability of such banks. There is an increasing call from the public sector to encourage volunteer donation of CBU to banks responding to the need of the unrelated general public. A central policy issue is whether obstetricians should encourage patients to choose the storage of placental blood for their own use (by for-profit companies) or to donate placental blood for the others (through not-for-profit organisations).

Economic issues are a very important consideration in the development of cord blood banks, the total cost of a single unit delivered to a patient has been estimated at 15 000 euros. This has to be considered carefully when planning the development of cord blood banks for allogeneic use. The main advantage of cord blood transplant is the decrease of GVHD, which opens the way to performing mismatched transplants while the results of unrelated bone marrow transplants are strongly dependent on HLA class I and II identity. This factor explains why, with a total of more than 5 million bone marrow donors available world-wide, the probability of finding a perfect match is only 50% in the white caucasian population while the probability of finding a 1 or 2 antigen mismatched cord blood donor in a bank of 25 000 units is close to 100%, providing that the number of cells be superior to 2 x 10^9/kg patient body weight.

Clearly, cord blood transplant is still an experimental procedure which requires co-operative protocols, carefully designed prospective studies, evaluation of the results and comparison with other therapies. Eurocord and Netcord are working together to provide the best unit to the patient in order to deliver the best possible care to all patients who need a transplant.

Will stem cells in cord blood, amniotic fluid, bone marrow and peripheral blood soon be unnecessary in transplantation?

Edwards RG, Hollands P.

Reproductive BioMedicine Online, Duck End Farm, Dry Drayton, Cambridge CB23 8DB, UK. rge@rbmonline.com

There are now various sources of stem cells. Those derived from blastocysts, named embryo stem (ES) cells, have attracted most attention and are highly multipotent. Human cord blood became widely used as a source of stem cells with differing properties to ES cells and their therapeutic application has grown steadily as they are stored in increasing numbers of stem cell banks. Other sources of human stem cells are derived from peripheral blood and amniotic fluid. They may arise from a common origin in epiblast. This review stresses the use of cord blood stem cells, but describes new approaches which may supersede the use of most stem cells. The advantages and disadvantages of these various classes are described in relation to potential methods involving gene conversion to change somatic cells to ES cells.

Is prenatal HLA typing of uncultured amniocytes before the collection of related allogenic cord blood helpful?

Abstract The collection of related allogenic cord blood is gaining increasing importance in families with one child affected by haematopoietic disease. Within a family, there is only a 25% chance of a full HLA match between siblings. 50% of all collected cord blood samples cannot be used because of poor quality. Because of this, the determination of HLA type is useful for planning the collection of related allogenic cord blood transplants. We studied whether HLA typing is possible during late pregnancy if amniocentesis has not been performed during the first trimester. HLA-A, -B and -DRB loci were detected in amniotic fluid, as well as in corresponding cord blood and maternal blood using PCR-SSP. For the first time, HLA typing was performed from uncultured amniocytes. Unambiguous results were obtained from all samples. Fetal HLA-genotype in amniotic fluid was confirmed by typing results from corresponding cord blood. HLA typing of uncultured amniocytes during late pregnancy is a reliable and fast method. For the first time, prenatal HLA typing by amniocentesis after week 38 of gestation is possible in less than 8 h and without fetal risk.

Keywords Stem cell transplantation · Prenatal HLA typing · Uncultured amniocytes

Introduction

Molecular genetic techniques for the examination of amniocytes from amniotic fluid are not only an essential tool in prenatal diagnostic for chromosomal aberrations but can also be used for prenatal determination of the HLA-genotype.

Allogenic transplantation of haematopoietic stem cells from umbilical cord blood of HLA identical siblings (related allogenic cord blood) is a therapeutic concept of increasing importance. In families with one child affected by haematopoietic disease, prenatal diagnosis of the HLA-genotype has moved into the centre of interest [1, 2].

In 25% of cases, the donating sibling has a complete HLA match with the affected sibling, whereas, in 50%, the use of an HLA-haploidentical CB has to be discussed critically with the transplant centre. In 25%, transplantations cannot be performed because of HLA-incompatibility.

If HLA typing has not been done until the day of delivery, there is the danger that a potentially curative transplant cannot be used because of inadequate precautions.

In the present study, we examined, for the first time, the possibility of fetal HLA typing from uncultured amniocytes during the last trimester and discuss clinical consequences.

Materials and methods

Amniotic fluid samples were collected during planned caesarean sections after week 38 of gestation. It was possible to collect nine portions of 22–25 ml, while one portion contained only 4 ml of amniotic fluid. Amniotic fluid samples were examined together with corresponding umbilical cord blood and maternal blood. Among these ten specimens were two twin pregnancies with different types of placenta. One of these was monochorionic, the other one dichorionic.

Amniotic fluid samples were stabilised by EDTA containing buffer solution. One sample from a singleton pregnancy showed a slight contamination by maternal blood. Amniotic fluid was centrifuged at 1000 x g for 10 min. The cell pellet was resuspended in 200 μl PBS (phosphate buffered saline; Gibco BRL). The QIAamp DNA blood mini kit (Qiagen, Hilden, Germany) was used to isolate DNA from 200 μl amniocyte suspension, as well as from corresponding 200 μl maternal blood and 200 μl cord blood samples. DNA was recovered from the spin columns by using 220 μl 1 M TRIS-HCL pH 8.3. DNA quality was evaluated by estimating the mean molecular weight and the presence of degradation products. PCR-SSP – (polymerase chain reaction – sequence specific primers) low resolution typing of HLA-A, -B and -DRB loci was per-

Prenatal HLA typing of uncultured amniocytes prior to the collection of related allogeneic cord blood.

Bugert P, Zieger W, Klüter H, Eichler H.

Institute of Transfusion Medicine and Clinical Immunology, Red Cross Blood Service of Baden-Württemberg, Mannheim, Germany.

DNA samples isolated from corresponding uncultured amniotic fluid, cord blood and maternal blood (n=5) were subjected to low resolution typing of the HLA-A, -B and -DRB loci by the polymerase chain reaction using sequence-specific primers (PCR-SSP). Furthermore, the effect of ethylene diamine tetraacetate disodium salt (EDTA) on the quality of genomic DNA isolated from amniotic fluid samples after long-term storage was evaluated. Unambiguous results of HLA typing could be achieved from all amniotic fluid samples stabilized with EDTA. PCR-SSP typing failed in DNA samples from amniotic fluid without the addition of EDTA. In all cases the fetal HLA type could be confirmed by the result from the corresponding cord blood typing. Contamination with maternal DNA led to additional weak PCR-SSP bands in one case, but data interpretation was still unambiguous. Reliable fetal HLA typing can be achieved directly from amniotic fluid and culturing of amniocytes is not required.

Liver stem cells: a scientific and clinical perspective.

Dan YY, Yeoh GC.

Department of Medicine, Yong Loo Lin School of Medicine, National University of Singapore, National University Hospital, Singapore. mdcddy@nus.edu.sg

The promise of liver stem cells lies in their potential to provide a continual and readily available source of liver cells that can be used for gene therapy, cellular transplant, bioartificial liver-assisted devices, drug toxicology testing and use as an in vitro model to understand the developmental biology of the liver. Both the rodent and human embryonic stem cell, bone marrow hematopoietic stem cell, mesenchymal stem cell, umbilical cord blood cell, fetal liver progenitor cell, adult liver progenitor cell as well as the mature hepatocyte have been reported to be capable of self-renewal, giving rise to daughter hepatocytes both in vivo and in vitro. These cells can repopulate livers in animal models of liver injury and seemingly improve liver function. However, significant challenges still exist before these cells can be used in humans. These include lack of consensus in immunophenotype of liver progenitor cells, uncertainty of the physiological role of reported candidate stem/progenitor cell, practicality in obtaining sufficient quantity of cells for clinical use and concerns over ethics, long-term efficacy and safety. Current molecular techniques of stem cell identification are confounded by cell fusion, horizontal gene transfer, incomplete differentiation and fetal microchimerism. Reports of stem cell transplantation and phase 1 trials of bone marrow transplantation in humans for liver diseases are exciting but require more robust verification. We review the evidence for various candidate stem cells, human clinical trials reported to date and highlight the challenges facing clinicians in their quest to use liver stem cells to save lives.

Phenotypic and functional analysis of human fetal liver hematopoietic stem cells in culture.

Rollini P, Paes-Van't Hull E, Kaiser S, Kapp U, Leyvraz S.

Centre Pluridisciplinaire d'Oncologie, University Hospital, Lausanne, Switzerland. pierre.rollini@insel.ch

Steady-state hematopoiesis and hematopoietic transplantation rely on the unique potential of stem cells to undergo both self-renewal and multilineage differentiation. Fetal liver (FL) represents a promising alternative source of hematopoietic stem cells (HSCs), but limited by the total cell number obtained in a typical harvest. We reported that human FL nonobese diabetic/severe combined immunodeficient (NOD/SCID) repopulating cells (SRCs) could be expanded under simple stroma-free culture conditions. Here, we sought to further characterize FL HSC/SRCs phenotypically and functionally before and following culture. Unexpanded or cultured FL cell suspensions were separated into various subpopulations. These were tested for long-term culture potential and for in vivo repopulating function following transplantation into NOD/SCID mice. We found that upon culture of human FL cells, a tight association between classical stem cell phenotypes, such as CD34(+) /CD38(-) and/or side population, and NOD/SCID repopulating function was lost, as observed with other sources. Although SRC activity before and following culture consistently correlated with the presence of a CD34(+) cell population, we provide evidence that, contrary to umbilical cord blood and adult sources, stem cells present in both CD34(+) and CD34(-) FL populations can sustain long-term hematopoietic cultures. Furthermore, upon additional culture, CD34-depleted cell suspensions, devoid of SRCs, regenerated a population of CD34(+) cells possessing SRC function. Our studies suggest that compared to neonatal and adult sources, the phenotypical characteristics of putative human FL HSCs may be less strictly defined, and reinforce the accumulated evidence that human FL represents a unique, valuable alternative and highly proliferative source of HSCs for clinical applications.

SPECIAL REPORT

The EBMT activity survey 2007 with focus on allogeneic HSCT for AML and novel cellular therapies

A Gratwohl1, H Baldomero1, A Schwendener2, V Rocha3, J Apperley4, K Frauendorfer3 and D Niederwieser3, for the Joint Accreditation Committee of the International Society for Cellular Therapy ISCT and the European Group for Blood and Marrow Transplantation EBMT (JACIE)

1Hematology, Department of Medicine, University Hospital, University of Basel, Basel, Switzerland; 2Institute for Operations Research and Computational Finance, University of St Gallen, St Gallen, Switzerland; 3Acute Leukemia Working Party EBMT, Hôpital St Louis, Paris, France; 4Department of Haematology, Hammersmith Hospital, London, UK and 5Department of Haematology, University Hospital, Leipzig, Germany

The 2007 report describes the current status of HSCT activity in Europe, highlights the increasing role of allogeneic HSCT in treatment of AML and gives the first quantitative information on novel cellular therapies. In 2007, there were 25563 first HSCTs, 10072 allogeneic (39%), 15491 autologous (61%) and 3606 additional transplants reported from 613 centers in 42 countries. The main indications were leukemias (8061 (32%; 89% allogeneic)); lymphomas (14627 (57%; 89% autologous)); solid tumors (1488 (6%; 96% autologous)) and nonmalignant disorders (1302 (5%; 91% allogeneic)). Peripheral blood was the main source of stem cells for autologous HSCT (98%) and the predominant source for allogeneic HSCT (71%). Among allogeneic HSCTs, the number of unrelated donor grafts equaled the number of HLA-identical sibling donor grafts for the first time (47% each). AML was the most frequent indication for allogeneic HSCT (32% of all allogeneic HSCTs), with an increase of 247 (8%). Information on novel cellular therapies was collected for the first time; there were 212 mesenchymal SCTs and 212 HSCTs for nonhematopoietic use. The indications for the latter were cardiovascular disorders (97; 46%), neurological disorders (94; 44%) and tissue repair (21; 10%). These data illustrate the expanding role of cellular therapies.

Bone Marrow Transplantation (2009) 43, 275–291; doi:10.1038/bmt.2009.7; published online 26 January 2009

Keywords: hematopoietic SCT; Europe; transplant rates; acute myeloid leukemia; mesenchymal stem cells; novel cellular therapies

Introduction

The annual European Group for Blood and Bone Marrow Transplantation (EBMT) activity report has become an established instrument to describe the current status of HSCT in Europe to observe trends and to monitor changes in technology use.1 2 It serves as a basis for decision making at the individual patient level as well as for health care agencies in planning and providing the infrastructure for this complex medical technology. In addition to the general description of the number of transplants by indication, donor type and stem cell source, the report has focused each year on specific aspects. The increasing use of cord blood as a stem cell source, the change from BM to peripheral blood or the utilization and integration of unrelated donor transplants were the key topics in the past.3 4 In the 2007 report, information on the use of novel cellular therapies was integrated for the first time. The numbers of mesenchymal SCTs and the numbers of HSCT for nonhematopoietic indications were requested.5 6 The most striking observation in the last year was the increase of allogeneic HSCTs for the treatment of AML and myelodysplastic syndromes (MDS). More detailed information is provided on the pattern of use for this indication.

Patients and methods

Data collection and validation

All participating teams were requested to report their data for 2007 by indication, stem cell source and donor type as listed in Table 1. Data were validated by three independent systems: through confirmation by the reporting team that received a computer printout of the entered data, by selective comparison with MED-A data sets in the EBMT ProMSE data system and by cross-checking with the National Registries. Onsite visits of selected teams were part of the quality control program (www.jacie.org).

Teams
A total of 628 teams in 45 countries (38 European and 7 affiliated countries) were contacted for the 2007 report, of which 613 reported their numbers. This corresponds to a 98% return rate of active teams and includes 509 active EBMRT member teams reporting to the survey. There were 15 teams known to have been performing HSCTs in 2007 that chose not to reply or failed to reply. The teams that were contacted are listed in the Appendix in alphabetical order according to country, city and EBMT center code. According to the information received, there were no bone or marrow transplants performed in Albania, Andorra, Armenia, Georgia, Liechtenstein, Malta, Moldavia, Monaco, Montenegro, San Marino and the Vatican in 2007. The non-European countries participating in the EBMT survey include Algeria, Iran, Israel, Lebanon, Saudi Arabia, South Africa and Tunisia. Their data are included in some of the analyses.

Definitions
Transplant numbers. The EBMT survey focused, as in previous years, on the number of patients treated for the first time with HSCT. 1 Information on additional transplants, for instance, a second, third or fourth HSCT in a patient with a previous HSCT was collected by disease category only for those patients with a planned double autologous after autologous transplants; for all other situations, this information was collected generically only. The following definitions were used: 'retransplants' (autologous or allogeneic) were defined as an unplanned HSCT for rejection or relapse after a previous HSCT; multiple transplants were defined as being part of a planned double or triple autologous or allogeneic transplant protocol. Information on stem cell source was collected as BM, peripheral blood or cord blood. Any transplants with a combination of stem cell source that included cord blood were reported as cord blood HSCTs. BM and peripheral blood combinations were reported as peripheral blood HSCTs. Information on reduced-intensity conditioning (RIC) was collected as a total for each team only and not for individual transplants. Definitions for RIC HSCT followed the recently published definitions.11

Transplant rates. Transplant rates were computed as the number of HSCTs per 10 million inhabitants as defined earlier.12 Transplant rates refer to the number of transplants in a given country compared with its own population. The survey cannot make adjustments for patients who cross borders and receive their HSCT in a foreign country. Population data were obtained from the US Census office (http://www.census.gov).

Economic factors. Economic factors considered in the analysis followed previously defined rules.12 Countries were categorized by their Gross National Income (GNI) per capita according to the World Bank definitions into high income (Austria, Belgium, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Ireland, Italy, the Netherlands, Norway, Portugal, Slovenia, Spain, Sweden, Switzerland and the United Kingdom), middle income (Bulgaria, Croatia, Hungary, Latvia, Lithuania, Poland, Romania, Russia, Serbia, Slovakia and Turkey) and low income countries (Azerbaijan, Belarus, Bosnia and Herzegovina, Macedonia and Ukraine). The latter category refers to the World Bank definition of 'lower middle income' (http://www.worldbank.org). Furthermore, the category of high income was subdivided into a very high-income group, consisting of those countries with a GNI/capita of >40 000 per capita (Denmark, Finland, Ireland, the Netherlands, Norway, Sweden, Switzerland and the United Kingdom).

The non-European countries that traditionally participate in the EBMT activity survey (Algeria, Iran, Israel, Lebanon, Saudi Arabia, South Africa and Tunisia) are included in the overall data presentation. They were not included in the analysis on economic factors. The same applies to Iceland and Luxembourg because of some missing data over the time span.

Statistical analysis. The relation of the macroeconomic factors (GNI/capita) with transplant rates was estimated by ordinary least squares by multiple regressions to measure the coefficient of determination (r²) or explanatory content.

Results
Participating teams
Of the 613 teams reporting HSCTs in 2007, 374 (61%) performed both autologous and autologous transplants; 225 (37%) restricted their activity to autologous transplants, 5 teams (1%) to autologous transplants only and 9 teams (1%) reported having performed no transplants in 2007.
A total of 216 teams (35%) reported fewer than 20 first HSCTs in 2007, 223 teams (37%) between 20 and 50 HSCTs, 121 teams (20%) between 51 and 100 HSCTs and 53 teams (8%) >100 HSCTs.
A total of 142 teams reported at least one cord blood HSCT in 2007 with 33 teams reporting >5.

Numbers of HSCT in 2007
First transplants in 2007. A total of 25 563 first transplants, 10 072 (39%) allogeneic and 15 491 (61%) autologous, were carried out in 2007 (Table 1). Overall, this corresponds to a slight increase in the numbers of HSCT compared with 2006 when there were 25 050 first transplants. The numbers of allogeneic HSCT increased by 4% from 9661 in 2006 to 10 072 in 2007, whereas the numbers of autologous HSCT remained similar at 15 389 in 2006 and 15 491 in 2007.

Additional transplants in 2007. There were 1662 retransplants (810 allogeneic/852 autologous) and 1944 additional planned multiple transplants (71 allogeneic/1873 autologous). Thus, there were a total of 29 169 HSCT procedures, 10 953 allogeneic (38%) and 18 216 autologous (62%), performed in 2007. This corresponds to an overall increase of 105 retransplants (38 allogeneic and 67 autologous) or 7% compared with 2006. A total of 522 transplants were reported as being part of a planned double autologous-
allogeneic HSCT. This corresponds to a decrease of 5% when compared with 2006, where a total of 531 planned double autologous-allogeneic HSCTs were reported. The main indications for the planned double transplant programs were, as in the previous year, multiple myeloma, non-Hodgkin's lymphoma and Hodgkin's disease. The evolution over time in the number of participating teams, numbers of allogeneic and autologous HSCTs is depicted in Figure 1.

Transplant rates in 2007. There were marked differences in transplant rates between European countries and countries affiliated with EBMT as presented in Figure 2. These differences relate to all transplants (Figure 2a) and to autologous HSCT (data not shown). The differences between Eastern and Western European countries have been reported earlier. It is interesting to note that countries with similar total transplant rates had similar transplant rates for allogeneic HSCT as well as for autologous HSCT.

Disease indications in 2007
The indications for HSCT in 2007 are listed in detail in Table 1. The main indications were 'lymphoproliferative disorders' with 14,627 patients (57%), 1,646 patients with allogeneic HSCTs (11%), 12,981 with autologous HSCTs.
(89%); 'leukemias' with 8061 patients (32%), 7153 patients with allogeneic HSCTs (89%), 908 with autologous (11%) HSCTs; 'solid tumors' with 1488 patients (6%), 63 with allogeneic HSCTs (4%), 1425 with autologous HSCTs (96%); and 'nongenetic disorders' with 1302 patients (5%), 1141 with allogeneic HSCTs (91%) and 161 with autologous HSCTs (12%). The latter, autologous HSCT for nongenetic disorders, predominantly includes patients (150) with autoimmune disorders. An additional 85 patients (0.5%), 69 with allogeneic HSCTs and 16 with autologous HSCTs, were reported as 'other indications'.

Stem cell source in 2007

Of the 15491 autologous first transplants, 256 (2%) were BM derived, 15234 (98%) were from peripheral blood stem cells or from combined BM and peripheral blood stem cells and one was from autologous cord blood cells (Table 1). Of the 10072 allogeneic first transplants, 23% were BM, 71% were peripheral blood and 6% were cord blood transplants. This corresponds to a stable proportion of peripheral blood as stem cell source compared with the 70% in 2006. The proportion of peripheral blood as stem cell source varied depending on donor type. It was 73% for HLA-identical sibling donor transplants, 68% for unrelated donors, 74% for HSCT from other family members and 73% for twin donors. Within allogeneic HSCT, the only disease indications with more BM than peripheral blood donors as stem cell source were BM failure syndromes (51% bone marrow) and congenital disorders (59% BM). The proportion of main indications varied as well within the three stem cell sources. Nonmalignant disease represented about a quarter of all indications for BM and cord blood but only a small fraction among the peripheral blood transplants.

Donor type in 2007

For the 10072 allogeneic first transplants, HLA-identical siblings were used as donors for 4716 (47%) of the recipients, other family members for 552 (5%) of the recipients, a syngeneic twin for 52 (1%) of the recipients and an unrelated volunteer donor for 4752 (47%) of the recipients. For the first time since the introduction of the EBMT activity survey, the proportion of unrelated donors was higher than the number of HLA-identical sibling donors.

Use of RIC in 2007

The numbers of RIC HSCT continued to increase from 3530 in 2006 to 3914 in 2007 at the same rate as allogeneic HSCT. RIC was used for 36% of all allogeneic HSCT. This information is collected in a generic way only; no information on disease distribution is possible within the activity survey.

Focus of the 2007 survey

AML. AML was the most frequent indication for an allogeneic HSCT in 2007. The 3269 allogeneic HSCTs for AML correspond to 32% of all allogeneic HSCTs. Together with the 1052 HSCTs for MDS, AML and MDS (4321 allogeneic HSCTs) correspond to 43%. There were more HSCTs for AML in the first CR (58%) compared with later stages of the disease. HSCT for AML in the first CR increased from 1354 in 2004 to 1903 in 2007. This is the highest increase for any indication over the recent years (Figure 3). Allogeneic HSCTs for all patients with AML increased from 2404 in 2004 to 3269 in 2007. In contrast, the numbers of autologous HSCT for AML in the first CR declined from 874 in 2004 to 577 in 2007.

Transplant rates for allogeneic HSCTs in AML and MDS differed significantly between participating countries (Table 2) and ranged from less than 5 per 10 million (several countries) to 135 per 10 million inhabitants in Belgium. Countries with high transplant rates for AML also showed high transplant rates for MDS, but transplant rates for AML did not necessarily parallel transplant rates in general (Figures 2b, c and d). It is interesting to note that transplant rates for AML in the first CR were very homogeneous with a coefficient of variation in high-income countries of 39, indicating a consensus among the participating countries. The transplant rates in high-income countries for MDS varied more with a coefficient of variation of 68; for autologous HSCT for AML (Figure 2d), the variation was even larger with a coefficient of variation of 119.

Similarly, the coefficient of determination for GNI/capita and transplant rates differed significantly between allogeneic and autologous HSCTs. It was high for AML allogeneic HSCT with an explanatory content of $r^2=64.27\%$, MDS allogeneic HSCT with $r^2=66.21\%$ or AML first CR allogeneic HSCT with $r^2=49.54\%$. It was low for autologous HSCT with $r^2=9.91\%$ for AML autologous HSCT, $r^2=9.21\%$ for MDS and $r^2=8.47\%$ for AML first CR only.

Novel cellular therapies. Table 3 summarizes the experience in Europe with novel cellular therapies. There were a total of 212 mesenchymal SCTs performed by 46 teams in 15 countries. The indications for these transplants are unknown. There were a total of 212 HSCTs for non-hematopoietic use. This includes 97 HSCTs for cardiovascular disorders, 94 HSCTs for neurological disorders and 21 HSCTs for tissue repair.

There were 1898 patients reported as having received donor lymphocyte infusions in 2007 (Table 3). This corresponds to about two-thirds of the number of reported patients with RIC HSCT. No information on the disease indication of those patients with donor lymphocyte infusion is available from the activity survey.

Discussion

Data from this report describe the current state of art of HSCT in Europe in 2007. They document the ongoing role of autologous and allogeneic stem cells for a broad range of malignant and nonmalignant disorders. Allogeneic HSCTs continued to increase, whereas the numbers of autologous HSCT remained within a similar range for most disease indications when compared with the previous years.

For the first time since the introduction of the EBMT activity survey, additional information was collected for novel cellular therapies. They confirm the importance of donor lymphocyte infusions, which parallel the development of RIC for which therapy donor lymphocyte infusion remains an integral part of the therapeutic concept.

More interesting and novel are the substantial number of mesenchymal stem cell grafts and the use of hematopoietic stem cell transplants for nonhematopoietic indications, for example, cardiovascular and neurological disorders, or for tissue repair. No specific information was collected for the donor lymphocyte infusions and the mesenchymal stem cell grafts. It is also clear from some feedback (www.euroct.org) that the numbers of HSCT for non-hematopoietic use as well as of mesenchymal stem cell grafts are probably larger than those reported within this survey. Such grafts are frequently performed outside the traditional hematopoietic SCT units. It will be a challenge for the scientific and political community to collaborate and to get comprehensive information on the numbers, indications and outcome of these grafts. Specifically, mesenchymal stem cells, more correctly called multipotent mesenchymal stromal cells, are being tested in various clinical settings to exploit their proposed antiproliferation and immunomodulatory properties. They are obtained by the ex vivo expansion of stromal cells from BM, cord blood, fat tissue or placenta, and the host does not require conditioning or immunosuppression. Mesenchymal stromal cells actively home to distressed tissue and act through paracrine-secreted molecules rather than by transdifferentiation. The main indications being tested are acute GVHD, myocardial infarct, critical ischemic and autoimmune disease.

Of specific interest is the rapidly increasing role of allogeneic HSCT for AML and MDS. Several prospective controlled trials have confirmed better outcome with allogeneic transplants, and there is often no therapy available for disease eradication other than an allogeneic HSCT. Currently available data are clear concerning an advantage for younger patients with intermediate or high-risk leukemia. The heterogeneity in use of HSCT for AML and MDS, as expressed by the $r^2$ analysis, and the heterogeneity in use in the first CR or at later stages of the disease clearly indicate a need for a continuous evaluation of the technology. This applies even more so for autologous HSCT for AML where the explanatory content is less than 10% (by $r^2$). Data from the survey does not indicate whether a transplant was the best therapy for the individual patient indication or not. Again, it will be the task of the working parties and the AML study groups to provide evidence on the role of HSCT in this clinical situation. Such trials have been initiated (www.ebmt.org).

It is specifically interesting to note that, for the first time since the activity survey began, the numbers of unrelated HSCT equal the number of HLA-identical sibling transplants. There are several reasons behind this development. The massive increase of unrelated donor registries has increased the likelihood of finding a well-matched unrelated donor (www.wmda.org). In addition, there is increasing evidence that the well-matched donor in certain situations might be preferable to a sibling donor, for example, in the situation of an older male patient with the choice between an older female sibling donor and a young well-matched unrelated male donor.

The activity survey does not provide any data on outcome. It also does not provide any information either on the age or sex of the patients or on their pre- or post-transplant therapy. Even more important is that there is no information on nontransplanted patients. Even though desired, this is not the purpose of this data collection. Its key focus is the rapid dissemination of the status quo in the field of HSCT. As such, this activity survey provides a formal basis for patient counseling and health care planning in the field of SCT.
Acknowledgements

The cooperation of all participating teams and their staff (listed in the Appendix), the EBMT Co-ordination office, Barcelona (F McDonald, E McGrath, SM Jones, EF Mac Hale), Paris (V Censes, C Kenfez, NC Gorin), London (C Ruiz de Eivera, S Hewerdine, S de Souza), the Austrian Registry (ASCTR) (H Greimix, B Lindner), the Czech BMT Registry (K Benevska, M Trakova), the French Registry (SFGRM) (D Blainc, E Marry, F Meunil), the German Registry (DRBT) (H Ottinger, K Fuchs, C Muller, S Allguesier, A Siebling, W Neulingger), the Italian Registry (GITMO) (A Bou, R Oneto, B Bruno), the Dutch Registry (HOVON) (A Schattenberg, A. v. Biezen), the Spanish BMT Registry (GETH) (F Carreras, I Espigado, J Lopez, A Cedillo), the Swiss Registry (STABMT) (U Schanz, H Baldomero, E Buhrfeind), the Turkish BMT Registry (G Gurman, M Arat, F Arpaci, M Ertem) and the British Registry (BSBMT) (D Marks, J Cornish, K Kirkland, R Paul) is greatly appreciated. We thank Alan Tyndall for his helpful comments on novel therapies, and also thank S Stoeckl for excellent secretarial assistance and D John for database support. This study was supported in part by the European Leukemia Net (ESN-2002-2.2.0-3, by a Grant from the Swiss National Research Foundation, 3200B-118176, the Swiss Cancer League, the Regional Cancer League and the Horton Foundation. EBMT is supported by grants from the corporate members: Agen Europe, F Hoffmann-La Roche Ltd, Gilead Sciences UK, Milttenyl Biotec GmbH, Schering-Plough International Inc., Celecgen International SARL, Genzyme, Viralharma Europe, Chugai sao—ventis, Fresenius Biotech GmbH, Gambro BCT, Bayer Schering Pharma AG, Therakos, Bristol Myers Squibb, Cephalon, Pierre Fabre Médicament, Alexion Europe, Pfizer, Biosoat SA, Merck Sharp and Dohme.

November 2008
REVIEW

The US National Marrow Donor Program role in unrelated donor hematopoietic cell transplantation

D Confer and P Robinett

The University of Minnesota and Membership Services, National Marrow Donor Program (NMDP), Minneapolis, MN, USA

The National Marrow Donor Program® (NMDP) is headquartered in Minneapolis, Minnesota, USA. Established in 1986, the NMDP currently operates the world's largest registry of unrelated adult donors and umbilical cord blood (UCB) units. Since its inception, the NMDP has benefited from continuous financial support provided by the US government through a series of contracts and grant awards. This funding has supported a large network of donor centers and the recruitment of millions of potential adult hematopoietic cell (HC) donors. More recently, the federal government has also supported a national registry for UCB units and expansion of the available UCB inventories. Today, the NMDP registry lists more than 6.7 million adult donors and 68,000 UCB units. Seventy-seven percent (5.2 million) of the adult donors and virtually all of the UCB units are fully typed for HLA A, B and DR. An additional 5 million donors are available for search through international collaborations. The NMDP currently facilitates more than 3600 recipients each year totaling more than 29,000 transplants since 1987.

Bone Marrow Transplantation (2008) 42, S3-S5; doi:10.1038/bmt.2008.102
Keywords: NMDP; registry; UCB

NMDP history and status

The National Marrow Donor Program® (NMDP) is headquartered in Minneapolis, Minnesota. It was established in 1986 through the combined efforts of families and physicians whose goal was a US national registry of adult, volunteer unrelated hematopoietic cell (HC) donors. Initial funding was provided through a grant to the American Red Cross. The history of NMDP's development has been recently reviewed.

Currently, the NMDP receives contracts from the US federal government to operate the CW Bill Young Cell Transplantation Program. This new program, named after Congressman Young who has been an ardent supporter of unrelated donor HCT and the NMDP, continues congressional support for a national BM donor registry and additionally calls for the development of enhanced capabilities to provide UCB units for transplantation. Funding provided under these contracts allows for the continued recruitment and support of adult donors as well as the collection, processing and storage of UCB units. The contracts further specify requirements for the identification and delivery of HLA grafts, support of patients and the collection of comprehensive donor and recipient outcome data.

In fulfillment of its mission and the government mandates, the NMDP functions as a network of participating organizations that perform the various functions involved in facilitating unrelated donor HC transplantation (HCT). The organizations include donor centers, which currently number 73 and are involved in the recruitment and subsequent management of adult volunteer donors. Donor centers are assisted in their recruitment efforts by 10 recruitment groups, which focus upon targeted recruitment within the US racial and ethnic minority populations. When an adult donor is matched with a recipient and a transplant occurs, the donor will donate either BM or PBSC, depending upon the wishes of the transplant physician. PBSC have been collected since 1999 and currently comprise nearly 70% of adult donor donations. BM collections occur at collection centers, which currently number 97, while PBSC collections occur at apheresis centers, which number 89. Twenty-four CB banks, which collect, store and manage UCB units, are currently participating with the NMDP. Transplant centers, which number 169, are typically based at major universities or large private hospitals. Among the many participating organizations are several headquartered outside the US, including seven donor centers and 43 transplant centers.

To further facilitate the international exchange of HC products, the NMDP has established formal cooperative registry relationships with 26 organizations. The NMDP is an accredited registry of the World Marrow Donor Association (WMDA) and a supporter of Bone Marrow Donors Worldwide (BMDW).

NMDP activity

Each month, the NMDP receives over 1200 search requests for new patients. However, not all of these searches result
BM. These observations led the US Blood and Marrow Transplant Clinical Trials Network (BMT CTN) to initiate a randomized comparison of BM vs PBSC in unrelated donor HCT. The trial has accrued more than 320 donor–recipient pairs en route to its target of 550. Accrual is expected to be completed in 2009. Also shown in Figure 1 is the rapid growth in UCB HCT. Currently, UCB recipients comprise 17% of all NMDP-facilitated transplants. On account of the increasing use of double UCB transplant protocols, UCB units represent 20% of all grafts procured by NMDP.

NMDP donor and cord blood unit recruitment

Not only has the number of transplants continued to increase in the past 20 years, but also the number of unrelated donors available on the registry has risen as well. The NMDP accepts donors in good health between the ages of 18 and 60 years to join the registry, although transplant centers prefer to select younger male donors. The NMDP expected to recruit 350,000 new adult donors in 2007. Increasing emphasis is being placed on recruitment within the US racial and ethnic minority populations; these donors were expected to comprise nearly half of the new recruits in 2007. Each newly recruited donor is typed at the intermediate level for HLA-A, B, and DRB1. Most donors now need only to provide a buccal swab sample for DNA-based testing rather than a blood sample. Buccal swabs from donors are stored for further testing as necessary, and have significantly reduced the effort and cost of donor recruitment.

Most donors join the NMDP Registry as a result of community donor drives, as opposed to donors who are recruited at blood centers. NMDP donor centers and recruitment groups plan and conduct hundreds of drives each month.

Although all newly recruited donors are HLA DRB1-typed at recruitment, there remain about 1.6 million donors who joined the NMDP in the early years that have been typed only for HLA A and B. This group of donors is functionally inactive because analysis shows that 99% of all transplants that NMDP currently facilitates utilize a donor who is selected from the A, B and DRB1-typed pool.

The search process

The process for identifying an unrelated donor or UCB starts with the transplant center. Each transplant center designates a transplant coordinator to be the primary communicator with the NMDP. The coordinator submits a search request through NMDP TRANS Link (described below) or through facsimile (fax) request. The request includes the age and diagnosis of the patient as well as the highest resolution of HLA typing available. This information is used to immediately search the 6 million NMDP donors and for an overnight search of several international registries. NMDP has published recommendations about how to search for adult BM donors, and a similar set of recommendations concerning UCB units is in preparation.
NMCPD provides software to transplant centers (TRANS Link®) that allow real-time searching of the complete NMDP inventory of adult donors and UCB units. TRANS Link produces a donor/UCB list that is sorted with the best of the potential donors/UCB at the top. Within HLA match grades, UCB is prioritized according to total nucleated cell content, whereas adult donors are prioritized by HLA-matching likelihood alone. An NMDP innovation called HapLogic predicts the likelihood of allele-level matching based on calculated HLA haplotype frequencies within major racial and ethnic populations. Currently, HapLogic predicts high-resolution matching at HLA A, B and DRBI, but future release in active development will also consider HLA C and DQ. TRANS Link allows the user to further customize the search results by prioritizing specific HLA loci or donor/UCB characteristics (age, sex, CMV status and so on). Currently, using TRANS Link requires that a software program be installed on the user’s computer that accesses the NMDP databases through the Internet. A future release of NMDP-matching software will allow access through a standard www browser interface (for example, Internet Explorer, Firefox).

Although the NMDP lists more than 1.5 million non-US donors from its participating international donor centers in the upfront TRANS Link search, an additional 5 million non-US donors are accessible only through cooperative registry agreements. Searching for a match among these donors is more cumbersome and difficult. BMDW provides its online search as a convenient way to target registries for further inquiries, so NMDP automatically searches BMDW with every new search submission. Several registries, including NMDP, also automatically exchange donor and UCB search information using the messaging protocol, EMDIS (European Marrow Donor Information System, www.xkrd.de/medis.html). For registries that have not implemented EMDIS, the searching process is largely manual, involving facsimile transmissions and e-mail messages.

The donor search process typically takes 3 months from the time the unit or donor is selected for additional testing to the date the transplant occurs. Some searches have taken as little as 2 weeks, but other searches may involve the testing of several CB units or donors and may take several months.

Research

The NMDP believes that research is essential for improving the outcomes of unrelated donor HCT. Controlling the complications of unrelated donor HCT ( drug-related toxicity, graft failure, acute and chronic GVHD) and preventing disease recurrence are the goals of carefully designed and conducted research projects. In 2004, the NMDP merged its research activities with the International Bone Marrow Transplant Registry (IBMTM) in Milwaukee, Wisconsin. The new research organization was dubbed the CIBMTR (Center for International Blood and Marrow Transplant Research) with a mission to conduct observational and interventional research in transplant outcomes, health services, immunobiology of transplantation and statistical methodologies. CIBMTR and NMDP jointly participate in the operation of the data coordinating center for the US national HCT clinical trials network, BMT CTN. In addition, CIBMTR has created a division for supporting smaller clinical trials to supplement the opportunities available through BMT CTN. Websites that present research information relevant to NMDP are www.cibmtr.org, www.bmtctn.net, www.nmcpdresearch.org and bioinformatics.nmdp.org.

Summary

In summary, the NMDP continues to grow and expand, seeking to facilitate more transplants, to improve the success of transplantation, to increase the number of transplant options available for each patient and to provide the best possible graft at precisely the right moment. These goals will be met through continued recruitment of high-quality HLA-diverse donors and UCB units, through improved processes that facilitate worldwide real-time communications and through a comprehensive program of carefully designed research initiatives.

The National Marrow Donor Program with emphasis on the early years

Jeffrey McCullough, Herbert A. Perkins, and John Hansen

Thanks to the pioneer work of Drs Robert A. Good, and E. Donnall Thomas, the latter a Nobel Prize winner for his work in the development of hematopoietic cell transplantation, marrow transplants have been able to cure certain diseases that previously were considered fatal. Appropriate genetic matching between donor and recipient, however, is essential to achieve a safe and effective transplant. Studies in mice in the 1950s and 1960s demonstrated the importance of gene matching for the major histocompatibility complex (MHC) to allow for sustained engraftment of donor hematopoietic stem cells and to minimize the potentially severe consequences of graft-versus-host disease (GVHD). The latter, originally known as wasting disease, was recognized as the major limitation to successful marrow transplantation. Clinical studies beginning in the late 1970s confirmed that the genetic rules of transplantation in mice also applied to humans. Matching for the human MHC, also known as the human leukocyte antigen (HLA) system, was shown to be necessary for avoiding the immunological complication of marrow transplants.

Initially, transplants were restricted to patients for whom an HLA-identical sibling donor was available. Unfortunately, fewer than 30 percent of patients had an HLA-identical sibling; thus, a transplant was not possible for a majority of patients who might otherwise benefit from this lifesaving treatment. Seeking an HLA match from the general population was generally considered futile for several reasons. The HLA system was known to be highly polymorphic, and the chance of finding HLA matches among the population at large was estimated to be very unlikely. More importantly, no system existed for recruiting donors, for HLA typing, or for oversight of the large number of volunteers necessary to meet the needs of the many potential transplant candidates. The development of the National Marrow Donor Program (NMDP), launched in 1986, has played a major role in demonstrating that marrow from an unrelated donor can be successfully used, provided that a close match for HLA antigens exists. Today more than 5 million volunteers have their HLA types listed in the NMDP database ready to donate their hematopoietic stem cells to someone unknown.

Robert Graves, a Colorado rancher and doctor of veterinary medicine, is largely responsible for the existence of the NMDP. In 1979, Dr Graves' daughter Laura received a marrow transplant for leukemia from an HLA-matched unrelated donor. Laura's leukemia had initially responded to conventional chemotherapy, but with subsequent recurrence, a marrow transplant was the only remaining option for saving her life; unfortunately, no one in the family matched. Refusing to give up hope for Laura, Dr Graves and his wife Sherry began exploring the possibility of an unrelated donor transplant.

Dr Graves arranged a visit with Dr John Hansen of the Puget Sound Blood Center and Fred Hutchinson Cancer Research Center (FHCRC) in Seattle, Washington. Dr Hansen was a specialist in HLA genetics and was known for his studies of HLA matching in bone marrow transplantation. He advised Dr Graves that unrelated donor transplants had been attempted in only a small number of cases in the early 1970s, but he also explained that important advances in HLA typing and matching had occurred during the intervening years. Dr Graves was sufficiently well prepared and informed to understand that Laura's HLA type was probably the most common HLA type found in the general population. He asked FHCRC to perform a transplant if an HLA match could be found. Dr Hansen conferred with colleagues at the Cancer Center and then began a search of the laboratory HLA research file. Fortunately, one of the research donors who was a Cancer Center employee was found to be an HLA-matched individual, and she agreed to be a marrow donor...
for Laura. In September 1979, following high-dose myeloablative chemotherapy and total body irradiation, 10-year-old Laura became the first patient with leukemia to undergo a marrow transplant from an unrelated donor, and a sustained donor cell engraftment was achieved with minimal side effects. Unfortunately, Laura’s leukemia relapsed 2 years later. Despite this disappointing outcome, her initial complete recovery from the transplant demonstrated the feasibility of the procedure. Her success prompted other parents from across the nation to contact Dr. and Mrs. Graves with requests to help them find a donor for their children. Encouraged by the need, Dr. Graves appeared before Congress multiple times to request funds for the establishment of a national registry of HLA-typed unrelated marrow donor volunteers.

Regardless of the initial demonstrations that successful marrow transplantation between unrelated HLA-matched individuals was possible, very little had been done to address the basic ethical issues on whether it was appropriate or reasonable to ask unrelated individuals to become marrow donors. In 1981, Dr. Jeffrey McCullough organized a conference to discuss the scientific, ethical, legal, financial, and practical issues of developing a volunteer marrow donor program as well as developing a framework for approaching community volunteers about marrow donation. The conference achieved clarification about the ethical approach to seeking volunteer marrow donations, and an important consensus was reached about the propriety of recruiting volunteers for a marrow registry. It was an essential milestone for those patients, families, and physicians who were desperately advocating unrelated donor marrow transplants.

One of the initial issues at the conference was to obtain a better understanding of marrow donation risks. Two comprehensive reports on the complications of marrow donations compiled data from several thousand individuals who had donated. From this information, it was then possible to develop a structured medical evaluation of potential marrow donors, although the difficulty in predicting the risks of general anesthesia in normal adults who would otherwise meet the medical eligibility criteria for marrow donation remained an issue.

Legal issues were also addressed, which raised a large number of potential concerns and problems. The discussion focused, however, on the view that the legal system should not be perceived as a barrier to this scientific and medical advancement as long as proper analysis and forethought were provided to the donor assessments and the consent process. Also dealt with were financial issues, which included allocating the donor’s medical costs of donation to a charging system for the patient, providing a life insurance policy for the donor, establishing a system to assure confidentiality and donor anonymity, and preventing the donor from making financial demands on the recipient.

The process of resolving these and many other issues led to the development of a set of operating principles, which later became the initial policies for the operation of the NMDP. These principles addressed the need for future studies on the effects of the request and donation process on donors. Several subsequent reports indicated that donors, when properly approached using the careful strategies designed by these donor programs, were quite willing to donate and did not experience adverse psychosocial effects. Thus, these early experiences with local marrow donor programs formed an excellent basis for the development of a large, multicenter national program.

Subsequent to the 1981 conference, the Blood Center of Southeastern Wisconsin recruited its first unrelated marrow donor from plateletpheresis volunteers, and in 1982, the American Red Cross Blood Center in St. Paul, Minnesota, established a similar program to provide unrelated marrow donors. These programs established the possibility of obtaining volunteer marrow donors through donor-based organizations that were not part of a transplant program.

These successes in finding willing donors substantiated Dr. Grave’s requests to develop a national center. After Dr. Graves obtained the help of Senator Paul Laxalt from Nevada, the National Organ Transplant Act of 1984 included language about marrow transplantation using unrelated donors. With this achievement, Senator Laxalt wrote a letter to the Secretary of the Navy recommending that the Navy, which had an existing marrow transplant research program, establish a national registry. On November 30, 1984, during the American Society of Hematology’s annual meeting in Miami, Captain Jim Woody (USN) called a meeting to discuss essential characteristics of a national registry and to consider the composition of a Request for Proposals (RFP). This RFP would be directed to institutions or groups capable of contracting to establish a national registry of marrow donors. Although the development of an RFP was an essential requirement for any future public funding, there remained significant obstacles to developing a functioning national registry.

The 1984 National Organ Transplant Act had directed the Secretary for Health and Human Services to study the feasibility and effectiveness of a national donor registry, and in May 1985, a Technology Assessment Meeting was held under the auspices of the National Institutes of Health. The panel concluded that although continuing efforts to use unrelated donors were certainly warranted, it was premature at that time to commit to a centralized national marrow donor registry. They suggested the establishment of a coordinating center to facilitate communication among regional registries, however, which were encouraged to continue and expand. The panel believed that the coordinating center should respond to requests.
from transplant centers and refer those requests to the regional registries.

On the assumption that the regional registries discussed by the Technology Assessment Panel corresponded to the donor centers visualized for the National Marrow Donor Registry, in early 1986 Senator Luault was able to attach an appropriation of $1.2 million to the Defense budget, which directed the Navy to establish a registry. With knowledge of the funding available and the Navy's plans to release an RFP, Dr Graves went to the boards of the national blood bank organizations hoping to secure their cooperation and support. These organizations represented multiple blood centers that could promote a national network of dedicated, professional facilities for donor recruitment and management as well as a strong, independent base for donor advocacy. Furthermore, the blood banks were well positioned to make two major contributions. First, they had access to donors of platelets (PLTs) by apheresis—individuals who had already demonstrated a willingness to take additional time and undergo discomfort to benefit a patient they did not know. Second, many of those PLT donors were partially typed for HLA antigens, which helped solve the dilemma of the lack of funds available for a HLA typing program. The HLA types available from PLT donor volunteers could be used to begin a search for a compatible donor; additional HLA typing could be done as needed, with the cost charged to the patient who requested the typing. It was agreed that the American Red Cross (ARC), American Association of Blood Banks (AABB), and the Council of Community Blood Centers (CCBC, now known as America's Blood Centers) would sponsor the marrow donor registry with the ARC taking administrative responsibility.

The ARC appointed Dr Jeffrey McCullough as its representative and proposed that the registry be established as part of its St. Paul center. The AABB appointed Dr Herbert Perkins, Scientific Director of the Irwin Memorial Blood Bank in San Francisco, California, and the CCBC appointed Dr John Hansen, from the Puget Sound Blood Bank and the Fred Hutchinson Cancer Research Center in Seattle, Washington. In addition to his role in Laura Graves' transplant, Dr Hansen had also accompanied Dr Graves on a number of trips to consult with members of Congress. Dr McCullough agreed to become Principal Investigator (PI) for the project, and together with Drs Hansen and Perkins, he began to assemble a plan and written proposal in response to the Navy RFP. The application was successful, and the Navy awarded the first contract for a national registry to the three sponsoring organizations. The contract became operational on July 1, 1986, and the National Bone Marrow Donor Registry established its National Coordinating Center within space provided by the St. Paul Red Cross Blood Services.19

The three investigators met frequently over the next months, accompanied by Dr Graves in his preferred role as the unofficial power behind the throne, to focus on the tasks necessary to complete the setup of the Registry. Staff was hired, a search algorithm was defined, and a subcontract was established with the biostatistical center at the University of Minnesota to provide data management and computer support. On October 28, 1986, a meeting of marrow transplant physicians and other experts was convened in St. Paul to establish by consensus membership criteria for participating transplant centers, indications for transplantation, and minimal requirements for HLA matching.

From the beginning, research was determined to be a major priority for the NMDP. Proof that unrelated donor transplants were sufficiently successful to warrant their routine use required agreement from the transplant physicians to report details of the courses of their transplanted patients to the NMDP. Subsequent research focused on the unique problems of unrelated donor transplants and how to achieve best results. A major focus has been on the role of HLA matching in this situation, and to meet that goal a repository of cells from the donors and recipients was established, which has permitted retyping of the donor-recipient pairs as histocompatibility testing improved. The repository contract was given to the Irwin Memorial Blood Bank in San Francisco because of its prior experience in long-term frozen storage of cells under sterile conditions.

The Navy contract's requirement to establish a Board of Directors was accomplished by Dr Graves and the three investigators. The Board's first meeting occurred in Minneapolis on January 15, 1987, where Dr Graves was elected to Chair and Admiral E.R. Zumwalt, Jr, former Chief of Naval Operations, was elected as Vice Chair. Other members of the original board included Walter Mondale, former Vice President of the United States; Armand Hammer, philanthropist; Dr David Rogers, Professor of Medicine at Cornell Medical School and former President of the Robert Wood Johnson Foundation; David Frohnmayer, Attorney General of the State of Oregon; Dr Bo Dupont of Memorial Sloan-Kettering Cancer Center and a major investigator in the field of HLA typing; Dr Arthur Caplan, Hastings Institute and distinguished medical ethicist; Dr E. Domall Thomas; and Dr Robert A. Good.

Almost immediately, concern arose about further financial support; the original appropriation funded the program for only 15 months. On January 25, 1987, Drs McCullough, Perkins, and Hansen were invited to a meeting on the NIH Bethesda campus involving representatives from the Office of Naval Research (ONR) and the National Institutes of Health to discuss funding for the NMDP. Senior ONR officials were reluctant to accept the responsibility for further funding, and National Institutes of Health officials considered the project inappropriate and of low priority for research support. With the efforts of Dr Graves, however, along with Admiral Zum-
walt and Mr Bart Fisher, funding from Congress for the NMDF continued. Mr Fisher, a Washington attorney who later joined the NMDF Board, had lost a son from aplastic anemia. A marrow transplant had been recommended, but no HLA-matched donor could be found.

In September 1987, the NMDF began accepting requests for donor searches. The first donor was provided in December 1987—a dramatic story chronicled in the *Readers Digest*. A fierce winter storm had closed the Milwaukee airport, and only the bravery of a private pilot in a small airplane made it possible to transport the marrow from Milwaukee in time to be given to a distant patient.

Over the next year, the number of transplants increased steadily and by February 1989, it was considered a remarkable achievement when marrow from an unrelated donor was delivered to the 100th transplant recipient. The White House commemorated this event by holding a celebration for the members of the board and staff hosted by John Sununu, the President's Chief of Staff.

Meanwhile, the recruitment of potential donors was vastly accelerated by the activities of families with children who needed a marrow transplant but found no compatible donor in the files. Early efforts by the family and friends of Allison Atlas recruited more than 70,000 donors, focusing on results on donors of similar ethnic background (Ashkenazi Jews), and the family and friends of Joanne Johnson recruited many tens of thousands of African-American donors. Community drives have continued to dominate NMDF's recruitment accomplishments, providing 75 percent of the donors in the Registry. Several large marrow donor registries that had been started independently of the NMDF became donor centers within the organization including the Heart of America (organized by Fred and Sandy Harris of Kansas City) and the New Jersey HLA Registry (a project of Dr Elie Katz). An additional mechanism for recruiting donors with emphasis on minority groups came with the establishment of recruitment groups targeted to specific populations. The first such recruitment groups to be formally accepted into the program were the Judy Davis African-American Marrow Donor Program and the Asian-American Donor Program, both located in Oakland, California. Along with the vigorous activities to enlarge the donor population, considerable effort was devoted to defining the risks of marrow donation and using this knowledge to establish criteria for the medical evaluation and suitability of potential donors.

The increasing growth of the program created a need for a full-time director of the Coordinating Center, and in April 1989, Douglas Shaw was hired as Executive Director. The three original investigators of the Navy registry contract were elected to the NMDF Board, with Dr McCullough serving as President, Dr Hansen as Secretary, and Dr Perkins as Treasurer.

Although Congress continued to allocate increasing amounts of funding to the NMDF through the Navy, the success of NMDF and increasing need for unrelated donor transplants created an inevitable requirement to move Federal oversight of the NMDF from the Navy to another Federal agency more appropriate for an emerging major domestic health care program. Congress subsequently redirected authority for the National Registry through funding for the Organ Transplant Amendments Act of 1986, which reauthorized funding for the NMDF with instructions to the Secretary for Health and Human Services to establish a national registry. In 1988, the Secretary assigned the oversight responsibility to the National Heart, Lung, and Blood Institute (NHLBI). The Navy, however, continued to provide the NMDF with additional funds to supplement selected program activities, especially minority donors and HLA research. The largely responsible for ongoing program support is Congressman Bill Young of Florida. Congressman Young has demonstrated remarkable commitment to the NMDF mission, his leadership has ensured continuing congressional support for the national effort to meet the needs of patients seeking transplantation.

In November 1989, Admiral Zumwalt was elected to succeed Dr Graves as Chair while Dr Graves remained as Vice Chair. Over the next six years, the Admiral presided over a series of dramatic changes that shaped the status of the NMDF. He and Dr Graves continued the critical process of building public and Congressional support. Although Dr Graves remained very active as Vice Chair for several more years, Admiral Zumwalt, who had a son who also had needed a marrow transplant, became the dominant figure. Admiral Zumwalt was a widely known and highly respected public figure. He was involved in the negotiations that led to the separation from the Red Cross and the establishment of the NMDF as an independent entity. Operational capability of the NMDF was further established with the transfer of the donor files and biostatistical unit from the University of Minnesota to a new bioinformatics and statistics unit within the NMDF coordinating center. Zumwalt was also highly influential in resisting NHLBI pressure to limit the role of the NMDF Board to that of an advisory group only. He also led the successful effort to integrate Lifesavers (an independent donor recruitment agency) into the NMDF, and he established The Marrow Foundation as a separate nonprofit organization dedicated to raising funds for NMDF programs.

In February 1990, Dr McCullough resigned to devote more time to his university and blood bank responsibilities. With continual program growth, an increasing number of member organizations, and expansion into an international presence, the NMDF no longer found it necessary or adequate to operate under the auspices of the ARC. Therefore, in 1990, the NMDF became a separate,
nonprofit corporation and assumed full responsibility for administration of the federal contract from the ARC. In December 1990, the coordinating center moved from its quarters within the St. Paul Red Cross Blood Center to a freestanding location in Minneapolis. Shortly thereafter, following extensive development of new software programs, the computer services for the registry were transferred from the University of Minnesota to the NMDP Coordinating Center.

The remarkable growth of the NMDP, the establishment of independence from the ARC, and a change in its federal oversight to the NHLBI led to a need for reorganization. On April 5, 1991, the board appointed an ad hoc committee for reorganization chaired by Dave Frohnmayer’s recommendations, which were subsequently adopted by the board. The primary focus of the changes was to provide a Chief Executive Officer (CEO) with stronger management and policy authority. A national search for a new CEO was undertaken, and Craig Howe, MD, PhD, a transplant physician and Professor of Medicine at the Medical College of Virginia in Richmond, Virginia, accepted the new position of CEO of the NMDP in May 1992.

With the Transplant Amendments Act of 1990, Congress further defined and expanded the functions of the program. Establishment of an office for patient advocacy was mandated, and the NMDP was directed to emphasize recruitment of minorities with the goal of providing equal access for patients of all ethnic groups. Subsequently, money from the OHR was made available for recruitment and HLA typing of minority donors.

In 1994, oversight was transferred from the NHLBI to the Division of Transplantation of the Health Resources and Services Administration (HRSA). This was recognition that the use of unrelated donors for marrow transplantation was no longer an experimental procedure but a vital service that needed to be provided to a larger number of patients, as indications for transplantation using unrelated donors became better defined and the chance of finding an HLA match steadily improved.

The NMDP story is not complete without reference to the extraordinary international collaboration that occurred among marrow donor repositories in different countries. The first large registry of potential marrow donors was the Anthony Nolan Registry located in London, which began providing some donors for US patients before NMDP existed. In addition to Anthony Nolan, the NMDP established donor exchange agreements with Australia, Austria, Belgium, Canada, Cyprus, Czech Republic, France, Germany, Hungary, Ireland, Italy, Japan, Portugal, Singapore, Slovenia, Spain, Switzerland, Taiwan, and the United Kingdom. Some foreign donor and transplant centers have elected to affiliate directly with NMDP for ease of access, as fully participating members of the NMDP network, including donor centers and transplant centers in Argentina, Denmark, Germany, Israel, and the Netherlands. Twenty percent of NMDP-facilitated transplants involve foreign donors or recipients and the bidirectional exchange has been approximately equal (D.Confer, personal communication, April 2005). NMDP provides financial support for a publication organized by Dr. J.J. Van Rood in the Netherlands (Bone Marrow Donors World Wide), which lists on the Internet all of the HLA types available from all of the significant marrow donor registries in the world. This publication provides access to more than 9 million donors including the more than 5 million listed with NMDP. The NMDP searches this file if it does not find a matched donor in its own registry (Fig. 1).

When the registry began in 1987 with fewer than 10,000 donors, we set a goal of 100,000 donors. This was based on economics (the amount of funds available for HLA typing) and political reality. We were unsure that there would be sufficient political will and funding to set more aggressive goals. It seemed more important to move quickly to expand the number of available donors so that more transplants could be done to move the field forward. In addition, we could not in the mid-1980s fully anticipate the extent of the polymorphism that became evident with the implementation of DNA typing methods in the 1990s. The registry now totals more than 5,000,000, and each month approximately 27,000 donors are added to the file and a mean of 210 transplants are carried out. Analysis of results published by NMDP-affiliated investigators demonstrates steady improvement in disease-free survival of recipients. Similarly, NMDP-affiliated investigators have carefully monitored and reported on the experiences of volunteer marrow donors and their recovery following marrow donations. Although GVHD is more common in HLA-matched unrelated transplants compared to HLA-genotypically identical sibling donor transplants, improvements in HLA typing and overall supportive care have significantly benefited unrelated donor transplants. For certain patients, overall survival is approaching that achieved with an HLA-identical sibling donor.
Although the NMDP name includes the word “marrow,” its activities have not been restricted to hematopoietic stem cells obtained from marrow alone. After there had been sufficient experience with peripheral blood progenitor cells (PBPCs) using related donors, NMDP began a cautious program of PBPC collection, initially for repeat transplant only and subsequently as a primary source. The concern was for the unrelated donor who had to receive multiple injections of granulocyte-colony-stimulating factor (G-CSF) and then undergo one or two apheresis procedures. G-CSF has uncomfortable side effects, and its long-term consequences are still unknown. NMDP studies of PBPC are conducted under Investigational New Drug (IND) approval from the Food and Drug Administration, and stem cells are collected only at centers that are approved after demonstrating that they meet NMDP standards. PBPCs are increasingly favored over marrow as a source of stem cells and currently about 60 percent of stem cell transplants through NMDP are from peripheral blood.

NMDP has also begun to include umbilical cord blood as a source of hematopoietic stem cells. NMDP lists cord blood from 15 cord blood banks containing approximately 42,000 cord blood samples. NMDP is thus the largest single source to be accessed for unrelated donor cord blood, also through an IND from the FDA. In 2003, 4 percent of stem cell preparations procured through NMDP were cord bloods.

The availability of both PBPCs and umbilical cord blood for unrelated donor transplantation opens an exciting new phase in hematopoietic reconstitution. As of April 24, 2005, 21,245 transplants have been performed through the efforts of the NMDP (Fig. 2), often in far from ideal circumstances. All patients were given a chance for life, which would otherwise not have occurred, and 25 to 75 percent (depending on the disease, its stage, and the age of the patient) are living disease-free.

The NMDP has also had a major impact on the development of HLA typing technology. Faced with the need for a very large volume of initial HLA typing at the time of donor recruitment, the NMDP established competitive contracts with typing laboratories at greatly reduced prices. Quality control procedures were initiated to monitor and provide HLA typing accuracy. In addition, the NMDP promoted the development of molecular typing technology as a way of overcoming the inaccuracies in serologic HLA typing. Their aggressive management of donor HLA typing was instrumental in advancing adoption of molecular typing, accelerating progress by years. An extremely low discrepancy rate now occurs in typing, as evidenced by ongoing monitoring by the NMDP, which sends blinded samples of known types to its contract laboratories. More recently, the NMDP has made high-resolution HLA typing needed for final donor selection available on a rapid 7- or 14-day turnaround schedule. This option has been essential for facilitating rapid donor workups for patients with urgent clinical conditions.

As already stated, one of the major goals of the NMDP from the beginning was to carry out research to prove the benefit of unrelated donor transplants and to identify ways to improve results. Transplant centers are required to report periodically on the results of their transplants and the clinical conditions of their patients. The repository of cells from the donor and recipient of each transplant has permitted updating their typing with high-resolution DNA techniques, providing the opportunity to relate HLA mismatching to clinical results. Currently, 198 individual studies approved by the NMDP Research and Publications Committee and/or its Histocompatibility Committee are in progress. An accelerated research program is anticipated since the NMDP has become an active participant of an NIH-organized and-funded clinical marrow transplant trials network (http://spitfire.emmes.com/study/bmtn/) and also has joined with the International Bone Marrow Transplant Registry to create a unified and coordinated research program that will increase the capabilities and productivity of both organizations.

In conclusion, the most important and primary accomplishment of the NMDP has been enabling more than 20,000 patients to receive a potentially lifesaving transplant, but this story of NMDP’s early days carries lessons far beyond this limited area. It demonstrates that one man can make a difference, that persistence in pursuing a valuable goal may be required to achieve success, and that the success obtained may far exceed the initial expectations of the investigators. The program has shown that very large numbers of individuals will commit to an uncomfortable and possibly risky procedure for the benefit of someone they do not know and that very large numbers of ordinary people will devote many hours and significant cash donations to help a procedure that has the promise of saving lives. It supports the old truth that success breeds success.
The program has demonstrated the value of considering the ethical implications of procedures, especially those involving unrelated volunteers and of the need to include patients, their families, and ethicists into the decision-making process.

Without the continual financial support from federal agencies from funding mandated by Congress, the program could not have achieved the success it has reached. Persistent lobbying and the establishment of committed friends in Congress have been essential, and transplant physicians, patients, and families have played a necessary role in obtaining this cooperation. Dr. Graves always tried to bring with him a patient whose life had been saved by a marrow transplant whenever he needed support from an agency.

The program has also demonstrated the possibility and benefit of cooperation among organizations. The program could not have been established without joint sponsoring of the American Red Cross, the AABB, and the Council of Community Blood Centers. Although these sponsors no longer play a direct role in NMDP activities, their importance to the start of NMDP cannot be overestimated. The program’s success led to the incorporation of previously independent donor centers, thus instituting a single-central source to which transplant physicians can turn when they need an unrelated donor, allowing them to select the best donor of marrow, PBPCs, or cord blood.

The large size of the program has permitted it to control the costs of HLA typing and to promote and monitor its accuracy.

The program’s growth and accomplishments have vastly exceeded the optimistic hopes of its founders, and contrary to expectations, the rate of donor recruitment and of transplantation show no signs of slowing down.

CHAPTER 7
SUMMATIVE COMMENT
UNPUBLISHED AND ONGOING WORK
**Perspective and justification**

Each of these active studies is continuing to generate new and relevant data relating to the central research theme. Superficial reflection might suggest that they are extraneous to the overall scope of this thesis whereas counter-argument highlights the need to capitalise on achievement in sustaining growth and utilisation of these often life-saving interventions. Emphasis, and indeed urgency, is found in the relentless contraction of specialised programs that enjoy international designation as centres of excellence. Acceptance of responsibility to safeguard these is reflected in the decision by the Faculty of Health Sciences at Stellenbosch University to bring at least one such facility formally within their academic ambit. Accordingly concepts and preliminary results generated under these circumstances be specifically included with the caveat that they are positioned in this separate chapter so giving focus to such somewhat limited information as may be available from developing countries²³,⁷⁴,⁸⁰,²¹³-²¹⁶.

Three broad considerations exist

**Immunologic reconstitution**

Little doubt exists that, once the immediate danger of haematologic cellular recovery has been successfully navigated, substantial risk persists from impaired defence against environmental pathogens that can reach life-threatening proportions. Additionally there is an increasing appreciation of other adverse events, exemplified by late rejection and graft-versus-host disease, continuing to occupy centre stage in determining both survival and quality of life. To further explore this important facet of post-transplantation pathophysiology two phases are projected. A reference group of individuals are to be characterised and could reasonably be designated as the learning set using appropriate laboratory measurements matched to clinical status. In parallel what might be regarded as a study or training set will serially examine the same parameters as a function of time. In context both innate and adaptive arms of our natural protective system be correlated with patterns of infection on the one hand and the spectrum of recipient tissue responses on the other. In sub-analysis relate these phenomena to different types of transplant across disease categories that will include both children and adults. Viability is to be vested in a collaborative masters project²¹⁷-²²⁰.
**Survivorship - a concept linking cure with care**

As life after stem cell grafting continues to extend it has become evident that late-presenting side-effects have been largely under recognised. This is a realisation of major importance and being actively and systematically evaluated in association with the PhD student. The experimental design rests securely on personal observations over more than a decade that have revealed, often subtle, tissue and organ injuries in pulmonary parenchyma, cardiac myocytes, both osteoclastic and osteoblastic skeletal integrity, gastrointestinal tract and skin. As experience accumulates treatment programs undergo continuous modification seeking to confer immediate benefit to recipients. Intellectually advances are integrated into outcome analysis adding a relevant further dimension to the more traditional end point of only survival\textsuperscript{221-224}.

**Current status and applicability of this study to an emerging South Africa**

Three consecutive but inseparable phases characterise the global project.

Firstly, as the starting point, experimental and developmental haematology was employed to standardise the fundamental technological aspects. There followed systematic translation into clinical programs that were constantly refined and upgraded to comply with world expectations. Procedures ranged from autologous reinfusion to various forms of allogeneic grafting with the initiating centre being at the University of Cape Town in Groote Schuur Hospital. Provision was made for all patients, without exception, throughout South Africa. New innovations were introduced and the entire project under constant supervision being accredited by international registries.

Secondly arose the appreciation that, as evident particularly in Europe and United States of America, a single centre wherever located, was somewhat restrictive in the light of emerging national requirements. Accordingly was the challenge to create a matching facility in the private sector. 15 years later the venture has clearly emerged as not only sustainable but entirely realistic thereby creating a precedent that has subsequently percolated widely throughout other parts of our country.
An unvarying theme has remained accountability reflected in a 30 year unbroken record of accreditation by worldwide registries with designation as a transplant, harvest and donor centre. Within this framework the successful establishment of a South African Bone Marrow Registry so ensuring access to matched unrelated volunteer donors from other participating countries.

Thirdly has been sustained leadership by undertaking the inaugural survey, with presentation and publication of outcome, for these activities in South Africa. This further imperative is similar to the exercise conducted by the European Bone Marrow Transplant Registry. It is anticipated that there will be two consequences. One that some degree of resource allocation should then be possible with properly performing centres enjoying endorsement on academic rather than the more popular incentive driven criteria. The other increasing commitment by interested investigators to undergo registration by international harmonisation mechanisms offered by The Joint Accreditation Committee of International and European Transplant Groups known as JACIE and the Foundation for the Accreditation of Haematopoietic Cell Therapy or FAHCT so demonstrating compliance with accepted standards of practice. A particularly desirable consequence of meeting these two important responsibilities is an opportunity for the Department of Health to impose some sort of long overdue, but hopefully rational, control as soon as the necessary regulations have been promulgated and registration introduced in the broad context of blood transfusion and human tissues act.

The simplification of the SCT procedures in developing countries has resulted in cost-lowering and availability to more patients.

Gómez-Almaguer D.

Hospital Universitario UANL, Monterrey Nuevo León, México.

In order to simplify and cutting down expenses of the bone marrow transplantation procedures we have made some efforts, trying to provide the best transplantation technique for the individual patient with scarce resources. In relation with the source of stem cells, we have found very attractive the use of peripheral blood stem cells (PBSC) instead of bone marrow cells. This procedure can produce substantially more rapid engraftment than observed with bone marrow. The rapid hematopoietic reconstitution in the recipient of PBSC lower expenses stemming from the use of antibiotics, blood bank products and days at the hospital. In Mexico, a country with a large number of cases of severe aplastic anemia we decided to use PBSC to transplant 10 patients with this disease, in order to take advantage of the large number of stem cells that this procedure can provide. We had excellent results in these patients, avoiding the high cost of the conventional transplantation and the use of ATG. In relation to autologous transplantation we have made efforts to perform autografts without the use of freezing devices, keeping the stem cells in liquid form using a conventional blood bank refrigerator for up to 96 hr. This modifications have resulted in diminishing costs and increasing the availability of the procedure to a large number of patients. Finally in Mexico we have had experience with non-myeloablative transplants, and obtained reasonably good results, with a median cost of 18,000 USD per allogeneic transplantation procedure. In some cases this is the only affordable therapeutic option. In developing countries where very few patients can afford the cost of conventional bone marrow transplants, any reasonable effort in the direction of simplification must be welcome.

Hematopoietic stem cell transplantation for autoimmune diseases in developing countries: current status and future perspectives

JC Voltarelli¹ and J Ouyang²

¹Division of Clinical Immunology and Bone Marrow Transplantation Unit, School of Medicine of Ribeirão Preto, University of São Paulo, Brazil; and ²Department of Hematology, Affiliated Drum Tower Hospital of Nanjing University Medical College, Nanjing, People's Republic of China

Summary:

In this paper we present preliminary results of hematopoietic stem cell transplantation for autoimmune diseases in Brazil and China. Chinese experience transplanting lupus is significant and the Brazilian experience with several autoimmune diseases is growing. We discuss peculiar conditions in developing countries which could affect the results, and future perspectives for the organization of phase III randomized trials in those countries.

Bone Marrow Transplantation (2003) 32, S69–S71. doi:10.1038/sj.bmt.1703947

Keywords: hematopoietic stem cell transplantation; autologous; autoimmune diseases; systemic lupus erythematosus; multiple sclerosis; developing countries

Application of hematopoietic stem cell transplantation (HSCT) for the treatment of systemic autoimmune diseases (AID) in developing countries requires consideration of peculiar aspects of the diseases and of the health system in those countries, including: (1) Probably a worse activity and prognosis of severe AID in the patient population treated with conventional therapy due in part to poor economical and social conditions.¹ (2) High prevalence of some autoimmune diseases such as rheumatic fever and some forms of pemphigus in Brazil and of systemic lupus erythematosus (SLE) in China (70/100,000). (3) Difficult access to new technologies (stem cell selection columns, monoclonal antibodies, etc) and therapies (anti-TNF agents, new immunosuppressive drugs), which impairs the capacity to deliver the best medical treatment to the patients and to participate in international cooperative trials. (4) Universal coverage of health care by the state, but in a highly regulated fashion for high-cost therapies such as HSCT. (5) Large availability of HLA-identical donors (>50%) in the general population in some countries, like Brazil² but not in others, like China. In this work we present preliminary results of HSCT for AID in two big developing countries, Brazil and China, and discuss characteristics and perspectives of the programs, which could apply to other developing countries.

HSCT for AID in Brazil

Bone marrow transplantation centers in Brazil have a large experience transplanting hematologic autoimmune diseases, such as acquired aplastic anemia, including the design of new conditioning regimens for hypertransfused/presensitized patients,³ and anecdotal cases of systemic autoimmune diseases submitted to autologous HSCT have been reported since 1996 with favorable results.⁴

In October 2000, a meeting was organized in Ribeirão Preto, Brazil, to launch a program of HSCT for autoimmune diseases in the country. International experts from USA (Richard Burt, Dhaval Patel, William Burns) and Europe (Rezae Arnold) met with representatives of main BMT/Rheumatology/Neurology Brazilian groups and it was decided to start a pilot, phase I/II national cooperative study of autologous transplantation for refractory systemic lupus erythematosus (SLE), systemic sclerosis (SSc) and multiple sclerosis (MS). Mobilization of HSC is performed with cyclophosphamide (2g/m²) plus G-CSF (10μg/kg/day) and conditioning is CY + ATG for SLE, BEAM + ATG for MS and CY + Fludarabine + ATG for SSc. Horse ATG is given at 15mg/kg/day (three doses before stem cell infusion and three doses after infusion) to replace in vitro T-cell depletion/SC selection.⁵ Conditioning for SLE and MS followed standard protocols used elsewhere,⁶ while for SSc a highly immunosuppressive combination was adapted from mini-allo transplants,⁷ The program started in June 2001 and eight transplants have been performed under the protocol (four for SLE, three for MS and one for an overlapping syndrome of SLE + SSc) in three centers, and other centers are obtaining IRB approval and accruing patients to be engaged in the protocol. Preliminary results show beneficial effects in most patients (three SLE and two MS patients) and an initial significant morbidity/mortality of the transplant procedure because of specific problems of the patient group (kidney failure and fluid overload in three
HSCT for autoimmune disease in developing countries

The first patient with an autoimmune disease transplanted with hematopoietic stem cells in China was a lupus patient treated in 1998 at the Affiliated Drum Tower Hospital of the Nanjing University Medical College. After a visit by Dr. Richard Burt at Nanjing in 1999, three other centers launched their programs of HSCT for AID: the Union Hospital in Beijing, the Third People's Hospital in Zhengzhou and the Taian People's Hospital in Shandong.

The initial experience of the Nanjing University was reported in 1999 at the Worcester Translational Research Conference and subsequently in Chinese. Autologous bone marrow was collected from three SLE patients, cryopreserved at 4°C and infused after 56 h and conditioning with Cytoxan (CY) 120 mg/kg and Melphalan (140 mg/m²). G-CSF was given after transplantation and the three patients achieved clinical and laboratory remission. Subsequently, conditioning regimen was changed to CY (200 mg/kg) plus ATG (90 mg/kg) for SLE and BEAM + ATG for MS, and CD34+ selected and cryopreserved PBSC were used as the source of SC. The group at the Nanjing University performed HSCT for 18 patients with AID (seven SLE and 11 MS). Most patients improved after transplantation (5/7 SLE and 7/11 MS), one patient with SLE and three with MS showed stabilization of the disease, one MS patient progressed and another with lupus died of uncontrolled pulmonary hypertension and congestive heart failure 6 months post-transplantation. The Nanjing group intends to expand its series of autologous HSCT for SLE and MS, and target other inflammatory diseases such as rheumatoid arthritis, SSc, inflammatory bowel disease and myasthenia gravis. There are also plans of participation in phase III trials active in developed countries.

During the EBMT meeting in 2002, the Zhengzhou group reported its experience in autologous HSCT transplantation of 18 patients with SLE. Six patients received BM (median of 1.1 x 10^6 nucleated cells/kg) and 12 patients received PBSC (3.01 x 10^6 CD34+ cells/kg), neither product was manipulated in vitro. Mobilization was accomplished with CY (2 g/m²) plus G-CSF (250 µg/day) and the conditioning regimen combined total lymphoid irradiation (0-12 Gy), CY (50 mg/kg/day x 3) and rabbit ATG (Fresenius, 10 mg/kg/day at days +1 and +2) for in vivo T-cell depletion. Haematopoietic engraftment was achieved in 100% of patients with a median time of 15 days (12-18). B lymphocytes were markedly reduced and NK cells were increased 8-12 months post-transplantation. Two-thirds of the patients (12/18) had complete remission, three patients had a partial response and three patients did not respond after a median follow-up of 12 months (3-26 months), and there were no transplant-related deaths.

The Beijing group performed CD34-selected autologous HSCT in 11 patients (eight SLE, one RA, one SSc, one SJS). Conditioning was Cy + ATG (N = 7) or Cy + TBI (N = 4). All patients achieved clinical remission and three patients developed CMV infection. The Shandong group apparently did only one HSCT for SLE and the patient relapsed after transplantation.

In conclusions

Developing countries are able to produce significant results using HSCT for AID. In fact, the Chinese experience with lupus is already impressive regarding the numbers and outcome and the Brazilian experience is growing. Engagement in phase III randomized trials needs careful selection to answer specific questions relevant for our conditions such as the role of expensive in vitro manipulation of stem cells and the comparison of HSCT with expensive medical treatments such as anti-TNF agents for rheumatoid arthritis. Development of those trials depends on the results of present pilot studies, encouraging referral of early-stage patients, and availability of resources. Alternatively, we may join phase III clinical trials active in developed countries, but we may need their help for some resources. Finally, in our countries, one-shot therapy like HSCT is usually cheaper and have a more favorable cost-benefit ratio than prolonged immunosuppression needed for a subgroup of severely affected AID patients. Thus, we can benefit a large number of patients and give a significant contribution to the field, like that shown by Fassas et al in Greece transplanting MS. Our experience certainly will encourage other developing countries to overcome various obstacles and implement programs of HSCT for AID.

The importance of lowering the costs of stem cell transplantation in developing countries.

Barr RD.

Department of Pediatrics, Pathology and Medicine, McMaster University, Ontario, Canada.

The effectiveness and efficiency of health care systems can be assessed by economic evaluation, comparing the costs and outcomes of alternative interventions. Direct costs include accommodation, nursing, physicians' fees, diagnostic tests and treatment. Indirect costs derive from the loss of a person's ability to use life in a productive way e.g. employment. In cost-effectiveness analyses, cost is the numerator and effectiveness (related to health outcomes) is the denominator. The unit of measurement of effectiveness is usually years of life saved. Cost utility analyses require a preference-based measurement of health-related quality of life (HRQL) to allow the calculation of utility scores for health states and so the adjustment of effectiveness for quality. Typically, this allows the calculation of quality-adjusted life years (QALYs). A review of published reports, to be presented in detail, yields the following summation. The greater cost of stem cell harvest from peripheral blood is more than offset by the reduced costs associated with a shorter hospital stay. Transplants early in first remission cost less than those undertaken at later points in disease evolution/treatment experience. Changing the primary locus of care from inpatient to outpatient may result in notable cost savings but can produce cost-shifting (from inpatient to outpatient). Nevertheless, in selected patient, the use of non-myeloablative transplants may offer a cost-effective option, especially in the developing country context.

Abstract Between July 2001 and June 2007, 48 consecutive patients with β-thalassaemia major received allogeneic haematopoietic stem cell transplants (allo HSCT) from human-leukocyte-antigen-matched siblings at the Armed Forces Bone Marrow Transplant Centre, Rawalpindi, Pakistan, using standard conditioning regimens. The median age of the patient cohort was 4 years (range, 1–14 years). Thirty-one patients were in risk class I, 11 in class II and six patients were in class III. Grafting was achieved in all patients. Survival was calculated from the date of transplant to death or last follow-up. Major post-transplant complications encountered were acute graft versus host disease (Ac GvHD) (grades II–IV), 35.4%; chronic GvHD, 8.3%; haemorrhagic cystitis, 12.5%; teno-occlusive disease (VOD) of the liver, 6.2%; bacterial infections, 37.5%; fungal infections, 19%; cytomegalovirus (CMV) infection, 6.2%; herpes infection, 6.2%; and tuberculosis in 2% of patients. Graft rejection was observed in five patients. Three patients received second transplants. Mortality was observed in 20.8% of patients. Major fatal complications included GvHD, VOD, intracranial haemorrhage, sepsicaemia, CMV disease and disseminated tuberculosis. Overall survival and disease-free survival were 79% and 75%, respectively, at 6 years post-HSCT.

Introduction

Thalassaemia probably represents the most common single gene disorder causing a major public health problem in the world. Thalassaemias are widely distributed in the Mediterranean, Middle Eastern and Asian countries and occur with significant incidence in populations that originate from these areas. In the Mediterranean and Arab gulf areas, there are more than 200,000 homozygous β-thalassaemia gene and homozygous birth rate is between 1:150 and 1:200. β-Thalassaemia is one of the major health problems in Pakistan. It is the most common genetic disorder in the country, with 5–8% gene frequency in the general population, and approximately 5,000 children are diagnosed each year in all ethnic groups [1–3].

Since the first successful case report of bone marrow transplant (BMT) in a child with β-thalassaemia in 1982, there has been ample evidence to show that BMT for clinically significant haemoglobinopathies can establish donor erythropoiesis and eliminate the underlying hereditary anaemia [4]. Bone marrow remains the predominant source of stem cells in allogeneic haematopoietic stem cell transplantation (HSCT) for non-malignant disorder like β-thalassaemia. During the past three decades, bone marrow transplantation has become a well-established treatment for β-thalassaemia [5, 6]. As per European Group for Blood and Marrow Transplantation registry 2312, thalassaemic patients received match-related donor transplants in 112 different centres by April 2004, and in 90% of transplant, bone marrow was used as stem cell source. Over the last 20 years, the Pesaro
Immune reconstitution and implications for immunotherapy following haematopoietic stem cell transplantation

Abstract

Recovery of a fully functional immune system is a slow and often incomplete process following allogeneic stem cell transplantation. While innate immunity reconstitutes quickly, adaptive B- and especially T-cell lymphopoiesis may be compromised for years following transplantation. In large part, these immune system deficits are due to the decrease, or even absence, of thymopoiesis following transplantation. Therefore, T cell reconstitution initially relies upon expansion of mature donor T cells; a proliferation driven by high cytokine levels and the presence of allo-reactive antigens. This peripheral mechanism of T-cell generation may have important clinical consequences. By expanding tumouricidal T cells, it may provide a venue to enhance T-cellular immunotherapy following transplantation. Alternatively, decreased thymic function may impair long-term anti-tumour immunity and increase the likelihood of graft-versus-host disease.

INNATE IMMUNE RECONSTITUTION: NATURAL KILLER, NEUTROPHIL AND DENDRITIC CELLS

The innate immune system is comprised of a collection of cells that recognize and eradicate pathogens or aberrant cells without priming or antigen presentation. Natural killer (NK) cells, neutrophils, monocytes, dendritic cells (DCs) and macrophages contribute to innate immunity. NK cells purge tumour or virus-infected cells. By 1 month post transplant, NK cells circulate at normal levels and confer some degree of immune protection (Figure 1).1-6 These donor-derived NK cell clones effectively lyse recipient leukaemia in vitro.7 Studies have also shown that the number of NK cells early after transplant correlate with remission rates, implicating the function of these early cells in the clearance of residual tumour.8-10 Data also suggest that killer immunoglobulin-like receptor (KIR) mismatch may play a critical role in NK-cell-mediated tumour eradication.11,12 Many, but not all, studies have associated NK cell KIR mismatch with protection from relapse and graft-versus-host disease (GVHD) in human leukocyte antigen haplotype mismatched and matched unrelated transplants for myeloid and acute lymphoid malignancies.5,11,12

CONFLICT OF INTEREST STATEMENT

None declared.
Like NK cells, recovery of neutrophils and monocytes is rapid following transplantation; however, the timeline for DC reconstitution is delayed and falls between that of innate and adaptive immune recovery. DCs process and present antigens to the adaptive immune system, while producing inflammatory cytokines important for stimulation of the innate immune system. After stem cell transplantation, although donor DCs can be detected in the peripheral blood within the first few weeks, the total number may not approach normal for more than 1 year in adults (Figure 1). Furthermore, studies suggest that while the peripheral blood DCs are largely of donor origin (>80% by Day 14), up to 70% of tissue DCs may remain of host origin after SCT. These host origin tissue DCs may persist for up to 1 year following SCT. Furthermore, the functional competency of these newly derived DCs is not yet well understood in the context of stem cell transplantation. As DC-loaded peptides engender better infectious responses than vaccine alone following transplantation, there is evidence that DC function may be impaired post-transplant, although these studies are limited by differing diseases and transplant conditions.

Collectively, these data suggest that many of the components of the innate immune system reconstitute relatively quickly and completely in the early post-transplant period. While this quick, functional recovery of innate immunity may be exploited for tumor immunotherapy, to date, few studies have demonstrated that these innate immune cells can be manipulated to maximize graft-versus-leukaemia (GVL) effects, with the one notable exception of acute myeloid leukaemia (AML). Some studies have suggested that a graft with KIR mismatch may predict a high probability of NK alloreactivity, augment the graft-versus-AML effect, and diminish the risk of relapse following transplantation. Unfortunately, for most patients and diseases, the data for this NK-alloreactive effect are limited. Additionally, because little is known about the kinetics and function of tissue DCs following transplantation, mechanisms to exploit this biology in vivo have yet to be elucidated. Indeed, the few studies that have investigated anti-tumour vaccination strategies after transplantation have included the administration of DCs loaded with specific peptides to obviate the need for functional donor DCs in vivo (see below).

**ADAPTIVE IMMUNE RECONSTITUTION: B AND T CELLS**

In contrast to innate immune cells, the lymphoid reconstitution of the adaptive compartment is delayed, resulting in persistent recognized deficits in terms of global immunity. In large part, deficiencies in T- and B-cell function after transplant are due to impaired thymopoiesis. As a result, T-cell reconstitution relies upon an alternate pathway of development, termed 'homeostatic peripheral expansion' (HPE). In HPE, mature donor T cells expand, rendering a limited repertoire of T cells available to recognize and signal B-cell counterparts. B and T cells require priming by antigen and engender long-term specific responses using unique receptor sequences. In non-transplant subjects, as B and T cells have the potential for long-term and specific immunity, they are attractive targets for cellular immunotherapy. However, the protracted timeline for lymphoid recovery after transplant remains a challenge to this approach following transplantation. Circulating B cells may not reach normal levels for at least 12 months post transplant and T-cell reconstitution may be delayed for more than 2 years. Despite this fact, there are aspects of the immediate post-transplant milieu that may be especially conducive to anti-tumour T-cell responses, whereas high levels of cytokine that can fuel cytotoxic T-cell proliferation and activation. Thus, an understanding of the cytokine- and antigen-driven responses that are possible following transplantation may permit the genesis of a platform for anti-tumour treatments, with cautious consideration to the potential for exacerbation of GvHD.
B-CELL IMMUNE RECONSTITUTION

B-cell development

B cells are lymphocytes generated in the bone marrow from common lymphoid progenitors. B cells possess immunoglobulin receptors that are generated by somatic recombination, whereby genes are re-arranged to create diverse receptor sequences. B cells undergo selection in the bone marrow prior to release into the peripheral blood. Naïve mature B cells emerge from the marrow with surface immunoglobulin (Ig) M and IgD receptors, then migrate to secondary lymphoid structures. Once a B cell encounters an antigen, often through interactions with CD4+ T cells or DCs, it becomes activated and releases IgM. The activated B cell then processes the antigen for presentation to T cells. After T-cell stimulation, the B cell may undergo isotype switching such that it expresses IgG, IgA or IgE on the cell surface. The B-cell receptor/immunoglobulin molecule may then undergo further receptor modification in the variable regions (VH), through somatic hypermutation, increasing the avidity of the antibody/epitope interaction.

B-cell development

Following allogeneic stem cell transplantation, B-cell development recapitulates that of normal ontogeny in terms of circulating cell types and numbers. In normal ontogeny, B-cell numbers rise until the toddler years, after which there is a gradual descent to normal adult levels in the peripheral blood. Following stem cell transplantation, levels of circulating B cells are very low for the first few months, but then reach levels exceeding normal adults by 1-2 years, approaching the range of normal neonates (Figure 1). 32 The levels then gradually fall. Post-transplant, donor B cells emerge with a naïve phenotype (IgM+ IgD+) initially, with memory B-cell development up to 5 years later.33,35 Consistent with this, IgM levels recover first, by 2-6 months,36 followed by IgG levels which approach normal between 3 and 18 months following transplantation. Finally, IgA reconstitution may be delayed for up to 3 years.6,37 It is important to note that the IgG levels may, in part, reflect residual host plasma cell production, and thus may not be entirely suggestive of donor B-cell competence because host plasma cells are relatively resistant to current preparative regimens and may persist for up to 2 years.38,39

B-cell function following transplantation

The function of B cells remains compromised for 1-2 years following stem cell transplantation. In part, this has been attributed to the T-cell defects during this time frame, with maturation arrest at the naïve stage due to insufficient CD4+ T-cell signalling. After transplant, memory B cells that require CD4+ help for isotype switching show a skewed pattern of complementary determining regions 3 (CD3) of the immunoglobulin heavy chain.40,41 In addition to the lack of CD4+ help, there appears to be an environmental defect following transplantation, because the rate of somatic hypermutation is decreased in mature B cells even in the presence of normal donor CD4+ T cells.42 Thus, following transplantation, B-cell immunity is impaired due to: (1) prolonged low levels of circulating B-cell numbers; (2) a relative defect of mature B cells secondary to decreased isotype switching; and (3) a diminished ability to undergo somatic hypermutation. Importantly, this decreased B-cell function following stem cell transplantation has resulted in diminished vaccine responses to infectious antigens, even after normal B-cell numbers have been achieved.26,43,44

T-CELL RECONSTITUTION

Thymic-dependent T-cell reconstitution

The thymus is the primary site for T-cell development. When peripheral T-cell populations are severely depleted, renewed thymic activity can contribute to T-cell reconstitution, producing naïve CD4 helper, CD8 cytotoxic effector and CD4+ CD25+ regulatory T cells. During
thymopoiesis, bone-marrow-derived T progenitors migrate to the thymus, expand and mature. Developing thymocytes acquire a T-cell receptor (TCR), generated through recombinant real-arrangement of variable (V), diversity (D) and joining (J) genes. The re-arrangement of these genes within the thymus ensures TCR diversity. Prior to emigration as naive T cells, these TCRs undergo positive and negative selection, deleting autoreactive clones termed 'central
tolerance'.

Renewed thymopoiesis may be assessed by several techniques including thymic imaging, naive T-cell frequency, TCR excision circle quantity, and spectrotopy pattern. With renewal of thymopoiesis, the proportion of cells with a 'naive' phenotype increases in peripheral T-cell populations. Measurement of TCR re-arrangement excision circles (TRECs) provides a means of quantifying thymic productivity. TRECs are episomal DNA circles that are generated as a byproduct from the spliced DNA elements remaining after re-arrangement of the VDJ genes encoding the TCR α and β chains. TRECs are not replicated during cell division but are retained in the thymic emigrant cell, and thus are diluted with cell division. Robust thymopoiesis will be reflected in high frequencies of TREC-bearing cells, termed 'recent
thymic emigrants'. In contrast, with intense peripheral expansion, peripheral TREC frequencies remain low. Finally, thymic function may also be evaluated by spectrotyping, a polymerase chain-reaction-based analysis of length variation in the CDR3 of the TCR β chain. A productive thymus is reflected in a Gaussian distribution of CDR3 lengths because of the enormous diversity generated by VDJ re-arrangement occurring in maturing thymocytes. In contrast, clonal expansion results in an oligoclonal pattern of limited CDR3 lengths. Renewal of thymopoiesis thus re-establishes polyclonal Gaussian patterns in the CDR3 spectrotypes, first in naive cells and subsequently in memory T cells.

T-cell reconstitution by homeostatic peripheral expansion

An alternate pathway for T-cell development is through the rapid cell division of mature T-cell clones, termed 'HPE'. This was first demonstrated in a murine model in which two very distinct patterns of T-cell reconstitution ensued following the adoptive transfer of syngeneic bone marrow cells and congenic lymph node cells into C57BL/6-irradiated, thymus-intact or thymecomized recipients. Thymus-bearing hosts largely reconstituted with syngeneic marrow-derived T cells through a thymus-dependent mechanism. Thymectomized mice derived the majority of peripheral T cells from the congenic lymph node innocula, via HPE. HPE drives T-cell reconstitution in lymphopenic hosts and is associated with a shift from naive to memory/activated phenotype in the proliferating cells.

HPE is dependent upon the support of homeostatic cytokines and cognate antigen-driven and regulatory cellular interactions. Interleukin (IL)-7 and IL-15 are the cytokines that drive HPE of naive and CD8+ memory T cells, respectively. Regulatory cells and tumour growth factor beta (TGFβ) provide cellular constraints on HPE. Finally, antigen presentation can drive HPE in lymphopenic and transplant recipients.

IL-7 is a critical, non-redundant cytokine required for stimulating naive T-cell expansion and sustaining naive T-cell survival. Human and animal studies have shown that IL-7 markedly increases naive CD4+ and CD8+ T cells, diminishing TRECs frequency. Conversely, IL-7 depletion restricts T-cell expansion through cytokine depletion by a consumption-based mechanism. Current data suggest that lymphocyte depletion following preparative regimens leads to an increase in cytokine availability (presumably due to lack of cells consuming the cytokine). Upon infusion of donor T cells, the surplus IL-7 drives native cells into proliferation until T-cell numbers return to a level at which IL-7 is once more a limiting factor. Human studies initially revealed this inverse correlation between serum levels of IL-7 and T-cell reconstitution after lymphodepletion; high serum levels of IL-7 coincided with severe
lymphopenia, which decreased rapidly with lymphocyte recovery following transplantation. 53,54

Recent evidence suggests that IL-15 as well as IL-7 may act as a homeostatic cytokine, supporting HPE in lymphopenic hosts. IL-15 enhances proliferation of human CD8+ memory populations in vitro. 55,56 It is produced constitutively by tissues and antigen-presenting cells, and is upregulated in the setting of inflammation. When lymphocytes have been severely depleted as in the setting of bone marrow transplantation, plasma IL-15 levels increase dramatically and exceed normal levels concomitant with a disproportionate expansion of CD8+ memory cells. 57-60 Consistent with this finding, IL-15R expression and responsiveness are highest on activated memory CD8+ T cells. 61-63

Since IL-15 and IL-7 are produced constitutively and could lead to unchecked T-cell expansion, these are balanced by factors that negatively regulate T-cell subsets. TGFβ antagonizes the effect of IL-15, curtailing the proliferation and persistence of CD8 central memory populations. 64,65 Administration of TGFβ to human and murine CD8+ memory cells in vitro decreases CD8 proliferation and attenuates effector function. 66,67 Similarly, regulatory T cells (Tregs) constrain the HPE of naive CD4+ and CD8+ T cells, influencing the host reactivity of T cells during immune reconstitution. 68 Tregs are CD127-CD25+ CD4+ T cells that function to control auto-immune responses. 69,70 Characterized by the expression of the transcription factor Foxp3 and a high level of glucocorticoid-induced tumour necrosis factor receptor, Tregs have been shown to modulate the peripheral expansion of T cells to low- and high-affinity antigen in lymphopenic hosts. 68,70 Treg levels appear to be low following transplantation or chemotherapy, but expand rapidly in the first month. 71,72

In addition to cytokine and cellular regulation of HPE, antigen presentation can also direct the recovering T-cell compartment. First demonstrated in murine models, peripheral expansion of TCR transgenic cells was increased substantially in the presence of cognate antigen. 73 This mechanism was further characterized as a rapid, IL-7-independent expansion of CD4+ and CD8+ T cells that is dependent on major histocompatibility complex II interactions and CD28 ligation, 74 and termed "endogenous proliferation," to differentiate it from homeostatic proliferation which is driven by cytokine signals. 75 In irradiated lymphopenic hosts, both processes could be demonstrated for subsets of CD4+ and CD8+ cells during immune reconstitution. 76 In allogeneic transplantation, the influence of endogenous proliferation is best demonstrated by the disproportionate expansion of cytomegalovirus (CMV)-reactive CD8+ T cells observed in CMV-positive individuals. 76,77 Thus, although homeostatic proliferation permits the expansion of the T-cell compartment as a whole following stem cell transplantation, endogenous proliferation directs T cells to proliferate in response to specific antigen stimuli early in T-cell recovery.

T-cell reconstitution by peripheral expansion in the initial post-transplant period and implications for immunotherapy

In the early post-transplant period, elevated levels of IL-7 and IL-15 drive homeostatic expansion of residual (host) or infused (donor) T-cell subsets. Thymopoiesis is significantly impaired due to thymic injury from the preparative regimen, diminished thymic function in adults, the lack of circulating T-cell precursors, and the absence of critical cytokines or growth factors. This early reliance of the T-cell compartment on HPE has profound consequences. The relative frequencies of the T subsets shift towards a preponderance of activated and cycling memory T cells. 78 As T cells expand through HPE, the frequency of TREC declines. 79 T cells, especially CD8+ subsets, expand rapidly in the first weeks, but this expansion is often unstable with longitudinal studies describing a sharp decline in overall T-cell numbers by 3-6 months. 58 Robust CD8+ proliferation and impaired CD4+ reconstitution lead to an inverted
CD4:CD8 ratio in the months to years following stem cell transplantation. The TCR repertoire resulting from these early expansions is typically skewed and oligoclonal.

This oligoclonal peripheral expansion of relatively few donor T cells potentially presents an opportunity for cellular immunotherapy. Murine models have shown that severe lymphodepletion establishes optimal conditions to promote graft-versus-tumour due to the high levels of homeostatic cytokines (IL-7 and IL-15) and the depletion of regulatory T cells that impede immune responses. Higher doses of irradiation yielded superior anti-tumour responses when mice were given transgenic melanoma-antigen-specific T cells. Furthermore, this effect was abrogated in the absence of IL-7 and IL-15 when these knock-out mice were used as recipients. Depletion of regulatory T cells also enhanced the tumouricidal effect. In the setting of vaccination, while Tregs can also proliferate rapidly and hamper effective anti-tumour responses in lymphoreplete hosts, following stem cell transplantation, the Treg compartment is constrained (by IL-2) while anti-tumour effectors expand and out-compete Tregs. Murine stem cell transplantation models showed that the post-transplant period provides an optimal milieu for cellular immunotherapy, demonstrating specific anti-melanoma immunity and tumouricidal effect when either a vaccine and cytokine adjuvant, a tumour lysate DC pulsed vaccine, or GM-CSF-producing tumour vaccine were administered in the post-transplant lymphopenic setting.

Human studies have corroborated murine data, showing maximal anti-tumour T-cell expansion in the setting of severe lymphopenia. Studies in the highly immunogenic tumour melanoma have demonstrated the potential for this platform. Ex-vivo-expanded melanoma-infiltrating lymphocytes administered with IL-2 after cytoreductive therapy led to clinical responses in up to 50% of patients evaluated. Furthermore, a single study has even demonstrated that T cells can be genetically engineered to target melanoma and affect clinical responses when given during intense lymphopenia.

Vaccination strategies using peptide-pulsed DC vaccines for melanoma have also demonstrated T-cell-specific responses with some clinical responses. It should be noted that these DC-pulsed peptide vaccines did not incorporate lymphodepletion in the regimens. In haematological malignancies, this framework for vaccines has only recently been incorporated into clinical trials, with few studies reported to date. In contrast to melanoma, when peptide-pulsed vaccines were administered in the post-transplant setting (autologous or allogeneic) for multiple myeloma or AML, some assays could detect an immunological response but clinical responses were absent. Notably, these studies administered the vaccines months following transplantation, after exponential T-cell proliferation has likely occurred and IL-7 and IL-15 cytokine levels would be expected to be low. These studies suggest that peptide-pulsed vaccines may be used safely after stem cell transplantation, and that alternative timing strategies may actually lead to a clinical response. Given the successful strategies in melanoma, future trials may seek to incorporate infusion of tumour-targeted T cells and/or the administration of DC vaccines in the early post-transplant period to capitalize on the cytokine storm and absent Treg populations to potentiate tumouricidal effects.

**T-cell reconstitution by thymopoiesis following transplantation and implications for cellular immunotherapy**

While early post-transplant T-cell reconstitution relies upon HPE, an optimal T-cell armamentarium with a diverse TCR repertoire is only achieved through the (delayed) recovery of thymopoiesis (Figure 2). This may have important implications for cellular immunotherapy, particularly in adults who demonstrate limited residual thymic activity. Without renewal of thymopoiesis, naïve T cells and total CD4 + T-cell reconstitution is impaired indefinitely. In paediatric patients, CD4+ naïve T cells are delayed for 1 year or more until thymic activity has resumed. Even 20 years following transplantation,
While the CD8+ rich, memory, oligoclonal population of T cells due to HPE may be beneficial as a platform for vaccination therapy, the delay in thymopoiesis following transplantation may ultimately restrict vaccine efficacy. The lack of diversity of TCRs could diminish the likelihood of an appropriate TCR for tumour antigen recognition. Murine models have demonstrated that decreased TCR diversity due to age or thymectomy correlated with diminished response to an infectious antigen. Furthermore, since CD4+ T cells are necessary for longlasting B- and CD8+ T-cell immunity, the persistent defects in CD4+ T cells likely contribute to impaired responses to infectious and tumour vaccines following transplantation. Murine data suggest that optimal vaccination responses occur in the setting of active thymopoiesis. In human trials, impaired thymic function has been correlated with increased incidence of relapse, suggesting that renewed thymopoiesis may enhance anti-tumour immunity.

In addition to mitigating the effects of cellular immunotherapy, thymic defects are associated with increased risk of acute and chronic GvHD which further impeded de-novo immune responses. In a paediatric population, GvHD and low TREC levels indicative of poor thymic function even conferred an increased risk of mortality. Post-transplant thymic dysfunction contributes to the onset and persistence of GvHD. While thymic damage permits the escape of alloreactive T cells that may engender GvHD, the thymus is also a target of these allo-reactive T cells, limiting thymic renewal. Thus, the regeneration of thymic structures is stunted and denovo diverse T production is impaired indefinitely. Of critical importance when considering T-cell immunotherapy in the context of stem cell transplantation is the barrier that factors that support GvL may worsen GvHD. In murine studies, high doses of IL-7 and IL-15, through exogenous administration or transgenic models, increased the severity and frequency of GvHD. In human studies, persistence of high IL-15 levels following allogeneic stem cell transplantation was correlated with severe acute GvHD. In contrast, factors that reduce peripheral expansion can reduce GvHD. Regulatory T cells could control homeostatic expansion in lymphopenic mice and prevent acute GvHD in murine models. Similarly, in clinical trials, the level of FoxP3+ T regulatory cells in the donor inoculum was inversely correlated with development of acute GvHD.

STRATEGIES TO OPTIMIZE CELLULAR IMMUNOTHERAPY FOLLOWING TRANSPLANTATION

As T- and B-cell reconstitution is critical to successful immunotherapy approaches following transplantation, maximal anti-tumour responses are likely to be elicited when lymphoid reconstitution is both rapid and functional. In part, efforts should be directed towards enhancing thymic recovery while potentially directing the immediate post-transplant HPE towards tumour-specific antigens. Thymic function is influenced by: age, stem cell source; GvHD (see above); the degree of damage due to the preparative regimen; and possible cytokine, hormonal and growth factors. Host age affects thymic recovery significantly, with each successive decade reducing the rate and potential for thymic renewal. In many older adults, recovery of naïve cells through thymopoiesis occurs 3-5 years following transplantation; in some, naïve cells remain below normal levels for decades after stem cell transplantation. While host age is an immutable challenge to thymic recovery, other factors may be influenced by transplant design. To reduce thymic damage, less intensive preparative regimens have enhanced CD4+ T-cell reconstitution and T-cell repertoire diversity, although these may also reduce the levels of HPE cytokines available for early T-cell expansion. Increasing the availability of functional T-cell progenitors has enhanced thymopoiesis in murine models. In human studies, umbilical cord stem cells resulted in higher TREC.

frequencies than adult bone marrow stem cells, possibly due to a higher frequency of T-cell progenitors in these marrows. Furthermore, manipulation of thymic cytokines, growth factors or hormones has improved thymic function after stem cell transplantation. As IL-7 is an important survival factor for developing thymocytes, administration of this cytokine in murine transplant models has enhanced thymopoiesis following bone marrow transplantation. Similarly, keratinocyte growth factor (KGF) has shown promise in boosting thymic productivity in murine hosts. Human studies utilizing KGF have not confirmed these data; however, they were not designed to evaluate enhanced thymopoiesis. Finally, androgen withdrawal and growth hormone have been associated with enhanced thymopoiesis in murine and human studies.

In addition to the factors that affect thymic recovery, the transplant design may enhance immunotherapy by targeting the initial expansion of allo-reactive T cells in the graft. Stem cell source has been studied separately and shown to influence HPE-derived early T-cell reconstitution. Peripheral blood stem cell grafts initially reconstitute peripheral T-cell numbers more rapidly. T-cell depletion and GvHD have also been shown to delay T-cell reconstitution. Degree of mismatch may also influence early T-cell recovery; partially matched or unrelated donors demonstrate delayed T-cell reconstitution with skewed repertoires and very low TREC frequency.

**SUMMARY**

Immune reconstitution following stem cell transplantation does not recapitulate that of ontogeny. This has important implications for the development and maintenance of tumour immunotherapy. While most of the innate immune system recovers quickly and completely, lymphoid reconstitution may be quite delayed in terms of cell number and global function. In large part, lymphoid recovery is hindered by the lack of thymopoiesis. As a result, T-cell reconstitution relies upon an alternate pathway of development that expands infused or residual cells in response to cytokines and antigens. Furthermore, donor DC renewal may also occur late after transplant, minimizing the capacity for these cells to present tumour antigens effectively and alert the developing immune system to the presence of minimal residual disease. These delays in lymphoid and DC reconstitution have significant clinical ramifications, permitting the exploitation of the initial T-cell expansion while challenging effective long-term immunity in the absence of thymopoiesis, appropriate B-cell signalling (due to the absence of CD4+ T cells) and functional donor DCs.

However, these components of immune reconstitution may be manipulated to aid GvL effects. Optimal stem cell transplantation involves eradication of residual tumour, long-term anti-tumour immunity, and minimal GvHD. For rare patient and donor pairs, the early functional recovery of NK cells affords considerable anti-tumour benefit. However, for most graft-host pairs, the optimal transplant entails achieving a balance between the peripheral expansion of anti-tumour T cells and thymic reconstitution, rendering a continuous infusion of de-novo T cells for tumour immunosurveillance with a diverse repertoire to minimize the likelihood of severe GvHD. To maximize stem cell transplantation for immunotherapy, future studies may alter the donor graft to direct the initial homeostatic T-cell expansion towards tumour eradication, either by infusing genetically engineered anti-tumour T cells, expanding naturally occurring GvL T cells prior to infusion, and/or administering DC vaccines loaded with peptides to drive a specific anti-tumour T-cell response. For the best effect, current immunological data suggest that these therapies should be given in the immediate post-transplant period to capitalize on the surfeit of cytokine levels. Alternatively, one could consider administering IL-7 or IL-15 after the first month to raise the levels and drive HPE of anti-tumour T cells after the cytokine surplus is depleted, although this should be considered cautiously in allo-transplantation because of the heightened risk of GvHD. While CD8+ T cells are typically
targeted for these therapies, treatments that employ CD4+ T cells may lead to longer lasting immunity and permit a more effective B-cell response. In the initial period, administration of CD4+ T cells may help to achieve B-cell responses, although the greatest immunotherapy benefit is likely to be obtained when thymopoiesis is augmented as well, replenishing naïve CD4+ T cells. Hopefully, future studies will advance thymic renewal while directing the initial homeostatic T-cell expansion towards tumour eradication. In this way, both pathways of T-cell development can be maximally exploited towards improved GvL immunotherapy without stimulating GvHD, leading to long-term fully functional lymphoid immunity and successful tumour and infection clearance.

**Practice points**

- Single immunity, including neutrophils and NK cells, recovers quickly and completely.
- Donor DC competence is delayed.
- T-celland, to some extent, B-cell immune reconstitution is delayed following stem cell transplantation.
- The initial post-transplant period is dominated by cytokine-driven peripheral expansion of mature donor T-cells.
- Recovery of thymopoiesis is impaired after stem cell transplantation and contributes to T- and B-cell incompetence.

**Research agenda**

- The initial post-transplant period may provide a platform for successful T-cell immunotherapy strategies, due to the robust peripheral expansion during this time frame.
- Strategies to aid in thymic renewal may improve long-term tumour immunosurveillance.

Figure 2.
Diagrammatic representation of the clinical consequences of the two types of T-cell reconstitution evident in the post-transplant period. Early after stem cell infusion, homeostatic proliferation drives the T-cell repertoire due to the high levels of cytokines and delayed thymic recovery. As a result, T cells in the donor product expand and mature into the memory pool, leading to an expanded memory pool with decreased diversity in both naïve and memory lymphocytes. Given the rapid proliferation of few T cells, this immediate post-transplant period presents an opportunity for immunotherapy, through the administration of tumour-targeted T cells or through vaccine administration. Later, in patients with the potential for thymic recovery (including younger patients without graft-versus-host disease (GvHD)), renewed thymopoiesis enriches the naïve T-cell pool. Due to the T-cell receptor re-arrangement in the thymus, these recent thymic emigrants enhance the diversity of the naïve, and subsequently the memory, T-cell repertoire (diagrammatically shown as multi-patterned cells). This has significant implications for long-term immunity. Not only are these patients less prone to life-threatening infections and GvHD, the enhanced T-cell diversity and renewed CD4+ cells likely confer improved tumour immunosurveillance, as shown by decreased rates of tumour relapse. Haploidentical stem cell transplantation after a reduced-intensity conditioning regimen for the treatment of advanced hematologic malignancies: posttransplantation CD8-depleted donor lymphocyte infusions contribute to improve T-cell recovery

Haploidentical hematopoietic stem cell transplantation provides an option for patients with advanced hematologic malignancies lacking a compatible donor. In this prospective phase 1/2 trial, we evaluated the role of reduced-intensity conditioning (RIC) followed by early add-backs of CD8-depleted donor lymphocyte infusions (DLIs). The RIC regimen consisted of thiotepa, fludarabine, cyclophosphamide, and 2 Gy total body irradiation. Twenty-eight patients with advanced lymphoproliferative diseases (n = 24) or acute myeloid leukemia (n = 4) were enrolled. Ex vivo and in vivo T-cell depletion was carried out by CD34⁺ cell selection and alemtuzumab treatment. The 2-year cumulative incidence of nonrelapse mortality was 26% and the 2-year overall survival (OS) was 44%, with a better outcome for patients with chemosensitive disease (OS, 75%). Overall, 54 CD8-depleted DLIs were administered to 23 patients (82%) at 3 different dose levels without loss of engraftment or acute toxicities. Overall, 6 of 23 patients (26%) developed grade II-IV graft-versus-host disease, mainly at dose level 2. In conclusion, our RIC regimen allowed a stable engraftment with a rather low nonrelapse mortality in poor-risk patients; OS is encouraging with some long-term remissions in lymphoid malignancies. CD8-depleted DLIs are feasible and promote the immune reconstitution. (Blood. 2009; 113:4771-4779)

Introduction

Allogeneic stem cell transplantation (SCT) is a curative option for several hematologic malignancies. However, its application is frequently limited by donor availability. Other sources of stem cells include matched unrelated donors, cord blood units, and haploidentical family donors. Haploidentical SCT was unsuccessful for many years because of graft rejection and high incidence of acute graft-versus-host disease (GVHD). The use of megadose of highly purified CD34⁺, pioneered by the Perugia group, allowed a high engraftment rate with a limited incidence of acute GVHD.¹,² Sustained engraftment and rapid natural killer (NK)-cell reconstitution were also achieved using CD3/CD19-depleted grafts.³

In adults, the relevant nonrelapse mortality (NRM) and disease recurrence remain the major obstacles to the routine use of haploidentical SCT. NRM is mainly caused by infections resulting from delayed immune reconstitution in the first 12 months after SCT. Disease recurrence may be partly explained by the use of extensive T-cell depletion, which impairs the graft-versus-tumor effect.

Donor-versus-recipient NK alloreactivity has emerged as a crucial factor for the outcome of haploidentical SCT. Ruggeri et al showed a low relapse risk for patients with acute myeloid leukemia transplanted from NK-alloreactive donors.⁴ Because the chance of finding an alloreactive donor is approximately 40% to 50%, new strategies are required for patients lacking an alloreactive donor or affected by hematologic malignancies that are resistant to NK-cell cytotoxic activity.

Adoptive immunotherapy, using unmanipulated donor T cells from haploidentical family donors, is probably not feasible because of the extremely high risk of severe acute GVHD. Infections of donor T cells, depleted of alloreactive lymphocytes by anti-CD25 immunotoxin or transduced with suicide genes, have been recently investigated to improve immune reconstitution.⁵,⁶

In human leukocyte antigen (HLA)-matched sibling transplantations, CD8 depletion of donor lymphocytes was used to reduce the incidence and severity of acute GVHD while preserving the anti tumor response.⁷,⁸ Nevertheless, contamination by residual CD8⁺ T cells was too high to allow its use in unrelated or haploidentical settings. In 2007, Meyer et al administered CD8-depleted donor lymphocyte infusions (DLIs) after unrelated SCT with an 18% incidence of GVHD. They obtained a very limited CD8⁺ T-cell contamination using the Miltenyi ClinMACS device (Miltenyi Biotech, Auburn, CA).⁹ In addition, Zheng et al have shown that CD4⁺ effector memory T cells could be added safely to T-cell-depleted major histocompatibility complex-mismatched allograft in the murine model.¹⁰ These cells promoted both graft-versus-leukemia and immune reconstitution with far less toxicity.

4771
GVHD than would be expected by unfractionated T cells or by naive CD4+ T cells.11

Here, we report the results of a phase 1/2 prospective trial in which haploidentical SCT using a reduced-intensity conditioning (RIC) regimen was followed by early add-backs of CD3-depleted DLIs.

Methods

Patient characteristics

Between January 2003 and January 2007, we conducted a prospective phase 1/2 trial. Twenty-eight patients received a transplantation from haploidentical family donors. Patients with advanced relapsed or refractory hematologic malignancies were eligible if they fulfilled the following criteria: (1) absence of HLA-related or unrelated donors and (2) a failed autologous SCT and a transplantation compatibility score more than or equal to 2. Nineteen patients younger than 50 years came from a failed autologous SCT (n = 17) or high-dose chemotherapy (n = 2). Eleven had a SCT compatibility score more than or equal to 2 according to SorREN et al.12

Family members were assessed for HLA compatibility by high-resolution molecular analysis (HLA-A,-B,-C,-DR,-DQ). Patients were screened for detection of anti-HLA antibodies by multiplex Luminex (Biosource International, Camarillo, CA) and excluded in case of positivity. Potential donor-versus-recipient NK-cell alloreactivity was analyzed according to missing expression of HLA-C groups 1 or 2 and of HLA-Bw4 alleles. The protocol was approved by the Institutional Review Board and Ethics Committee of the Fondazione Istituto di Rienner e Curara Carattere Scientifico Istituto Nazionale dei Tumori. All patients gave their written informed consent to participate in accordance with the Declaration of Helsinki. Patient and disease characteristics are summarized in Table 1. Median age was 38 years (range, 15-65 years). Only 13 patients were chemosensitive at the time of transplantation (n = 8 complete remission, n = 5 partial remission). The median time from diagnosis to transplantation was 29 months (range, 7-130 months). Twenty-one of 28 patients (75%) came from a failed autologous SCT. Twenty-three patients (83%) were at risk for cytomegalovirus (CMV) reactivation (CMV-seropositive recipient (R CMV+ receiving graft from CMV-seroconjugous [D CMV+] or -seronegative donors [D CMV−]).

Conditioning regimen, stem cell mobilization, and supportive care

The preparative regimen included thiopeta (10 mg/kg) on day −7; cyclophosphamide (30 mg/kg) on days −6 and −5; and fludarabine (30 mg/m2) from day −6 to day −3, aldesleukin (15 mg/m2) on day −2, and total body irradiation (2 Gy) on day −1. Donors received eflizumab 8 μg/kg twice daily beginning 4 days before leukapheresis. CD34+ cells were selected using the CliniMACS device (Miltenyi Biotec). The target doses of CD34+ and CD19+ T cells were 8 × 10^6/kg and 10^6/kg, respectively. No immunosuppressive therapy or posttransplantation granulocyte colony-stimulating factors were given. Patients were managed in laminar airflow rooms. Red cell and platelet transfusions were given according to institutional policy. Prophylaxis against viral and fungal infections consisted of high-dose acyclovir (500 mg/m2 every 8 hours daily) and liposomal amphotericin-B (1 mg/kg daily) from day −7 until the end of neutropenia. Prophylaxis after neutrophil recovery consisted of acyclovir, flucytosine, sulfamethoxazole, and trimethoprim-sulfamethoxazole until recovery of CD4+ cells. Blood samples from patients were screened weekly for CMV and Epstein-Barr virus (EBV).
CD8-depleted DLIs

Donors collected lymphocytes 2 weeks before allograft mobilization. The depletion of CD8+ T cells was performed using ClinMACS CD5 Microbeads and the ClinMACS CD8+ device (Miltenyi Biotec) with a good manufacturing practice procedure. Patients received CD8-depleted DLIs after SCT if they had no signs of active GVHD or rapidly progressive disease. Dose level 1 consisted of 10-fold CD8-depleted T cells on days +45, +75, and +105. If one case of acute GVHD more than 2 occurred in this cohort, the DLI program would have been stopped. Dose level 2 consisted of 5 × 106/kg CD8-depleted T cells on days +45, +75, and +105. Dose reduction was required if 2 cases of acute GVHD more than 2 occurred at this level.

Chimerism analysis and immunophenotype analysis

Chimerism was assessed on DNA extracted from peripheral blood samples by multiplex short-tandem repeat analysis (AmpliTSTR Profiler Plus PCR kit; Applied Biosystems, Foster City, CA). Peripheral blood was collected in ethylenediaminetetraacetic acid for lymphocyte analysis at 1, 3, 4, 5, 6, 9, 12, and 18 months after haploidentical SCT. Direct 2- or 3-color flow cytometric immunophenotyping was performed to analyze lymphocyte subsets, including CD3+, CD19+, CD14+, CD56-1, CD3-CD19+, and CD3-CD16/CD56+. CD3+CD14+ cells were scored. CD14+ monocytes were identified from the CD14+CD106+ population and were not part of the T cell population. CD3-CD56+ cells were identified from the CD56-1 population. Samples were analyzed using the FACSComp flow cytometer (BD Biosciences). Assays were not performed if the T cell dose was less than 106/kg.

Endpoints of the study and statistical analysis

The primary endpoints of the study were engraftment and NRM at 1 year. The secondary endpoints were the incidence of grade II-V acute GVHD before and after CD8-depleted DLIs; GVHD was assessed by consensus criteria.16,17 Overall survival (OS) and progression-free survival curves were estimated by the Kaplan-Meier method and compared using the log-rank test. Crude cumulative incidence curves of relapse and NRM were estimated in a competing risk framework.18 Comparative analysis between dose level 1 and dose level 3 was performed with Mann-Whitney test.

Results

Engraftment and chimerism

The stem cell target dose was achieved with a median of 2 leukaphereses (range, 1-3). The median number of CD34+ and CD3+ cells infused was 10.5 × 106/kg (range, 1.5-15 × 106/kg) and 1 × 106/kg (range, 0.5-5 × 106/kg), respectively. Median CD3+ purity, using the Miltenyi Biotech device, was 95% (range, 81%-98%). The median number of CD19+ and CD56+ cells was 9.5 × 106/kg (range, 1.70-10 × 106/kg) and 1.1 × 106/kg (range, 0.23-10 × 106/kg), respectively. One donor was a poor mobilizer (final inoculum contained only 1.5 × 106/kg CD34+); the donor received a combination of peripheral blood and bone marrow cells achieving long-term engraftment. Potential donor-versus-recipient NK alloreactivity was detected in 11 patients (39%).

All patients had a sustained engraftment as defined by neutrophil counts more than 0.5 × 109/L and untransfused platelet counts more than 20 × 109/L for at least 3 consecutive days. The median time for an absolute neutrophil count of 0.5 × 109/L was 14 days (range, 8-18 days); median time for platelet count more than 20 × 109/L was 11 days (range, 8-17 days). One patient (4%) experienced secondary graft failure at day +150, but she did not receive a second SCT from a different donor because of rapidly progressive disease.

To avoid the binding of alemtuzumab to CD8-depleted DLIs, plasma levels were measured by enzyme-linked immunosorbent assay in the first 10 patients at day 30 after SCT: in only 2 patients was the drug detectable at a lympholytic level (> 0.1 µg/mL).

We assessed chimerism in peripheral blood for all patients at day +30: 26 (92%) had full donor hematopoiesis (≥ 95% donor cells) and 2 (8%) were mixed chimeras. All patients achieved full
after CD8 depletion, were 12.3 x 10^9/kg and 8.3 x 10^9/kg, respectively, which was slightly higher than the median value).

Feasibility of CD8-depleted DLI

Processing with ClinMACS CD8 Microbeads was performed on 28 lymphoprepeses. The median CD4+ T-cell recovery was 84% (range, 31%-130%). CD8-depletion reduced the content of CD8+/CD3+ T cells by a median value of at least 3.3 log (range, 1.7-4). The median CD3+, CD56+/CD16-, and CD19+ cell recovery was 55% (range, 25%-91%), 50% (range, 17%-82%), and 68% (range, 23%-128%), respectively (Table 3). The median number of total CD3+, CD3+/CD4+, CD56+/CD16+, and CD19+ achieved after CD8 depletion was 18.6 x 10^9/kg, 17.4 x 10^9/kg, 3.2 x 10^9/kg, and 2.8 x 10^9/kg, respectively. We also analyzed the total amount of CD4+/CD25+ T cells infused into each patient with CD8-depleted DLI. Recipients experiencing GVHD did not receive a statistically different amount of CD4+/CD25+ T cells (median, 0.26 x 10^9/kg; range, 0.011-1.1 x 10^9/kg vs 0.08 x 10^9/kg, range, 0.001-1.21 x 10^9/kg; P = .4). These CD4+/CD25+ T cells were confirmed FoxP3-positive.

Twenty-three of 28 patients (82%) received CD8-depleted DLI. The total number of infusions was 54, with a median of 2 per patient (range, 1-3). The median dose per patient was 6 x 10^9/kg (range, 2.15 x 10^9/kg). Five patients did not receive the scheduled DLI because of acute GVHD (n = 2), early death for progressive disease (n = 2), and rapid immune reconstitution with T cells more than 1000/mL (n = 1). Interestingly, no systemic acute toxicity or loss of engraftment was observed after CD8-depleted DLI.

No GVHD was observed in the first group of patients (dose level 1) receiving 3 doses of 1 x 10^9/kg CD8-depleted T cells on days +45, +75, and +105. Because of the absence of major complications, dose escalation was started. Only 5 of 11 patients (45%) of the second group (dose level 2) completed the planned 3 doses of 5 x 10^9/kg CD8-depleted T cells because of GVHD (n = 4) or disease progression (n = 2). A patient developed GVHD after all the 3 planned doses. Because this dose level was found to be associated with an unacceptably high incidence of GVHD, the remaining patients (n = 8) received a desescalated schedule (1000 kg day +45, followed by 5 x 10^9/kg on days +75 and +105; dose level 3): 6 patients completed all the infusions without any GVHD; one experienced skin grade 2 acute GVHD; one died of pneumonia and did not receive the day +105 infusion.

Overall, 6 of 25 patients (26%) developed acute GVHD (n = 4 grade II, n = 2 grade III/IV) after DLI, requiring systemic immunosuppressive treatment. Acute GVHD resolved after a brief course of therapy in 2 of them. Chronic GVHD was observed in 4 patients (limited, n = 1; extensive, n = 3) and was de novo in only one patient; the limited form resolved after topical steroids.

Evaluation of T- and B-cell immune reconstitution

We observed a statistically significant increase of circulating CD3+/CD4+ T cells (median, 107/μL; range, 1-600/μL) at day +120 post-DLI, compared with day +30 (P = .002, unpaired t test) with a higher proportion of CD4+/CD45RO+/CD45RA- versus CD4+/CD45RO-/CD45RA+ T cells (88% vs 12%). At day +120, the expansion of CD3+/CD8+ was not significant (compared with the day +30 value) with a median value of 23/μL (range, 2-490/μL), which expressed the CD11a/CD54 memory/effector phenotype (P = .07). NK-cell levels did not change significantly before and after DLI. CD19+ B cells increased from a median of 10 cells/μL (range, 2-100 cells/μL) at day +30 to 135 cells/μL at day +120 (range, 6-300 cells/μL) (P = .01; Figure

2). The median numbers of CD3\(^+\)/CD4\(^+\), CD3\(^+\)/CD8\(^+\), CD19\(^+\), and CD56\(^+\) cells were 187/\( \mu L \), 120/\( \mu L \), 186/\( \mu L \), and 813/\( \mu L \) at day 150, respectively.

We performed a comparative analysis between the dose level 1 and 3 groups: the median value of circulating CD4\(^+\) T cells at day +120 was 57/\( \mu L \) versus 136/\( \mu L \), respectively \( (P = .03) \). No statistically significant difference was observed in the subsequent time points. We observed a trend for a better immune reconstitution at dose level 3 also for CD19\(^+\) cells: the median value of circulating CD19\(^+\) at day +120 was 37/\( \mu L \) (dose level 1) versus 105/\( \mu L \) (dose level 3: \( P = .08 \)). Of note, circulating T cells in the dose level 2 group were very low because of the immunosuppressive therapy with corticosteroids (5 patients had acute GVHD, thus preventing any comparison with the other dose levels).

In 20 patients (72%), TREC counts per microgram (TRECs/\( \mu g \)) of DNA were determined by quantitative PCR in PB lymphocytes, with a median observation time of 360 days (range, 180-990 days). The median value of TREC/\( \mu g \) of DNA was 2.2 \( \times 10^8 \) (range, 0.4-14 \( \times 10^8 \)) in 15 normal donors with the same median age. TREC counts were very low before SCT in the majority of patients (75%). Median baseline TREC values were lower also in patients younger than 50 years (median value, 0.4 \( \times 10^7 \)). Ten of 20 (50%) patients showed measurable TREC at 1 year with a median value of 1.3 \( \times 10^7 \) TREC/\( \mu g \) of DNA (range, 0.6-18 \( \times 10^7 \); Figure 3). Nine of 10 patients with measurable TREC were younger than 50 years and are alive.

In 10 patients, TCR spectratyping was performed before and at days +180 and +360 after SCT. The TCR complexity score was evaluated as previously reported by Bomberger et al.\(^{14} \); in a control group of 10 normal donors, the median TCR complexity was 98% (range, 85%-109%). Before conditioning, most patients had a Gaussian-like TCR-\( \beta \) repertoire pattern (median, 97% TCR complexity; range, 82%-112%). At 1 year after SCT, median TCR complexity was 70% (range, 49%-120%); Figure 3). All the patients showing posttransplantation thymopoiesis had a high TCR complexity score at 1 year after SCT.

IgH CDR3 spectratyping has been analyzed in 9 patients: a partial return to a polyclonal repertoire at 1 year after SCT was observed. Median number peaks at day 360 in Vh1, Vh2, Vh3, Vh4a, Vh4b, Vh5, and Vh6 were 21, 16.5, 17, 15, 15.5, 17, 16.5, and 20 in normal donors and 11.5, 10.5, 12.5, 10.5, 8.5, 13, 7.5, and 16.5 in patients (Figures 4 and S1, available on the Blood website; see the Supplemental Materials link at the top of the online article). The majority of the patients achieved normal level of IgM at 6 months after SCT (median, 94 mg/dL; range, 27-230 mg/dL); only at 1 year after SCT, the majority of the patients had normal values of IgG and IgA: median, 746 mg/dL (range, 440-1500 mg/dL), median 78 mg/dL (range, 50-161 mg/dL).

CMV- and EBV-specific T cells after CD8-depleted lymphocyte infusions

After SCT, we examined functional immune recovery in 6 patients of dose level 3, longitudinally from day +45 until day +450 (Figures 5, S2). To confirm the specificity of antigen-induced CD137 expression, we first analyzed PBMCs from CMV-negative (\( n = 5 \)) and CMV-positive healthy donors (\( n = 5 \)) stimulated with CMV peptides: the median frequencies of CMV peptide-reactive CD137\(^+\)/CD8\(^+\) and CD137\(^+\)/CD4\(^+\) T cells were 0.2% (range, 0.1%-0.4%) and 0.3% (range, 0.1%-0.6%), and 2.5% (range, 0.1%-0.4%).
2.1%-3.5%) and 1.4% (range, 1%-2%), respectively. The median frequencies of CD137+/CD8+ and CD137/CD4+ T cells in donors after activation with CytoStim (Miltenyi Biotec), were 10.2% (range, 4%-15.2%) and 14% (range, 9%-15.8%), respectively. Responses to CytoStim (Miltenyi Biotec) were detected for both CD8+ and CD4+ T cells in all the patients analyzed (median CD137+/CD8+ and CD137+/CD4+ T cells were 4% [range, 1%-7%] and 4.5% [range, 1%-8.5%], respectively).

Before CD8-depleted DLI, we did not observe any CMV response in all 6 patients analyzed. Only 2 of 3 CMV+ patients were allografted from CMV+ donors, and CD8 T-cell responses were observed after CD8-depleted DLI; the frequencies were 2.4% and 2.0%, respectively, at day +200 after SCT. In 2 other patients (R CMV+/D CMV-), the frequency of CMV-specific CD8+ T cells was 3.7% and 2% at day +200. All the aforementioned patients did not experience further episodes of CMV reactivation. In the last patients analyzed (R CMV+/D CMV-), the frequencies of CMV-specific CD8+ T cells were less than 0.5%. The expansion of CMV-specific CD8+ T cells in 4 of 6 patients exceeded the one of CD4+ T cells (median frequencies CD4+/CD8+; 0.9% range, 0.1%-1.4%), although frequencies of CD4+/CD137+ T cells tended to increase progressively starting from day +200.

EBV-specific T cells (CD8+ and CD4+) against BZLF1 and EBNA1 antigens were evaluated in the same 6 patients from day +100 to day +450. All patients received allografts from EBV+ donors. EBV-specific responses were detected in 4 of 6 of them: the median frequencies of BZLF1- and EBNA1-specific CD3+/CD8+ T cells were 2.1% (range, 0.5%-5%) and 1.5% (range, 0.3%-2.5%), respectively. Only 2 patients showed an early response to BZLF1 at day +200; 1 patient showed a concomitant expansion of CD4+ and CD8+, the other one showed an expansion of CD4+ only (Figure S3).

OS, progression-free survival, and disease response to CD8-depleted lymphocytes

At a median follow-up of 28 months (range, 6-65 months), 12 patients (45%) were alive and 16 died of disease (n = 10); NRM (n = 6). Nine of 12 patients were in complete remission (n = 1 chronic lymphocytic leukemia (CLL), n = 2 HL, n = 3 aggressive lymphomas of T phenotype, n = 1 follicular cell lymphoma, n = 1 multiple myeloma, and n = 1 acute myeloid leukemia; Table 4). The estimated 2-year OS and progression-free survival were 44% (95% confidence interval, 26%-62%) and 45% (95% confidence interval, 25%-63%), respectively (Figure 6). Patients with chemoresistant disease had a better outcome: 2-year OS 75% versus 30% of the chemoresistant group (P < .004).

Disease relapse or progression occurred in 14 of 28 (30%) patients at median time of 4 months after SCT (range, 1-11 months), causing death in 10 of them (n = 4 aggressive NHL, n = 1 CLL/Richter, n = 4 HL, n = 1 multiple myeloma). Four patients with refractory disease (n = 1 acute myeloid leukemia, n = 2 HL, n = 1 CLL) responded to CD8-depleted DLI; all these patients achieved complete remission coincident to a GVHD flare (median duration of response, 14 months; range, 7-19 months), but unfortunately they died because of disease progression (n = 1) or toxicity (n = 3).

Discussion

In this prospective phase 1/2 trial, we showed that (1) RIC regimen allows a stable engraftment of haploidentical stem cells with a
limited incidence of acute GVHD; (2) younger patients with chemoresistant lymphoid malignancies can attain a long-term disease control; and (3) CD8-depleted DLIs are feasible and promote immune reconstitution.

Myeloablative haploidentical SCT with megadoses of CD34+ cells and no GVHD prophylaxis, pioneered by the Perugia group, had some limitations, including graft failures, an NRM rate ranging from 25% to 40%, and the occurrence of organ toxicity related to high-dose conditioning in poor-risk patients. For these reasons, the use of RIC regimens and the new methods for graft manipulation became an appealing area of investigation. Rizzieri et al. used a RIC regimen, unmanipulated grafts, and GVHD prophylaxis, reporting a 63% 1-year OS in standard-risk patients. More recently, a strategy including a RIC regimen followed by CD3/CD19-depleted grafts has been proposed as an alternative option for haploidentical transplantations. Despite the rapid and sustained engraftment and the accelerated immune reconstitution, a relevant incidence of acute GVHD was reported.

Although the escalation of the stem cell dose played a crucial role to favor a high engraftment rate, graft failures ranging from 5% to 14% have been frequently reported after haploidentical SCT. In our study, only one secondary graft failure was observed; probably the pretransplantation screening for anti-HLA antibodies has limited this complication. Indeed, the detection of donorspecific HLA class I and II antibodies was associated with engraftment failure in unrelated transplantsations. Despite the inclusion of poor-risk advanced malignancies, an encouraging 26% NRM rate and 44% OS at 2 years were observed in our study. Interestingly, late NRM was restricted only to 2 patients dying 1 year after SCT. Possible explanations for the promising clinical results are (1) RIC could have reduced acute organ toxicity and thymic damage; (2) drugs used in the conditioning regimen as well as alemtuzumab had a significant antitumor activity; and (3) low-dose alemtuzumab allowed the use of early DLI add-backs.

The occurrence of defective immune recovery after haploidentical SCT was associated with a high risk of severe infections, which heavily affected morbidity and mortality. Nonetheless, adoptive immunotherapy was investigated mostly in children who have a functional thymus and lower incidence of GVHD compared with adults. Azaroliz et al. demonstrated that the infusion of low-dose donor T cells, depleted of alloreactive lymphocytes, significantly increased CD4+ and CD8+ T cells, accelerating CMV- and EBV-specific immunity in the first 4 months after SCT. In adults, data concerning the use of T-cell add-backs are very limited. Perruccio et al. described the immune recovery in myeloablative haploidentical SCT, indicating that (1) CD4+ cell counts were inferior to

Figure 6. Kaplan-Meier plot of estimated progression-free survival and overall survival for all the patients.
In the clinical setting, haploidentical SCT has been usually employed for salvage of acute myeloid leukemias, and few data on its use in lymphomas are available. Sykes et al\(^{20}\) reported a very small study in which 2 of 5 lymphoma patients with refractory disease had a clinical response. In addition, Burroughs et al\(^{21}\) in patients with Hodgkin lymphoma, obtained an encouraging 69% progression-free survival. Our study reports the data on a larger number of lymphoma patients and shows that those with chemosensitive disease had a better outcome and could experience long-term remissions. Larger prospective trials are required before considering this promising therapeutic option as a routine salvage strategy for advanced hematologic malignancies.

Cellular Immune Reconstitution and Its Impact on Clinical Outcome in Children with β Thalassemia Major Undergoing a Matched Related Myeloablative Allogeneic Bone Marrow Transplant

Reena Rajasekar, Vikram Mathews, Kavittha M. Lakshmi, Biju George, Auro Viswabandya, Mammen Chandy, Alok Srivastava

We have prospectively analyzed cellular immune reconstitution (IR) in 63 consecutive pediatric patients with β thalassemia major who underwent an HLA matched related allogeneic bone marrow transplant (BMT). Samples from bone marrow graft and posttransplant peripheral blood samples from recipients at specified time points were assessed for IR of cellular subsets. The median age of the cohort was 7 years, and there were 37 (59%) males. A CD34 cell dose above the median value of 7.3 × 10⁶/kg had a lower incidence of bacterial (P = .003) and fungal (P = .003) infections in the posttransplant period, and was not associated with an increased risk of graft-versus-host disease (GVHD). Among cases that did develop grade II-IV GVHD the absolute CD8 (116 versus 52 cells/µL, P = .012), CD8 naïve (74 versus 9 cells/µL, P = .005), and CD8 memory counts (44 versus 21 cells/µL, P = .010) were significantly higher on day 15. Fifteen patients (24%) rejected their graft (7 primary and 8 secondary). The day 28 natural killer (NK) cell count was significantly associated with secondary graft rejection, event-free survival (EFS), and overall survival (OS) (P = .044, .013, and .034, respectively). On a multivariate analysis, patients with a day 28 NK cell count below the median value of 142/ µL had a significantly higher rejection rate (hazard ratio [HR] = 11.1, P = .038) and a lower EFS (HR = 16.3, P = .034).

KEY WORDS: Immune reconstitution, Bone marrow transplantation, Thalassemia major, NK cell reconstitution, Graft rejection

INTRODUCTION

An allogeneic stem cell transplant (SCT) remains the only curative option for numerous malignant and inherited hematologic conditions. The clinical efficacy of an SCT is limited by regimen-related toxicity secondary to the conditioning regimen, immune response by donor cells to recipient antigens resulting in graft versus host disease (GVHD) and delayed or inadequate immune reconstitution leading to infections, recurrence of a malignancy, and occasionally rejection of the graft [1,2].

Although immune reconstitution post-SCT has been extensively studied in adults, there is limited data in the pediatric population [1]. An early low plasmacytoid dendritic cell count has been reported by us and others to be associated with acute and chronic GVHD (aGVHD, cGVHD) [3,4]. Rapid lymphocyte and lymphocyte subset recovery have been reported to be associated with a favorable outcome [5-7]. It is known that the ability to generate CD45RA⁺ (naive T helper cells) decreases with age, because this is thymic dependent [8,9]. It is also recognized that there is earlier generation of helper T cells and B cells in children than in adults [1]. There is, however, limited data on the impact of these variations in the pattern of immune reconstitution on clinical outcomes post-SCT in a uniform cohort of children.

Natural killer (NK) cells are innate immune cells critical to host defense against invading pathogens and malignant transformation. NK cells have been extensively studied in the posttransplant period, as they are potentially associated with both rejection and a graft-versus-leukemia (GVL) effect [10,11]. Experimental data suggests that they have a number of
potentially beneficial effects, including an NK cell-versus-leukemia effect reducing relapse, NK cell-versus-residual host T cell reducing graft rejection rate, and NK cell-versus-host dendritic cells, potentially reducing the risk of GVHD [10,12,13]. In the pediatric population with high-risk thalassemia major, graft rejection is a major problem, and can occur in 20% to 50% of cases [14]. The impact of the pattern of NK cell reconstitution in this population has not been studied.

We prospectively analyzed the effect of immune reconstitution in a pediatric population of patients with β thalassemia major undergoing a myeloablative HLA matched related allogeneic SCT.

PATIENTS, MATERIALS, AND METHODS

This prospective study included all consecutive patients who underwent an allogeneic HLA matched related SCT for β thalassemia major at our center, between December 2003 and December 2006. All patients had 6 antigen HLA-matched sibling or family donors. A written informed consent was obtained from parents or legal guardians for all patients.

Pretransplant Evaluation

All patients were evaluated with a complete blood count (CBC), biochemical profile, and serology for human immunodeficiency virus (HIV), hepatitis B virus (HBV), hepatitis C virus (HCV), and cytomegalovirus (CMV). A liver biopsy was performed at the time of Hickman catheter insertion.

Conditioning

Patients were conditioned using a conventional myeloablative regimen consisting of busulfan (Bu) from 16 mg/kg (1 mg/kg/dose 4 times daily × 4 days) administered orally (dose adjustment based on pharmacokinetic levels was not attempted), cyclophosphamide (Cy) 200 mg/kg given over 4 days (50 mg/kg/day i.v. over 1 hour), and antilymphocyte globulin (Pasteur Merieux, Lyon, France) or antithymocyte globulin (ATG; Pharmacia and Upjohn, Kalamazoo, MI) 30 mg/kg/day for 3 days as previously reported [15]. In 25 patients, a new preparative regimen of fludarabine (Flu; 150 mg/m² over 5 days), Bu (14-16 mg/kg over 4 days), and Cy (160 mg/kg over 4 days) was used.

Graft Source and Engraftment

The stem cell source was bone marrow (BM) for all except 2 cases. BM was harvested under general anesthesia from the iliac crest and the target cell dose was 3 x 10^6 nucleated cells/kg body weight of the recipient. Unprimed BM was used in majority of the patients (59%). Twenty-four (38%) patients received granulo-
cyte colony stimulating factor (G-CSF) primed BM (G-CSF 10 µg/kg/day × 2 days prior to BM harvest).

GVHD Prophylaxis

Cyclosporine (CsA) and a short course of methotrexate (MTX) was used as GVHD prophylaxis; CsA was administered at a dose of 2.5 mg/kg i.v. over 4 hours twice daily starting on day -4 and changed to oral administration at 5 mg/kg twice daily when mucositis had resolved. CsA levels were monitored and the dose adjusted to achieve a target level of 100-400 ng/mL. CsA was administered for 6 months, and over the next 6 months the dose was gradually tapered and stopped. If there was active GVHD, tapering and continuation of GVHD CsA beyond this period was left to the treating physician’s discretion. The MTX dose was 10 mg/m² on day -1 and 7 mg/m² on days 3, 6, and 11. If mucositis was severe (grade IV) or bilirubin >20 mg/L, the day 6 and day 11 doses were omitted.

Supportive Care

All patients were nursed in a positive pressure HEPA-filtered transplant unit. Prophylactic acyclovir was administered for the first 100 days; it was continued beyond day 100 if patient had GVHD and required additional immunosuppression. Quantitative CMV polymerase chain reaction (PCR) analysis was done from day 30 onward, once in 2 weeks up to day 100, more frequently if there was evidence of CMV reactivation. Trimethoprim-sulphamethoxazole and oral penicillin prophylaxis was initiated after stable engraftment and continued for a year.

Flow Cytometric Analysis

Harvest samples from donors and peripheral blood samples from posttransplant recipients were assessed for stem cells, lymphocyte subsets, and dendritic cells subsets. Posttransplant peripheral blood samples were obtained from patients on day 15, day 28, day 45, 2 months, 3 months, 6 months, 9 months, and 12 months for flow cytometry analysis. Briefly, cells were labeled using a panel of monoclonal antibodies (mAbs) to CD34, CD133, CD3, CD4, CD45RA, CD45RO, CD8, CD25, CD69, CD19, CD56, CD16, CD11c, CD123, HLA-DR, and lineage cocktail antibodies directly conjugated with either fluorescein isothiocyanate (FITC), phycoerythrin (PE) or peridinin chlorophyll protein (PerCP) (Becton Dickinson, San Jose, CA), followed by red cell lysis with ammonium chloride. The cells were then washed and analyzed using FACSCalibur (Becton Dickinson, Mansfield, MA). Data analysis was performed using CellQuestPro software (Becton Dickenson). Dead cells were gated out before the final analysis using forward versus side-scatter dot-plots. Lymphocyte subset
percentages were calculated from the lymphocyte gate as appropriate. The absolute lymphocyte subset counts were then calculated from a routine automated leukocyte count (Beckman Coulter LH 750, Fullerton, CA). A previously described method for identification and enumeration of dendritic cell subsets was used [16]. For stem cell enumeration (CD34+) in the graft, ISHAGE gating strategy was performed as described previously [17].

Definitions and Definition of Outcomes

Incidence and severity of GVHD was defined as per established criteria [18]. Time to engraftment for neutrophils was defined as the first of 3 consecutive days on which absolute neutrophil count (ANC) was >500/mm³. Time to engraftment for platelets was defined as the first of 3 consecutive days on which the unsupported platelet count was >20,000/mm³. Primary graft failure was defined by lack of neutrophil engraftment (ANC <0.5 x 10⁹/L) measured for 3 consecutive days by 28 days posttransplant. Secondary graft rejection was defined when initial engraftment was followed by subsequent development of ANC <0.5 x 10⁹/L for 3 consecutive measurements, recurrence of transfusion dependence, or paucity engraftment with a hypocellular marrow [19]. Secondary graft rejection was further defined as early (graft rejection within 60 days after initial engraftment) or late (graft rejection occurring after 60 days from SCT and initial engraftment).

The data from pretransplant counts were used as reference range for each of cellular subsets analyzed. Achievement of the median pretransplant cellular subset value was considered an event on a Kaplan-Meier analysis. Patients who died before engraftment or had a graft rejection after transplantation were censored at that time point for immune reconstitution studies.

Conventional Lucarelli risk stratification for patients with β thalassemia major undergoing an allogeneic SCT was used [20]; additionally, a high-risk subset of class III cases as previously described was also utilized for analysis [21]. Event-free survival (EFS) was defined from the time of transplant to an event; an event was primary graft failure, death, or recurrence of transfusion dependence. Stable mixed chimerism with transfusion independence was not considered an event for this analysis. Overall survival (OS) was defined as the time from transplant to death from any cause.

Bacterial infection was defined as positive culture from blood and any other sites (urine, sputum, pus, abscess, and catheter). Bacterial pneumonia was also diagnosed when there were clinical and radiologic signs of pneumonia with or without positive sputum culture or a pneumonia that improved after antibacterial therapy [22]. CMV infection was defined as 2 consecutive positive PCR assays within 1 week or a CMV copy number >140 copies/mL whole blood performed using artus CMV PCR Kits (Qiagen, Hilden, Germany). CMV disease was defined as the demonstration of CMV by biopsy specimen from visceral sites (by culture or histology) or the detection of CMV by culture in broncho-alveolar fluid in the presence of new or changing pulmonary infiltrates [23]. All fungal infections were documented as probable, possible, and proved fungal infections based upon the CDC criteria [24].

Statistical Analysis

For comparison of dichotomous variables, a χ² test was done while continuous variables were compared using either a Student's t-test or a Mann-Whitney U-test as was deemed appropriate. The probability of survival was estimated using Kaplan-Meier method for rejection, EFS, and OS, and compared by the log-rank test. Cox models were used to assess the proportional hazards of various subsets both in the graft and those engrafted after transplant on clinical outcomes such as rejection, GVHD, day 100 treatment-related mortality (TRM), EFS, and OS. To confirm outcomes and to adjust for potential confounding factors, multivariate Cox proportional hazards models were also performed. Kinetics of lymphocyte recovery was also evaluated by calculating area under curve (AUC) using trapezoidal method [25]. For all the tests, a value of P < .05 was considered statistically significant. Statistical analyses were performed using SPSS for Windows 11.01 version (SPSS Inc., Chicago, IL).

RESULTS

Demographic and Baseline Characteristics

A total of 63 patients with β thalassemia major underwent an SCT between December 2003 and December 2006 at our center. The median age of this cohort was 7 years (range: 2-14 years). There were 37 (59%) males and 25 (41%) females. By conventional risk stratification [20], there were 7 (11%), 25 (40%), and 31 (49%) transplants in class I, II, and III, respectively. The baseline patient and graft characteristics are summarized in Table 1. The median pretransplant value of the total count and all the subsets analyzed except for dendritic cell count was significantly lower than age matched donors and that of age-matched children as reported previously (supplementary data) [26,27]. Achievement of the median pretransplant cellular subset value was considered an event on a Kaplan-Meier analysis. Patients who died before engraftment or had a graft rejection after transplantation were censored at that time point for immune reconstitution studies.

</table>

Table indicates Bu = Busulfan; ATG = antithymocyte globulin (Pharmacia Upjohn); ALG = antilymphocyte globulin (Pasteur-Merieux); Cy = Cyclophosphamide; Flud = Fludarabine; CSA = Cycosporine; MTX = Methotrexate; BM = bone marrow; PBSC = peripheral blood stem cells.

The median BM cell dose was 4.4 x 10⁹ (range: 1.7-22.7) total nucleated cells/kg and 7.3 x 10⁶ CD34/kg (range: 1.2-23). The total WBC count in the harvested product was higher in G-CSF primed BM (BM = 19.7 x 10⁹/L vs. G-BM = 37.75 x 10⁹/L, P = .000), resulting in a lower volume of marrow harvested to achieve the target cell dose of 3 x 10⁹ total nucleated cells/kg (BM = 430 mL versus G-BM = 280 mL, P = .000). The graft characteristics were similar in both BM and G-CSF-primed BM sources for stem cell content (CD34, CD133), but significantly differed in NK, CD19, CD8CD45RA, and plasmacytoid dendritic cell content (Table 2).

Clinical Outcomes

Of the 63 transplants, 2 patients had peritransplant deaths related to regimen-related toxicity (RRT). Among the 61 patients who could be evaluated for engraftment, 54 (89%) achieved sustained engraftment. Seven patients (11%) had primary graft failure. Five of these patients died prior to day 28 (time point for the first chimerism analysis). Two patients had autologous reconstitution by day 20, and chimerism analysis on day 28 revealed a complete absence of a donor band; both are transfusion dependent and have remained alive on follow-up for more than a year. Of the 54 who had achieved sustained engraftment, 2 (4%) had early (>28 days and <60 days posttransplant) and 6 (11%) had late secondary graft rejections (>60 days posttransplant). On day 28, the time point when the first chimerism analysis was done, 7 of these patients had a mixed chimerism pattern with a median donor band of 79% (range: 26-91), whereas 1 patient had documented complete chimerism (100% donor band) at this time point. The median time to graft rejection among these patients was 77 days (range: 53-184 days).

Among the 54 who had engrafted, 2 died, 1 each on day 17 and day 23 secondary to RRT complicated by infections (prior to documentation of chimerism status). Of the remaining 52 patients who could be evaluated for aGVHD, 8 (15%) developed aGVHD grade (II-IV), whereas 5 of 45 (11%) patients surviving >100 days developed cGVHD. The Kaplan-Meier 3-year EFS and OS for the entire cohort was 67% ± 6% and 78% ± 5%, respectively, at a mean follow-up of 37 months. The EFS and OS according to risk stratification was, class I: 86% ± 13% and 86% ± 13%; class II: 75% ± 9% and 83% ± 8%; class III: 57% ± 9% and 66% ± 10%, respectively.

Immune Reconstitution Post-SCT

The data from pretransplant counts were used as reference ranges for each of the cellular subsets analyzed. Achievement of the median pretransplant cellular subset value was considered an event on a Kaplan-Meier analysis. NK cells were the first cells to recover, within a month, in the early posttransplant period. Following immune reconstitution of NK cells, there was a transient increase in NK cell numbers above pretransplant baseline levels, and thereafter remained within the normal range throughout the rest of the posttransplant period (Figure 1). Dendritic cells (monocytoid and plasmacytoid) also recovered by day 30 posttransplant and thereafter remained within the normal range. The Kaplan-Meier estimate of the mean time for CD3 recovery is 9.7 months (95% confidence interval [CI]: 8.5-12). Recovery of CD4 cells to baseline levels is even further delayed with the mean Kaplan-Meier estimate not being achieved in the 1 year study period of this analysis. At the end of 1 year, IR analysis revealed that only 7 of 54 (13%) patients who had sustained engraftment achieved the pretransplant median CD4 levels. However, CD8 cells reconstitute fairly rapidly with a median Kaplan-Meier estimate of 2 months (95% CI: 0-4 months) resulting in an inverted CD4/CD8 ratio for a prolonged period following transplantation. CD4⁺CD45RA⁺ (helper naive T cells) subset recovery is delayed more than a year, whereas CD8⁺CD45RA⁺ (cytotoxic naive T cells) normalize within the first month post-SCT. There was a correlation with the donor age and speed of recovery of CD4⁺CD45RA⁺ T cells, with younger age of the donor being significantly associated with a faster recovery (r = .3; P = .032). Kaplan-Meier estimates showed that the median time for 6 cell (CD19) reconstitution was 4 months (95% CI: 1-7 months).

There were too few and insignificant variations in immunosuppression withdrawal to comment on the
impact this could have had on immune reconstitution. The immune reconstitution data of this cohort is summarized in Figures 1 and 2.

Factors Influencing Immune Reconstitution Post-SCT

Stem cell source and conditioning regimen

The Kaplan-Meier estimates of NK, cytokine induced killer cells (CIK-CD3-CD56+CD16+), B and T cell subsets (CD4, CD4D45RA, CD4D45RO, CD4DCD25, CD8, CD8CD45RA, CD8CD45RO, and CD8CD25), and plasmacytoid dendritic cells recovery were not significantly different between transplants utilizing either a BM or G-BM graft source. However, the AUC values of NK, B, T cell subsets (except for CD8, CD8CD45RO, and CD8CD25), and dendritic cells were all significantly higher in patients receiving G-BM compared with BM grafts, although this did not translate into a significant improvement in EFS, OS, or reduction in the incidence of infections (Table 2). These graft sources also differed in reconstitution of monocyctic dendritic cells. The day 30 Kaplan-Meier estimate for MC recovery was 32% ± 10% and 18% ± 9% for BM and G-BM, respectively (P = 0.029). There were no significant differences in the immune reconstitution patterns among patients who received antilymphocyte globulin (ALG) as part of the conditioning regimen versus those who did not (Table 3).

Acute GVHD

Patients with aGVHD grade II-IV had higher CD3 (P = 0.012), CD8 (P = 0.002), CD8CD45RA (P = 0.027), and CD8CD45RO (P = 0.005) AUC values compared with those who did not develop GVHD. Among cases that did develop grade II-IV GVHD the absolute counts were significantly higher on day 15 in the following cellular subsets; CD8: 116 versus 52 cells/μL, P = 0.012, CD8CD45RA: 74 versus 19 cells/μL, P = 0.005, and CD8CD45RO: 44 versus 21 cells/μL, P = 0.010. Only 1 of 8 patients who eventually developed aGVHD had evidence of aGVHD at this timepoint.

Infections

Patients who had evidence of viral infections post transplant (within study time period of 1 year) had
a significantly higher CD8CD45RA AUC value ($P = .021$) compared with those that did not. None of the other cellular subsets AUC or absolute values at any time point significantly differed in those who had and those who did not develop a viral infection. Similarly, there was no obvious correlation with cellular subset recovery kinetics and bacterial, fungal, or viral infections.

**Impact of Graft Characteristics and Day 28 Lymphocyte Subset Counts on Clinical Outcomes**

After extensive immune reconstitution analysis and its impact on clinical outcomes, the only time point where differences in cellular subset levels had a significant impact on clinical outcome after engraftment was the day 28 subset values. Eleven of 63 patients were excluded for day 28 subset analysis. Nine died before day 28, whereas in 2 patients a blood sample was not available at this particular time point. Fifty-two patient’s values were available for evaluation at this time point. The day 28 values represent an early period of measurable donor immune reconstitution and could also potentially be a clinically useful early predictor for outcomes after SCT. Hence, further detailed analysis of this time point along with graft characteristics on clinical outcomes was undertaken in this study.
**Engraftment and rejection**

The median time to neutrophil and platelet engraftment was 16 days (range: 10-23) and 26 days (range: 10-49), respectively. Patients with day 28 NK above the median value (>142/μL) had faster platelet engraftment compared with those below the median value (26 versus 30 days, \( P = .031 \)) (Table 4). None of the other cellular subset had an impact on the time to neutrophil and platelet engraftment. Fifteen of 63 patients (24%) rejected their graft; 7 of 15 were primary graft failures and were excluded from day 28 analysis. Among the 7 cases with primary graft failure the median leukocyte counts on day 28 was \( 0.3 \times 10^9/\text{L} \) (range: 0.2-0.8). At this time point and at an earlier (day 15) time point the leukocyte count was too low to make a meaningful assessment of subset cellular immune reconstitution. Of the remaining 8 patients, 2 (13%) had early and 6 (40%) had late secondary graft rejections post-SCT. After excluding primary graft failures (\( n = 7 \)), the median day 28 NK count in patients who rejected their graft (\( n = 8 \)) was significantly lower compared to those who did not reject (\( n = 42 \)) (91/μL versus 150/μL; \( P = .013 \)) as shown in Figure 3.

None of the other cellular subsets at this time point was significantly associated with graft rejection. There was no evidence that graft rejection was preceded or directly related to any infective process. Posttransplant chimerism at day 28 was complete in 37 of 52 patients (71%) with only donor-specific bands. Among the patients with mixed chimera (15/52 = 29%), the donor band contributed a median of 87% (range: 26-98).

**GVHD**

Eight of 52 (15%) patients who could be evaluated developed aGVHD grade (II-IV). Five of 45 patients (11%) surviving >100 days developed cGVHD. None of the subsets that were found to be a risk factor in univariate analysis retained significance for aGVHD (CD4CD45RO and CD4CD25 cell dose) and cGVHD (CD34 cell dose, day 28 activated NK and day 28 CD8CD25 cells) in a multivariate analysis. There was no association of day 28 dendritic cells with development of GVHD. Similarly, neither the graft source (BM or G-BM) or the use of ALG in the conditioning regimen had an

MC indicates monocyctoid dendritic cells; PC, plasmacyctoid dendritic cells; EFS, event-free survival; OS, overall survival; GVHD, graft-versus-host disease; ANC, absolute neutrophil count; TNC, total nucleated cells; HSC, hematopoietic stem cell; ATG, antilymphocyte globulin; ALG, antilymphocyte globulin.

Influence on development of aGVHD and cGVHD (Tables 2 and 3).

Infections

During the posttransplant study period 22% of patients had documented bacterial, 13% had viral, and 11% had fungal infections (proved, possible, and probable), which were microbiologically or clinically documented. Patients who received a higher than median CD34 cell dose (median = 7.3 × 10^9/kg) had lower incidence of bacterial (P = .003) and fungal infections (P = .005), whereas viral infections were not influenced by stem cell dose. The median time to neutrophil engraftment was not different between these groups (17 versus 16 days, P = .53). The protective effect of increasing CD34 cell dose was retained in a multivariate analysis (hazard ratio [HR] = 0.3, P = .044) after adjusting for factors that had significance in univariate analysis such as patient age, high-risk group (age ≥7 and liver size ≥cm), and NK cell dose. Neither the graft source (BM versus G-BM) or the use of ALG in the conditioning regimen had an effect on post SCT infections.

Survival

The 3-year Kaplan-Meier estimate of EFS and OS was 67% ± 6% and 78% ± 5%, respectively, at a mean follow-up of 37 months. Eleven of 63 patients (18%) died of TRM within day 100. Among the 11, 8 (73%) deaths were because of RRT, whereas 3 (27%) died of primary graft failure and secondary infections. None of the cellular subsets, either in the graft or those that reconstituted by day 28 influenced the day 100 TRM. However, the day 28 NK counts were found to be statistically significantly associated with EFS and OS when analyzed as continuous variables in a univariate analysis (P = .013 and .034, respectively).

There was no significant difference in the OS and EFS between BM and G-BM stem cell source. Similarly, there was no correlation with OS and EFS among those receiving ALG versus those that did not (Tables 2 and 3).

MC indicates monocytoid dendritic cells; PC, plasmacytoid dendritic cells; EFS, event-free survival; OS, overall survival; GVHD, graft-versus-host disease; ANC, absolute neutrophil count; TNC, total nucleated cells; NK, natural killer.

**Impact of Day 28 NK Counts on Clinical Outcomes**

The day 28 NK counts were found to be statistically significantly associated with secondary graft rejection, EFS, and OS when analyzed as continuous variables in univariate analysis (P = .044, .013, .034, respectively). None of the other lymphocyte subsets that constituted post-SCT at this timepoint had an impact on these clinical outcomes. Hence, a further detailed analysis was done based on the day 28 NK cell count. The median day 28 NK cell count for those who could be evaluated (52 patients) was 142 cells/µL (range: 3-718 cells/µL).

Patients were grouped based on median value for day 28 NK cells (≤142/µL) as low and the rest as high group (>142/µL) to calculate relative risk for transplantation outcomes. The low and high day 28 NK (N = 26 each) groups were comparable with regard to age, sex mismatch transplant, Lucarelli class III, high risk class III, conditioning regimen, GVHD prophylaxis regimen, and graft characteristics (CD34, CD133, CD3, CD4, CD8, and NK cell dose) as shown in Table 4. However, the CD19, monocytoid cells (MC) in the graft and engraftment kinetics of CD3, CD4, CD8, and MC cells were significantly different between the 2 groups (Table 4).

**Rejection**

The factors that influenced graft rejection in univariate analysis was low day 28 NK ≤142/µL (HR = 8.2, 95% CI: 1.0-66.7, P = .049) and splenectomy (HR = 46.5, 95% CI: 2.9-743, P = .007). Because only 2 patients had splenectomy, this variable was excluded for multivariate analysis. On a multivariate analysis adjusting for patient age, sex mismatch transplant, Lucarelli class, high-risk class III (age ≥ and liver size ≥5 cm), conditioning regimen, and graft sources only a low day 28 NK (≤142/µL) retained statistical significance for rejection (HR = 11.1, 95% CI: 1.14-106.81, P = .038) (Table 5).

Cumulative incidence of rejection compared by log rank test revealed that the low NK group had a significant risk for secondary graft rejections (P = .019) (Figure 4). The sensitivity and specificity for low day
28 NK count in predicting secondary rejection is 88% and 60%, respectively.

**GVHD**

There was no association of day 28 NK cells with regard to development of aGVHD and cGVHD ($P = .620$ and .736, respectively).

**Survival**

On a multivariate analysis with standard risk factors such as patient age, sex mismatch transplant, Lucarelli class, high risk class III, aged 7 years and liver size $\geq 5$ cm, conditioning regimen and graft sources, only a low day 28 NK ($\leq 142/\mu$L) retained statistical significance for EFS (HR = 16.3, 95% CI: 1.6-161, $P = .017$) along with patient's age (HR = 0.7, 95% CI: 0.6-1, $P = .034$). Survival curve analysis also showed that a low day 28 NK cell count ($<142/\mu$L) was a risk factor for EFS ($P = 0.006$) and OS ($P = .017$) as illustrated in Figure 4.

**DISCUSSION**

The factors that influenced immune reconstitution in our analysis was similar to those that have been reported previously [28-30]. Our analysis was consistent with previously reported data in which NK cells were noted to recover to normal levels within 1 to 2 months following SCT, and remained the predominant lymphoid subset in the peripheral blood regardless of transplant type, stem cell source and quantity, patient age, and occurrence of GVHD [1]. Similarly, consistent with reports in the literature, CD8+ levels recovered rapidly as their reconstitution is possibly favored by extra thymic origin, whereas CD4+ subset recovery (thymic dependent) is impaired [8]. CD45RO+ T cells are memory cells, which respond in vitro to recall antigens, whereas CD45RA+ T cells are naive cells, recently issued from the thymus. It has been reported that children have faster recovery of CD45RA+ T cells than adults because of the potential for thymic rebound posttransplantation, and this in turn, could contribute to the reduced risk of infections in children in the posttransplant period [2,3,1,32]. In this study recovery of CD4+CD45RA+ naive T cells was slow, consistent with the pace of recovery that has been reported in the literature [1], and remained below normal levels for the period of this study (1 year), whereas CD8+CD45RA+ naive cells normalized within the first month posttransplant. Previous reports had suggested that the younger the donor age the faster the recovery of CD4+ CD45RA+ T cells [31]. In this analysis we have also noted a similar correlation between donor age and CD4+CD45RA+ T cell recovery, with transplants involving younger donors having a faster recovery of this subset (r = 3, P = .032). Although we did notice a decreased risk for bacterial and fungal infections among patients who received a higher stem cell dose, we could not correlate this to faster CD4+CD45RA+ T cell recovery (data not shown).

Both dendritic, subsets, namely, monocytoid and plasmacytoid cells, in our analysis recovered within a month following transplant, which is consistent with a previously reported data [33]. We and others have reported that in the setting of a peripheral blood SCT a low day 28 plasmacytoid dendritic cell count was associated with aGVHD and cGVHD [3,4]. In this study we were unable to demonstrate a similar effect. This could be because of the small numbers that actually developed GVHD, or it could be that low day 28 plasmacytoid DC count is not predictive of GVHD when the graft source is bone marrow. Larger studies will be required to clarify this further.

Data from this analysis suggests that in this cohort of patients, increasing the stem cell dose reduces the risk of posttransplant bacterial and fungal infections. We hypothesize that faster immunologic recovery occurs with higher CD34 cell doses, and consequently, diminishes the risk of bacterial and fungal infections as observed in a previous report [34]. However, we were not able to demonstrate a correlation in speed of recovery of any specific cellular subset in relationship to the stem cell dose. We also noted that patients in the highest quartile of the stem cell dose did not
have an increased risk of aGVHD or cGVHD (data not shown). Although the number of events is few and the cohort studied small, it would still be reasonable in future to target a CD34 cell dose of $10 \times 10^6$/kg or an MNC dose of $6 \times 10^7$/kg in the graft (lower limit of the fourth quartile values of graft cell dose) in these patients. At these doses, our data would suggest that there should be a significant reduction in posttransplant bacterial and fungal infections without an increased risk of GVHD.

Studies in major histocompatibility complex (MHC) mismatched transplants done in mice and humans have shown that donor NK cells target hematopoietic tissues of the host, eliminating host antigen-presenting cells (APCs) and exerting a GVLM effect against leukemia [35]. A similar effect has been noted with the NK cell dose in the allograft, a higher dose of NK cell infusion being associated with a lower risk of GVHD even in matched sibling transplants [36]. Savani et al [13] have demonstrated that rapid NK cell recovery (NK >150/μL around day 30) as an independent determinant predicting less relapse and better survival after T cell-depleted matched SCT in patients with myeloid malignancies. Previously, the same group had shown that the day 30 NK cell count was a surrogate marker for rapid molecular remission in CML patients [37]. Matthes-Martin et al [38] highlighted the role of NK cells during the early posttransplant period. This group has shown a strong correlation of secondary graft rejection and detection of recipient NK cells on day 28. Our observations in this cohort of patients are consistent with some of the above reports.

Among the lymphocyte subsets at day 28, a prominent role for NK cell reconstitution was noted. Our data suggests for the first time that the absolute numbers of NK cells after allogeneic SCT for patients with β thalassemia major is a strong predictor of secondary rejection and EFS. We have noted that patients who had less than the median number of NK cells on day 28 had a higher incidence of rejection and an inferior EFS and OS. It is important to emphasize that our low and high day 28 NK patient groups (n = 26 each) were comparable with regard to recipient age, sex mismatch transplants, lucarelli Class III, and graft characteristics (CD34, CD133, CD3, CD4, CD8, and NK cell dose). However, there were differences between these 2 groups for the CD19 and monocyteid dendritic cell (MC) dose in the graft, and there were significant differences in the engraftment kinetics of CD3, CD4, CD8, and MC cells between the 2 groups; none of these differences except for a low day 28 NK cell count was associated with rejection in a multivariate analysis. Among patients who had a secondary graft rejection we attempted but failed to demonstrate a subset cellular immune reconstitution parameter beyond day 28, which could predict eventual graft rejection. A limitation of this study was that in the patients who did reject their grafts we did not have cellular subset chimerism data. Twenty-five of our patients were treated with a new Flu-based conditioning regimen that could have had an impact on rejection rates. On
multivariate analysis even after adjusting for this variation in conditioning regimen low day 28 NK cell count was significantly associated with secondary graft rejection. On subset analysis a low day 28 NK cell count was significantly associated with reduced EFS and OS in patients who received either of these conditioning regimens (data not shown). Also, neither conditioning regimens were independently associated with secondary graft rejection ($P = .69$).

Identifying potential causes of low peripheral blood day 28 NK counts after SCT among those who reject their graft needs further investigation. We could not find any association between graft characteristics and the day 28 NK cell count nor could we identify any predictors of a low day 28 NK cell count.

Conventional risk stratification for patients with $\beta$ thalassemia major is based on presence of hepatomegaly, evidence of portal fibrosis in the liver, and inadequate iron chelation therapy (Lucarelli class I, II, and III) [20]. This classification has been validated by different groups, and remains the most important prognosticator for patients with $\beta$ thalassemia major undergoing an allogeneic SCT. In our study, besides the lucarelli class III status at transplantation the only other factor significantly affecting clinical outcome was the day 28 NK cell count. The day 28 NK cell count was noted to be independent of the Lucarelli risk stratification and would serve to complement it as a posttransplant parameter to stratify patient's risk of secondary rejection. Whether interventions based on the day 28 NK cell count would alter the rejection rates remains to be validated in prospective clinical trials.

In summary, this analysis confirms that immune recovery posttransplant in pediatric patients with $\beta$ thalassemia major undergoing a matched related myeloablative allogeneic SCT follows similar recovery kinetics as observed previously with different hematologic disorders [39]. The present study on graft and immune reconstitution characteristics has also helped better define the optimal stem cell dose that one should target, and could not find any clinically significant advantage of using G-CSF primed BM as a stem cell source. The results also suggest that a low day 28 NK cell count increases the risk for secondary graft rejection and might predict death in patients with $\beta$ thalassemia major undergoing a myeloablative matched-related allogeneic SCT. The day 28 NK cell count, a technically easy, highly reproducible and inexpensive assay, could serve as an important posttransplant prognosticator for these patients.

As shown by graft-versus-leukaemia effects induced after haemopoietic stem-cell transplantation, the immune system can be used in the control of cancer. [1] During the past three decades, haemopoietic stem-cell transplantation has progressed from being an experimental procedure to a curative option for many patients; [2] and graft-versus-cancer effects have been noted for renal carcinoma, colon carcinoma, and other tumours. [3]

The ideal donors, HLA-identical siblings, are only available for a thir...

Survivorship issues in hematopoietic stem cell transplantation.

Buchsel PC.

Seattle University, Seattle University College of Nursing Clinical Faculty, 901 12th Ave, PO Box 222000, Seattle, WA 98122-1090, USA. buchsepc@seattleu.edu

OBJECTIVES: To review recent research of long-term complications and prevention techniques in hematopoietic stem cell transplantation (HSCT). DATA SOURCES: Peer review journals, books, and research studies. CONCLUSION: Increasing numbers of HSCTs are performed worldwide, leading to an escalating increase in the number of survivors. Only by increased awareness in prevention, diagnosis, and lifelong surveillance can multiorgan toxicities be decreased. IMPLICATIONS FOR NURSING PRACTICE: Community nurses as well as oncology nurses practicing in research and clinical settings have unique access to patients before and after HSCT. Educating and caring for survivors throughout the entire trajectory of stem cell transplantation can assist in establishing best practice techniques to diminish these complications.

Pediatric Cancer Survivorship Research: Experience of the Childhood Cancer Survivor Study

A B S T R A C T

The Childhood Cancer Survivor Study (CCSS) is a comprehensive multicenter study designed to quantify and better understand the effects of pediatric cancer and its treatment on later health, including behavioral and sociodemographic outcomes. The CCSS investigators have published more than 100 articles in the scientific literature related to the study. As with any large cohort study, high standards for methodologic approaches are imperative for valid and generalizable results. In this article we describe methodological issues of study design, exposure assessment, outcome validation, and statistical analysis. Methods for handling missing data, interrater correlation, and competing risks analysis are addressed; each with particular relevance to pediatric cancer survivorship research. Our goal in this article is to provide a resource and reference for other researchers working in the area of long-term cancer survivorship.

J Clin Oncol 27:2319-2327. © 2009 by American Society of Clinical Oncology

INTRODUCTION

The remarkable successes in treating childhood cancers over the past 40 years have made it imperative to study the long-term outcomes after pediatric cancer and its associated intensive treatments. The Childhood Cancer Survivor Study (CCSS) is one of the first large cohorts of pediatric cancer survivors to be formed and followed successfully. The purpose of this article is to summarize many of the methodological lessons learned over the past 15 years of our experience carrying out survivorship research.1,3 Our intent is to provide a comprehensive document that will prove to be a resource to other researchers in the field.

The topics covered are divided into four main areas. First, we describe the study design and issues involved in contacting and recruiting members of the cohort. This includes the recent changes required as a consequence of the Health Insurance Portability and Accountability Act Privacy Rule (HIPAA). Second, we describe methods for obtaining high quality treatment data that have proven to be vital to the success of CCSS. The third important topic deals with outcome data that are necessarily gathered via self-report mechanisms. For certain outcomes, we have undertaken a validation process to ensure data quality and this is described. Finally, we summarize a number of topics related to statistical analysis of the data, such as handling missing data and competing risks analysis.

MAY DESIGN ANDES OF PAY RECRUITEMNT

Much of the early research conducted on long-term survivors of childhood cancer was carried out as single-institution studies. These early studies documented the occurrence of a variety of late effects of therapy, but were limited in scope due to small number of participants and homogeneity in treatment. Also, because the concept of survivorship was still fairly new, many of these single institution studies only followed participants 5 to 10 years after diagnosis. Early research on survivorship was also performed within the cooperative clinical trials groups. However, because of the therapeutic intent of these protocols, they were not designed for long-term follow-up and often suffered from incomplete participant ascertainment. Thus, much of the early research was restricted to events in the first 5 to 10 years from diagnosis on limited participant populations. Finally, lack of appropriate comparison populations often made interpretation of rates and effect sizes difficult.

The CCSS was designed as a multicenter hospital-based retrospective cohort study with longitudinal follow-up.1 The CCSS has been estimated to have captured approximately 40% to 45% of 5-year survivors diagnosed between 1970 and 1986 in the United States and, in doing so, has established a cohort of sufficient size and heterogeneity to overcome many of these previous limitations.

© 2009 by American Society of Clinical Oncology
The CCSS identified and recruited all survivors meeting eligibility criteria (Table 1) at 26 institutions in the United States (n = 25) and Canada (n = 1). Ascertainment and registration of participants occurred at each center using a comprehensive unified protocol to achieve complete ascertainment of eligible participants. Of the 22,124 participants initially registered with the CCSS Coordinating Center (Memphis, TN), 20,691 were confirmed to be eligible.

Contact began in 1992, and after an initial letter from the treating institution, a letter from the CCSS Coordinating Center containing the baseline survey, informed consent, and a request for medical record release was sent to each eligible patient (or parent if the patient was younger than 18 years at the time of contact). If no response was received, a postal reminder was sent, ultimately followed by a telephone call from the Coordinating Center by a trained telephone interviewer who provided the option of completing the baseline survey by telephone. For eligible participants who were known to have died after achieving 5-year survivorship, their next of kin were contacted and asked to complete the baseline questionnaire. For 7,030 participants unable to be located using the address obtained from the treating institution, a tracing protocol was completed by a national survey research firm (Westat Inc., Rockville, MD). Tracing was successful for 4,188 persons (60%). 

Overall, 3,058 participants (15%) could not be located and were lost to follow-up, 3,205 (15%) declined participation, and 65 participants were unable to participate due to language difficulties. Ultimately, 14,357 eligible participants completed the baseline questionnaire, representing 69% of the total eligible population (approximately six other patients agreed to participate and did so only for subsequent questionnaires). Since the time of the baseline questionnaire, the CCSS has completed three additional follow-up surveys of this cohort, achieving participation rates between 77% and 81% among those participants who were eligible and successfully contacted (Fig 1). In addition, this cohort has been contacted for participation in several other survey-based investigations regarding barriers to health care, sleep and fatigue, use of mammography, health information, and men's and women's specific health issues, in addition to questionnaires specifically targeting quality of life in survivors of bone tumors, and health behaviors in survivors during adolescence.

Comparisons of available demographic and cancer-related characteristics between participants and nonparticipants at the initial base-

relatively small (Table 2). Thus, comparative analyses are always adjusted for these factors.

The CCSS is currently expanding its cohort to include patients diagnosed between 1987 and 1999. This expansion will provide important information regarding late effects of more modern therapeutic protocols, and will employ similar methods of data ascertainment to assure comparability of data with the original cohort. However, a number of challenges to recruitment of this cohort in the current era have been identified. Most importantly, modern privacy laws, including the HIPAA, place limits on contact with eligible participants until their consent for study participation is obtained. In addition, survivors from this era who are age 20 to 39 years are a highly mobile group and not as available or as responsive to contact by traditional mail mechanisms or traditional land-line telephone. Successful recruitment of this population will require innovative use of electronic methods of contact including e-mail and Web-based modalities.

Assessment of therapeutic exposures has been critical to the correct attribution of late outcomes. The CCSS used a methodology of case-by-case chart abstraction for each member of the cohort. Individual abstracters for each center were centrally trained to carry out abstraction of chemotherapy, surgery, and radiotherapy for those consenting cohort members using a standardized medical records abstraction form (MRAF) and treatment data were abstracted from the medical record for each case. In the MRAF the abstractor was asked to specify the dates of therapy covered by that abstraction form, the protocol the patient was treated on (if applicable), and then provide specific data for the treatments of interest (ie, chemotherapy, radiation therapy, and surgery). An individual MRAF form was completed for each treatment plan, but it was recognized that the medical record may not be complete or that some treatments would have been given outside of the participating CCSS centers. In those instances, abstracters were asked to infer doses given for patients and remark on the incompleteness of the dose information so that the incompleteness could be accounted for in the subsequent analyses.

As many pediatric patients were treated on cooperative group studies (Children’s Cancer Group and Pediatric Oncology Group during the treatment era of this cohort) expected doses were calculated for the most common protocols used by both groups. As a quality control measure, abstracted treatment information for each case was compared with the calculated expected doses within each protocol. Outliers were returned to the abstracter to double check the medical records and verify data.

**Chemotherapeutic Agents**

A yes/no evaluation of exposure was asked for each of 42 common chemotherapeutic agents used during this time. For 22 specific agents of the 42, the quantitative dose was abstracted as outlined above. These agents included anthracyclines, alkylating agents, epipodophyllotoxins, and platinum compounds.

For many drugs, the cumulative dose can be used as a measure of total exposure. However, when a number of agents fall into a single class, such as anthracycline or alkylating agents, to enable a succinct assessment of exposure effects for the class, several methods were used. For anthracyclines, the cumulative dose of doxorubicin, daunomycin,
and idarubicin (multiplied by three) were summed. The cumulative platinum compound exposure was calculated by summing the cisplatinum and carboplatinum (carboplatinum divided by four) exposures. Given the wide variety of alkylating agents used, a summary variable was created as follows: First, the dose of each agent was abstracted. Across all patients exposed in the cohort, the dose (standardized by body-surface area) was divided into tertiles of exposure for the individual agent. Each participant was assigned an exposure code of 0 (no exposure), 1, 2, or 3 for each alkylating agent he/she had received. The cumulative score for each individual was summed, and then, across the cohort, these summed exposures were again assigned tertiles. This resulted in individual alkylating agent exposure scores ranging from 0 to 3 for each cohort member which can be utilized in analyses.

**Surgical Procedures**

Surgical procedures were also abstracted and entered into the MRAF. Each procedure requiring general anesthesia was abstracted with the exception of procedures for the placement of vascular access devices. The date, name of procedure, and International Classification of Diseases (9th revision, clinical modification) code were requested for each surgery performed.

**Radiation Dosimetry**

Radiation therapy was also indicated in the MRAF. Abstracters were, however, asked only whether the participant had received radiation, the dates of treatment, and the names of the radiation oncologist and facility where it was given. The abstracters then copied records from the radiation oncology department, including treatment plans, patient placement photographs, daily treatment logs, and radiation summaries; these records were sent to the Radiation Physics Center at the M. D. Anderson Cancer Center (Houston, TX), where the records were scanned and stored in an image database.

The aim was to provide for each patient in a study the radiation absorbed dose to organs or anatomic sites appropriate to the outcome under investigation. Basic treatment information was abstracted for the entire cohort and entered into a database. This first-level abstracting included first and last date of treatment, body region treated, beam energy, treatment field size, configuration and laterality, and total treatment dose. The basic coding is useful for study planning and sufficient for many cohort analyses. Table 3 shows body regions treated for all patients in the database who had radiation therapy, stratified by disease.

Case/control studies and some cohort analyses with specific interest in radiation exposure effects require additional record review, with more detailed coding, in particular where the organ or anatomic site of interest was shielded during treatment (eg, ovaries, testes, breasts, kidneys, or eyes). Dose to the site of interest for each patient is estimated by applying out-of-beam data measured in a water phantom to an age-specific mathematical phantom. Detailed dosimetry is provided for each of these studies, depending on the regions of interest and study population determined by the investigators.

### Validation of Self-Reported Medical Outcomes

Validation of medical outcomes has been an important topic in the CCSS. Due to the increase in the personnel effort and cost required to conduct validation through medical records, however, careful consideration has to be made as to what major end points require this.

additional effort. At the conception of the CCSS, six primary hypotheses were postulated to be addressed: excess risk of mortality; risk of a therapy-related subsequent cancer; risk of clinically apparent cardiopulmonary events; loss of fertility, adverse pregnancy outcomes, and abnormalities in offspring; distinct patterns of family history of cancer; and increased risk of adverse health events due to health behaviors. Of these hypotheses, the first four listed outcomes were selected for validation in this study.

Vital status and the cause of death were determined through the National Death Index (NDI). There is extensive documentation of the advantages and limitations of the use of the NDI, which is covered in another article in this issue. The remaining three outcomes of interest within CCSS (subsequent cancers, cardiopulmonary outcomes, and adverse pregnancy outcomes) are described in detail herein.

The validation procedure used within CCSS, which has been successful in other large epidemiologic studies, is depicted in Figure 2. Medical outcome data were collected using a self-report survey sent to the home of the eligible participant. A HIPAA form requesting release of medical records was also requested from the participant. On return, a request for photocopies of relevant medical records is then made to the hospital/clinic where the participant was diagnosed for this condition; medical records are reviewed and data coded by trained abstractors/physicians.

Validation through medical records of self-reported medical outcomes from mailed surveys have significant limitations in our current medical care environment. One change to the procedures was brought about by the enactment of the HIPAA Privacy Rule during 2001 and 2002 (modified rule). During recruitment for CCSS, we were able to obtain medical release on 93% of the survivor participants. We subsequently needed to obtain signed HIPAA release for future medical record validation. Although we have ultimately been successful in obtaining these consents for 95% of our participating participants, accomplishing this required significant added resources. Secondly, as these survivors age and become adults, their medical care has transitioned from the pediatric institutions where they were treated for their primary diagnosis to adult care facilities. Because of this transition, and the constant change in health care providers within the current medical system, collection of records from such facilities can be costly and inefficient.

Medical records are useful for identifying false-positive self-reported outcomes; however, it is difficult to identify false-negative outcome events that are not reported by the respondent. In our experience with validation of self-reported outcomes, concordance between self-report and medical records was good for well-known complications that have clear diagnostic criteria, such as the occurrence of subsequent cancers, and for records where the patient had good recollection of where they were seen for the condition, such as pregnancy records and place of delivery. Conditions, however, with nonestablished diagnostic criteria such as cardiac outcomes demonstrated a lower level of agreement and the ability to successfully collect records.

Subsequent Neoplasm Validation

Subsequent neoplasms (SNs) were initially identified by self-report of any relapse or recurrence of their original cancer and/or the occurrence of a new cancer after treatment for their primary malignancy. The name of the hospital where the subsequent cancer had been diagnosed was also requested. All positive responses were screened by a CCSS investigator (J.P.N.), and those responses considered likely or possible SNs were forwarded to the CCSS Pathology Center (Columbus, OH) for verification. Reports of late recurrences of the original cancer (10 years or more after the original diagnosis) were also forwarded for verification. For all positive responses from individuals who signed a medical release, a copy of the pathology report was requested. Returned reports were reviewed by the CCSS pathologist for inclusion or exclusion in the study. Data collected included the specific type of SN, date of diagnosis, and location of tumor(s). If a pathology report could not be obtained, the patient and/or parent response or death certificate and/or other institutional records were reviewed to determine the presence of an SN.

At the time of this report, we had reviewed and verified a total of 2,508 SN events using the above methodology. Among these, 2,196 were verified from the pathology report, and an additional 17 were confirmed from death certificates. The remaining 295 were determined to be valid using participant or proxy responses or other sources as described above. 154 of these neoplasms were in participants who had not signed a medical release.

Adverse Pregnancy Outcomes

To study adverse pregnancy outcomes and possible germine mutations, we evaluated self-reported genetic and congenital diseases among the approximately 6,100 offspring of survivors and the 3,100 offspring of sibling controls. The self-administered questionnaire included questions on pregnancy histories, live births, stillbirths, miscarriages, abortions, cancers, birth defects, and hereditary conditions. Genetic disease included cytogenetic abnormalities, single-gene birth defects, and simple malformations. The approach to validate or confirm the self-reported conditions began with an initial review, including family history, by a cancer geneticist. A decision was made as to whether the self-reported condition could be accepted, rejected, or
that additional information was required. In instances where additional information was required, individualized scripts or questions were prepared for each participant, who was then contacted by CCSS staff to provide additional clarification of the self-report and/or to obtain a medical release for medical records.

All available information on the self-reported condition was then reviewed by a three-person panel to reach a consensus decision. The final decision could be accept, accept but not count because the condition could be explained by family history or nongenetic factors; or reject. Validated genetic and congenital diseases were ascertained in 157 (2.6%) of the children of survivors, compared with 111 (3.6%) of the children of sibling controls. There were no apparent differences in the proportion of offspring with cytogenetic syndromes (seven in case offspring, six in sibling offspring), single-gene defects (14 and eight), or simple malformations (136 and 97). Analyses based only on the self-reported genetic diseases were reassuring and were then confirmed through the validation procedure.

Cardiac Outcome Validation

For survivors who reported a specific cardiopulmonary outcome and were still alive at the time of contact, an additional stage of validation was incorporated which consisted of a series of telephone-based questions (telephone script) to further document the specifics of selected self-reported adverse cardiopulmonary events and to determine the patient's condition another chance for the reported outcomes. Participants contacted by telephone were also asked to sign a HIPAA form and return it to the CCSS Coordinating Center. Once received, medical records were obtained from the physicians listed and were returned to the CCSS Coordinating Center. The first 100 medical records that were returned were reviewed independently by two physicians. Consensus among the physician's validation was reached when two differed and a standardized protocol was developed to come to a consensus of each condition. Subsequent records were reviewed and validated by one physician.

As an example, a flowchart summarizing the validation of 292 survivors who reported congestive heart failure (CHF) is detailed in Figure 3. Among participants for whom validation was successfully carried out, CHF was confirmed for 83% and 67%, and determined to be observed in 11% and 9%, respectively. CHF was confirmed for 83% and 67%, and determined to be observed in 11% and 9%, respectively. CHF was confirmed for 83% and 67%, and determined to be observed in 11% and 9%, respectively. CHF was confirmed for 83% and 67%, and determined to be observed in 11% and 9%, respectively.

Analyses. Instead we have relied on self-reported outcomes for current analyses.

STATISTICAL METHODOLOGY

In the course of analyzing the data from the CCSS over the past 10 or more years, we have needed to carefully consider a number of key statistical issues. Many of these issues are generalizable to other settings, although they have the common theme of being specifically applicable to survivorship research and thus are useful tools for anyone else carrying out statistical analyses on similar data.

Long-Term Survivor Cohort Definition: Impact on Analyses

The requirement that participants have attained 5-year survivorship for eligibility into the CCSS cohort has implications on late events that can be utilized in valid and generalizable analyses. Because our questionnaires are typically worded to ask the first time at which an event occurred, it is not unusual for the first time event to be before the cohort inception time point of 5 years after diagnosis. It is tempting for researchers to examine the rates or carry out time-to-event analyses that incorporate these events. However, caution must be taken since potential patients who died during those first 5 years are not part of the CCSS cohort and have been removed from the denominator; hence,
the full cohort of patients who were at risk for events in the first 5 years are not all included in a survivorship cohort. As such, any time-to-event analyses would not accurately represent true rates or relative risks in that time period and would not be generalizable to any existing prospective population. In statistical terms, this analysis would violate standard principles of time-to-event analyses by conditioning on the future event of survival to 5 years. The most appropriate way of handling time-to-event analyses in a 5-year survivor cohort is thus to begin analyses at the 5-year postdiagnosis time point, only prospectively considering events that occur after the inception of the cohort. One way that outcomes occurring before 5 years could be reported would be as the proportion (or prevalence) of participants who had experienced at least one event by the time the cohort was formed at 5 years. However, for the reasons stated above, one should avoid use of time-dependent rates, or time-to-event analyses. The key point must be emphasized; these results are only generalizable to the population of participants who have survived at least 5 years after their diagnosis of primary cancer.

**Accounting for Correlation Between Survivors and Siblings**

A statistical issue that needs to be addressed in any analysis that incorporates both survivors and siblings is the independence of the outcomes from members of the same family. Since siblings would be expected to have more similar health outcomes than a randomly selected individual from the general population, standard assumptions of independence required for most statistical analyses are violated. In a correlated data setting such as this, unadjusted statistical methods typically lead to incorrect estimation of the variability of measures of association and thus, resulting naïve $P$ values and CIs are also incorrect. To appropriately handle this issue in analyses, a generalized estimating equation approach with robust variance estimates can be used in analyses. These methods have been developed for use with generalized linear models (e.g., logistic and Poisson regression) as well as Cox proportional hazards models. The idea behind the methodology is that it incorporates an appropriate adjustment that accounts for the intraclass correlation and assures that inferences are valid. Other methods for handling the correlation between survivors and siblings that we have used are generalized linear mixed models and bootstrapping approaches.

**Impact of Attained Age on Risk of Disease: Appropriate Methods for Analyses**

The risk of many key outcomes in long-term survivorship studies, especially those of childhood-disease survivors, can be highly dependent on the attained age of the participant and thus, attained age should be incorporated in a meaningful way into analyses. Indeed, if time since diagnosis is used as the time scale for relative risk analyses, rather than age of participant, for example, this can lead to flawed conclusions. In a cohort such as CCSS, participants who enter the cohort between the ages of 5 and 20 years, with 20 years of follow-up, will be age 25 to 40 years at last contact, an age range in which risks of some chronic diseases increase considerably with age. If time since diagnosis were used as the scale for analyses, then participants who were age 25 years would be treated on equal footing with participants who were age 40 years, two groups who might have markedly different risk of disease. As an example, Figure 4 illustrates the difference in expected number of breast cancer cases between three groups of 5,000 participants diagnosed at ages 5, 10, and 15 years, respectively, based on Surveillance, Epidemiology, and End Results (SEER) incidence rates, assuming these participants had the same rates of breast cancer as the general population. Without appropriately taking attained age into account, an analyst might erroneously conclude that girls treated at older ages were more likely to develop breast cancer. One can ameliorate the impact of attained age in descriptive analyses by utilizing standardized incidence rates, adjusted for age. Moreover, for multivariable regression analyses, the use of age as the time scale in a Cox proportional hazards model is an elegant way to directly adjust for changes in risk with age, without needing to incorporate age as a covariate or assuming a specific form for its effect. In this setting, participants enter the analysis at the age at which they enter the cohort and are followed until their attained age at end of follow-up. Another method for analysis is to use Poisson regression models to directly model standardized incidence ratios (SIR) in multivariable models. This method uses external reference age-specific rates such as the rates from SEER to adjust for the effects of attained age on risk of disease. Both these methods provide valid ways of adjusting for the effects of age on outcome and are useful tools for a long-term survivorship data analyst.

**Cumulative Incidence for Nondeath Outcomes**

Most health outcomes of interest are reported using time-to-event analyses and results are often illustrated with figures displaying their cumulative probability over time. Because cohort participants could die any time before that outcome, an analysis of nondeath outcomes must appropriately consider death as a competing risk event when evaluating the probability of these outcomes. Readily available software provides Kaplan-Meier methodology that can be erroneously used in such situations. As described elsewhere, since Kaplan-Meier estimates treat time of death exactly the same way as a censored outcome, the estimates can become overly inflated when many deaths occur during the follow-up period. The appropriate methodology in this setting is to utilize cumulative incidence estimates, which handle deaths differently from censored observations. With the long follow-up period and high mortality rate present in the survivor population, this is an important issue for any analyst to address appropriately in order to obtain valid estimates of cumulative probability.
Missing Data

In any epidemiological study, missing data raise concerns as a potential source of bias. In the CCSS, we have dealt with two types of missing data. The first type arises due to nonparticipation of eligible patients, where all data from the surveys and MRAF could not be obtained. The second type occurs among participants, where some of the survey items or MRAF elements were not answered or collected; this includes survivors who participated in the surveys but did not consent for medical record release.

The first type is difficult to deal with as we have no data on nonparticipants' outcomes and exposures, except their cancer type, age at diagnosis, sex, diagnosis year, and treating institution, which were collected for the initial eligibility establishment. We have compared and reported these characteristics between the participants and nonparticipants, and also made an aggregated-level comparison of MRAF data between the two groups. The CCSS mortality analyses have been an exception. For these analyses, all eligible participants' vital status was ascertained by the public NDI data, and mortality-risk analyses by cancer type, age at diagnosis, sex, and diagnosis year were conducted. When assessing treatment effects on mortality risk, however, we used multiple imputation under the assumption of missing at random of treatment data, given the known characteristics. Note that the multiple-imputation approach imputes missing data multiple times to construct multiple complete datasets, runs an identical analysis with each of the complete datasets, and makes statistical inference using results from the multiple analyses. This is in contrast to the single-imputation approach, where the imputed and observed data are not distinguished in the single analysis of the complete data set; in multiple imputation, the variability across the multiple complete datasets appropriately reflects the uncertainty in the missing data.

For the second type of missing data, the frequencies in the CCSS are mostly no more than 10%, often 0% to 5%. In many CCSS analyses, therefore, we confirm that the extent of missing data in key outcome and exposure variables is small and proceed to perform complete case analyses. When the extent of missing data is large (i.e., the number of incomplete cases is appreciable), or when an adverse event occurrence was indicated in the survey but the age at the occurrence was not reported (thus, a complete-case analysis would bias time-to-event analysis), we used multiple imputation under the assumption of "missing at random." Specifically, we extensively used the multiple-imputation method of Taylor et al with slight modifications for the cases where there were an appreciable number of participants who reported an adverse event of interest, but did not report their age at its first occurrence. This method employs piecewise exponential models to describe the rate of development of each adverse event by relevant demographic, clinical, and treatment variables with possible interactions. Its model fitting uses an expectation-maximization algorithm before proceeding to multiple imputation.

Currently, the Statistical Center (Seattle, WA) of the CCSS is constructing ten complete datasets of CCSS survey participants through an extensive application of multiple imputation so that those who answered the surveys but did not consent medical record release can be entered into analyses of treatment effects. This work involves (1) elicitation of clinical knowledge from pediatric and radiation oncologists on the treatments used from 1970 to 1986 by diagnosis type, age, treating institution, and calendar period; (2) construction of imputation models based on the elicited knowledge as well as statistically driven model selection; (3) imputation of missing data ten times using the models; and (4) checking the imputed data by pediatric and radiation oncologists to see if they are sensible clinically. Such central multiple-imputation of missing data to construct multiple complete datasets has been successfully used in other large epidemiologic studies.

This article summarizes many of the procedures and methodologies implemented in the successful conduct of the CCSS over the past 15 years. These represent our efforts to ensure that conclusions drawn are unbiased and generalizable to the larger population of long-term pediatric cancer survivors. Challenges that require further development of methodology will continue to arise with continued follow-up of the current CCSS cohort and as the more recently treated expansion cohort is incorporated. We already confront issues related to recruiting and maintaining contact with a younger, more mobile cohort. There is an urgent need for recruitment strategies that utilize modern means of contact (e.g., via cell phones and the internet). As we continue to collect data on an aging population, the patterns of missing data will be monitored and documented to assess the need for multiple imputation strategies for additional specific data elements. In addition, the participation rates and demographics of the participating CCSS population will be regularly evaluated. Applying appropriate methodology to the data to adjust for under- or overrepresentation of certain subpopulations will be important if disparities develop. Continued efforts at maintaining high levels of participation will be a priority to reduce any potential biases and to maximize statistical power.

CCSS has been and will continue to be successful at its goals of better understanding and quantifying risks of sequelae to cancer and its treatment. As new knowledge is developed there will be more opportunity for focused interventional studies aimed at reducing the morbidity due to these outcomes. Typically, these will be in the form of screening interventions studies, which can require large numbers of participants to see a significant impact on patient survival or morbidity. This will require the development of efficient study designs, with accurately characterized high risk populations and well defined and meaningful end points that best utilize the available resources and answer the cogent questions.

The new standard of quality cancer care: integrating the psychosocial aspects in routine cancer from diagnosis through survivorship.

Holland J, Weiss T.

Department of Psychiatry and Behavioral Sciences, Memorial Sloan-Kettering Cancer Center, New York, NY, USA. hollandj@mskcc.org

This article highlights recent findings from the Institute of Medicine of the National Academies of Sciences' evidence-based report Cancer Care for the Whole Patient: Meeting Psychosocial Health Needs published late in 2007. This landmark report lends new credibility to the field and its evidence-based clinical interventions, while outlining a new standard of quality cancer care which mandates that psychosocial aspects must be integrated into routine cancer care. Patients should be screened at their initial visit for psychosocial needs and survivors should have a treatment plan that includes attention to possible increased anxiety on completing treatment, development of posttraumatic stress symptoms, and mixed anxiety and depressive symptoms. Survivors with greater chance of psychosocial sequelae and diminished quality of life are those with chronic physical symptoms, physical impairment, or change in appearance or function. Referrals should be made to proper psychosocial resources (local when possible or by use of the support given by telephone from many site-specific cancer advocacy organizations with telephone help-lines).

Survivorship care: models and programs.

McCabe MS, Jacobs L.
Memorial Sloan-Kettering Cancer Center, New York, NY 10021, USA.
mccabem@mskcc.org

OBJECTIVES: To review models of care for adult cancer survivors and the challenges in program development. DATA SOURCES: Review of the literature.
CONCLUSION: As the number of cancer survivors continues to grow, so does the need to develop unique evidence-based programs and services for this population. Survivorship should become a distinct phase of care and include: surveillance for recurrence, evaluation of and treatment for medical and psychosocial consequences of treatment, recommendations for screening for new primary cancers, health promotion recommendations, and provision of a written care plan to the patient and other health professionals. IMPLICATIONS FOR NURSING PRACTICE: Many challenges remain to evaluating care models and actualizing clinical services nationally, but oncology nurses are uniquely positioned to take the lead in the care of cancer survivors of all ages.

Pediatric immunohematopoietic stem cell transplantation at a tertiary care center in Cape Town

Lucille Wood, June Juriitz, Jonathan Havermann, Jo Lund, Herman Waldmann, Geoffrey Hale, Peter Jacobse

INTRODUCTION AND STUDY DESIGN: We conducted a retrospective analysis of consecutive referrals of patients under 18 years of age undergoing immunohematopoietic stem cell transplantation to assess the influence of age, diagnosis, graft type and gender on survival. We also contrasted program activity and outcome to that reported from a state hospital in the same geographical area over a comparable period.

METHODS: Conditioning employed either a sequential combination of fractionated 12 Gy whole body and 6 Gy total nodal irradiation separated by 120 mg/kg of cyclophosphamide in patients over 15 years of age. Alternatively, the latter agent was combined initially with oral busulphan and later the intravenous equivalent. Neuroblastoma cases were prepared using a different regimen. In autologous grafted patients underwent ex vivo T-cell depletion with the humanized version of anti-CD 52 monoclonal antibody designated Campath 1H. No additional immunosuppression was given except where matched unrelated volunteer donors were employed.

RESULTS: Sixty-eight procedures were carried out in 61 patients over a 6-year period. Of 11 with acute myeloid leukemia, 8 are alive and well whereas 8 of the 14 with the lymphoblastic variant have died. Of the remaining 12 with hematologic malignancy, all but 2 are alive. Ten of the 17 with aplasia are alive as are all with thalassemia or sickle cell disease. None of the four variables tested affected survival.

CONCLUSION: Our analysis indicates that the standardized preparative regimen, coupled with a new well-established immunosuppressive regimen, is as effective in patients under 18 years of age as in adults. Our analysis also indicates that in a resource-scarce or developing country, it is mandatory to limit high-risk and relatively expensive procedures to active teams that enjoy international accreditation, whether these be in the state or private sector.

Historically, the introduction of classical bone marrow transplantation into this country some thirty years ago centered on adults with problems in the form of rejection and acute and chronic graft-versus-host disease contributing to morbidity and mortality. Despite our early involvement in the use of cyclosporine A as a new generation immunosuppressive agent, these complications continued, although of decreased incidence and severity. The major advance in their reversal was initiation of a series of studies that eventually led to the landmark description of ex vivo T-cell depletion using Campath monoclonal antibodies and our experience continues to accumulate.

Notwithstanding the unquestioned benefits, and in contrast to elsewhere in the world, there remained a substantial local resistance to subjecting children to what was perceived as a still unduly hazardous undertaking! Nevertheless, within 10 years of commencement, it became more generally appreciated that idiopathic and irreversible aplasia could only be cured by allografting whereas a variable response was obtained with antiglobulin globulin and high-dose methylprednisolone. From that time the eligibility for grafting was modified to accommodate younger cases and our initial
results that were reported whilst still at Groote Schuur Hospital.20–22 have recently been updated.23

From January 1995, our established and approved protocols were transferred in to a custom built facility in the private sector. In the new location consecutive procedures continue to be reported to the Center for International Blood and Marrow Transplant Research and this specific team was again re-accredited in January 2003, thereby maintaining a 30-year unbroken record of achievement. Thus, the following analysis from the Department of Haematology and the Bone Marrow Transplantation Unit incorporating The Searll Research Laboratory for Cellular and Molecular Biology at the Constantiaberg Medi-Clinic brings international perspective to outcomes in the pediatric age group undergoing immunohematopoietic grafting in South Africa.

The available facilities, when we pioneered the use of this technology in the Groote Schuur Hospital at the beginning of 1972, were such that management of the young was logistically difficult. This hurdle was overcome by providing separate rooms when the newly dedicated reverse isolation unit was designed and then commissioned in 1982. Given the upgraded physical plant, and expansion of staff to include a social worker, a physician and a psychiatrist with interest in adolescents, it became a realistic option with the first child grafted in 1978. The multi-disciplinary approach was consolidated by participation of Dr Paul Rogers following his return after a period of overseas postgraduate training.24,25

With the relocation of this fully integrated group to an independent academic center it was soon demonstrated, both logistically and functionally, that there was no impediment to providing costly and high technology activities in such an environment.26–28 Continuing outcome analysis from this reverse isolation unit, staffed by nurses trained in all relevant facets with a virtually full-time commitment from pediatricians already in the hospital, rapidly confirmed the feasibility of using advanced protocols approved by Institutional Review Board for conventionally defined indications, in a protected environment dedicated to tertiary hematologic care.17

In the last decade a number of refinements have become standard practice. Among these was the use of matched or minimally mismatched family members and the availability of donations from histocompatible, unrelated volunteers via the South African Marrow Donor Registry.19 To this end, center designation by the European Group for Blood and Marrow Transplantation18 and by the National Marrow Donor Programme followed.29

A priority remains the commitment to whatever innovation is necessary to keep abreast of relevant advances such as the study of chimerism using short term repeat assay.21 This has included exploring the role in thalassemia, sickle cell disease,22 mucopolysaccharidoses,23 common variable immunodeficiency,24 and Fanconi anaemia.25,26 The latter is currently linked to gene therapy being evaluated jointly with Professor Chris Walsh initially in North Carolina,27 and now currently in New York, where special attention has been given to complications from older forms of conditioning that included cyclophosphamide or, even earlier, radiotherapy. Accordingly, this phase has been revised to the use of fludarabine and intravenous busulfan.28

The latter model is to be tested as the basis for contrasting the previously favored myeloablative combinations to primarily immunosuppressive options across the age spectrum.29,30 The rationale for this focus lies in harnessing the formidable capacity of the immune system to identify and eradicate tumor cells and creates a platform for the use of immunotherapy based on subsequent delayed or donor lymphocyte infusions.31 Whether such a theoretically attractive modification will represent a significant advance awaits longer follow up.32

Among the remaining challenges is the problem of mucositis, which impairs nutritional intake, and has led to a focus on the need for developing a structured approach to nasojejunal feeding rather than the more traditional total parenteral approach (Wood, O’Keefe, Jacobs, Dubrovskaya, unpublished). Additionally, there is an increasing appreciation of infections particularly cytomegaloviremia that may progress to organ involvement as in pneumonia and this, together with other infections, possibly related to the use of monoclonal antibodies,33–35 predicated the ongoing study of immunologic reconstitution and viral surveillance with proactive ganciclovir therapy.36

It is against this brief historical outline that outcome in children is presented; the corresponding results in those over 18 years are in preparation (Jacobs, Wood, Juritz, unpublished).

STUDY DESIGN

Our analysis is tabulated for consecutive entries seen in the 6-year period to allow comparison to updated results from the State.13 Additionally, we explored the practicability of operating such a facility, with the specific focus on childhood referrals, outside the confines of the usual base in teaching hospitals. With appropriate attention to financial imperatives and, notwithstanding the ever-constricting focus of changing health care, it
also tests the possibility of maintaining, and continually developing new aspects of this technology in more innovative indications, to keep abreast of worldwide advances.30,31

One modification has been a switch from oral to intravenous busulphan.32 A further logical step will now be the increasing use of fludarabine as a component of mini- or so-called reduced-intensity conditioning regimens that have, as a backbone, sufficient suppression of the immune system primarily to allow host acceptance of the incoming graft. The anticipation is that a graft-versus-leukemia effect will be retained whilst, at the same time, the more serious consequences of the classical myeloablative regimens will decrease.40 Furthermore, in addition to confirming the pattern of hematopoietic reconstitution, a secondary end-point is that of defining immunologic reconstitution.41,42 This endeavor aims to decrease the hazards of infection that notably include those attributable to cytomegalovirus.43,44

METHODS

After recording a detailed history and completing a physical assessment, standard hematologic procedures were employed for a full blood count, aspiration and trephine biopsy.46 The malignancies were classified using conventional cytomorphology supplemented by flow cytometry,47 and cytogenetics48 to precisely delineate each case after which treatment was by risk-stratification to standardized protocols.49-50 The malignancies were classified according to World Health Organization criteria.51 Aplasia was similarly categorized and in those with Fanconi anemia, additional studies included chromosomal fragility after exposure to clastogenic agents.52 Hemoglobinopathy was subdivided by electrophoresis and appropriate biochemical tests.53

For donor selection, histocompatibility testing employed conventional methodology and matching between donor and recipient using international standards via the Hub center of the South African Bone Marrow Donor Programme.59 Donations for matched unrelated volunteers were provided in collaboration with the Anthony Nolan, Australian, German and Leiden Groups as well as The National Marrow Donor Programme.50

All aspects of the treatment including indication, anticipated benefits and potential risks were fully explained by means of extensive counseling after which written informed consent was obtained. Recipients and donors were assessed to ensure suitability for participation and this included clinical examination and non-invasive cardiac and respiratory testing. Placement of a double-lumen catheter54,55 was followed by nursing in reverse isolation.56 Selective decontamination of the bowel was performed with daily fluoroquinolone57 and oral prophylaxis for cytomegalovirus and Pneumocystis carinii, respectively, with acyclovir or valaciclovir58 and co-trimoxazole, or in the case of allergy, an appropriate equivalent.59

Conditioning was 12 Gy fractionated total body irradiation over 3 days at rates of approximately 10xGy per minute, 60 mg/kg of cyclophosphamide over 2 days with intensive hydration, protection of the urothelium with mesna and total nodal irradiation at 1.5 Gy over 2 days.4 The alternative regimen comprised 120 mg/kg of cyclophosphamide combined with 16 mg/kg of oral busulphan,49 or 3.2 mg/kg per day intravenously for 4 days. Patients with Fanconi anemia received cyclophosphamide at reduced doses.51 Irrespective of body weight, a quantitative and qualitatively adequate harvest was obtained after mobilization with stimulatory peptides for 5 consecutive days, by using constantly upgraded apheresis technology on the Cobe Spectra as previously described.60

No prophylaxis was employed against graft-versus-host disease except in those undergoing matched unrelated donations where cyclosporine was maintained at a therapeutic level for 6 months using the C2 assay64 and then tapered to zero over the following half year. Nutrition was a high priority and, whilst intravenous supplementation was not used, there was early recourse to fine-bore nasojejunal tube feeding when needed,65,66 (Wood, O'Keefe, Dubrowsky, Vincent, Jacobs, unpublished).

Comparisons of results between the state and private hospital were made using Pearson's chi-squared tests. Survival time after transplant between groups was assessed using Kaplan-Meier survival curves. Survival times between groups were compared using log-rank tests.

RESULTS

The total number of procedures including retransplants 68 at Constantiaberg Medi-Clinic and 31 at Groote Schuur Hospital. The median age of the patients treated at Constantiaberg was 11.7 years (range 1.7-18.7 years). Hematologic malignancy accounted for 37 cases at Constantiaberg Medi-Clinic (Table 1) and 16 at Groote Schuur Hospital. Benign conditions included aplasia (n=17 at Constantiaberg Medi-Clinic, n=11 at Groote Schuur Hospital) or miscellaneous conditions (n=14 at Constantiaberg Medi-Clinic, n=1 at Groote Schuur Hospital) (Table 2). Apart from the

original research report

larger numbers and additional indications in this series, the populations were comparable.13

Day 0 was designated as graft infusion. The median time to reach 0.5 x 10^9/L and 1.0 x 10^9/L neutrophils were 18 days (range, 9-34 days) and 28 days (range, 10-59 days), respectively. The median time for platelets to reach 25 x 10^9/L and 100 x 10^9/L was 17 days (range, 5-32 days) and 27 days (range 13-127 days), respectively.24,26

Transplant-related mortality was death attributable to infection within the first 100 days in the absence of any disease recurrence25 and it accounted for all the patients except for one due to dilated cardiomyopathy. An unusual variant of the acute syndrome of graft-versus-host disease occurred within the first 6 months that was distinctly different from the classical chronic disease.6,26 This was regarded as a forme fruste due to altered immune status consequent upon the ex vivo T-cell deletion,70,71 and occurred in only two cases with successful reversal using topical steroids combined with a short course of oral prednisone.70,73

Cytomegalovirus was demonstrated using the PP 65 assay in two instances that were treated intravenously. One died and in the second no further isolates were present at two weeks although a further 14 days of outpatient oral antiviral treatment followed. Anorexia with nausea and vomiting was readily controlled with seroton and dopamine receptor antagonists although occasionally prochlorperazine was added.24 Diarrhea was assessed with stool culture and treatment of Clostridium difficile when present;25 otherwise simple diarrhea modulation using loperamide hydrochloride, a combination of kaolin with bismuth carbonate, pectin coupled to chlorodyne was used.26 Particular attention has focused on maintaining optimum fluid and electrolyte balance.27 Pain was a major problem when mucositis occurred and initially required oral or parenteral opiates.28 This symptom has been dramatically reduced by the use of sucralfate.29

Hematologic malignancies (Table 1)
Acute myeloid leukemia (11 procedures, 10 patients at Constantiaberg Medi-Clinic) (9 procedures, 8 patients at Groote Schuur Hospital), once disease-free, was treated on this regimen. Nine were allogeneic. One died from cardiomyopathy, a second died in relapse and a third died from recurrence after a second technically successful transplant. Acute lymphoblastic leukemia, most of whom were in second remission (14 procedures, 11 patients at Constantiaberg) (4 procedures, 4 patients at Groote Schuur), were autografted in 9, of whom 5 died in relapse. Of the allografts (n = 2) from siblings 1 died of aspergillosis. A further 3 employed matched unrelated volunteers with 1 dying from multiorgan failure and 1 with recurrent disease. Patients with juvenile myelomonocytic leukemia (1 procedure, 1 patient at Constantiaberg) (1 procedure, 1 patient at Groote Schuur) remain alive. Chronic granulocytic leukemia (6 procedures, 5 patients at Constantiaberg) (2 procedures, 2 patients at Groote Schuur Hospital) was autografted in one who did not achieve cytogenetic remission and after matched unrelated volunteer donation achieved this status by molecular criteria. One syngeneic, three sibling allografts and one further unrelated graft were successful of which one died from cytomegaloviral pneumonitis. The remainder were disease free at the time of writing. Hodgkin (2 procedures, 2 patients at Constantiaberg) (n = 0 at Groote Schuur) and other lymphomas (3 procedures, 3 patients at Constantiaberg) (n = 0 at Groote Schuur) received allografts in 2 and autologous infusion in 3 case. One died from infection and 4 remain in remission.

Benign Diseases (Table 2)
In cases of aplastic anemia (6 procedures, 5 patients at Constantiaberg Medi-Clinic) (10 procedures, 7 patients at Groote Schuur Hospital),8 were allografted and 3 were alive and well at the time of writing. One failed to engraft and despite a repeat procedure died from septicemia. Two received matched unrelated donations: 1 died from septicemia and the other is well. Fanconi anemia cases (11 procedures, 10 patients at Constantiaberg) (5 procedures, 4 patients at Groote Schuur) were all allografted. One required a second attempt and died with septicemia, another developed secondary lymphoproliferative disorder and two died from cytomegaloviral infection and another from multiorgan dysfunction. In this category, damage to the oropharynx and gastrointestinal tract made enteral feeding unreliable and added the costs for limited periods of total parenteral nutrition.8,31 Hemoglobinopathy (6 procedures, 6 patients at Constantiaberg) (n = 0 at Groote Schuur) were all allografted, and were alive and well at the time of writing, although two still had disease present on sensitive biochemical testing.

A miscellaneous group was made up of 1 patient with germ cell tumor that was autografted and died from cytomegaloviral pneumonitis, and 5 patients with neuroblastoma that were autografted and 1 patient died with relapse. A further patient with mucopolysacchari-
original research report

Figure 1. Kaplan-Meier survival for all patients. Kaplan-Meier analysis shows that at 6.8 years there is a stable plateau consistent with cure. It is notable that results are similar for idiopathic aplasia, Fanconi anemia and acute myeloid leukemia with non-significant differences for lymphoblastic leukemia and the remaining cases. There is also no difference in outcome for graft source, but a slight benefit for the female gender, which did not attain statistical significance.

Overall Survival
Overall survival was 60% at 7 years of follow-up (n=59 at Constantiaberg Medi-Clinic) (Figure 1). Notably, survival was similar for idiopathic aplasia, Fanconi anemia and acute myeloid leukemia with non-significant differences for lymphoblastic leukemia and the remaining cases. There is also no difference in outcome for graft source, but a slight benefit for the female gender, which did not attain statistical significance. Given the small numbers it is not surprising that none of the variables achieved significance. Quality of life studies\textsuperscript{223} were not formally carried out in this investigation.

DISCUSSION
These results are comparable to published first world outcomes. Our analysis allows four conclusions. Firstly, the scientific and ethical aspects of immunohematopoietic stem cell transplantation, whether the graft is derived from bone marrow or peripheral blood, when conducted by an appropriately constituted and functioning multidisciplinary team, operating in a private academic center, demonstrably meets worldwide standards of practice. This is reflected in satisfactory audit with ongoing re-accreditation of this particular team by the International and Autologous Bone Marrow Transplant Registries now combined as the Centre for International Blood and Marrow Transplant Research with endorsement as a transplant, harvest and donor center by the European Group for Blood and Bone Marrow Transplantation as well as for performing these procedures as designated by the North American National Marrow Donor Program.

Secondly, while indications continue to undergo redefinition, correct case selection is imperative, if the best needs of the community are to be served. Thus, access to the technology must be widely available and, by definition, this includes responsible resource allocation between state and private sectors. To this end it is constructive to contrast the present experience to our initial reports\textsuperscript{40-41} that were recently updated from a state hospital.\textsuperscript{19} It can be seen that there is no substantial difference in demography, procedure or results other than, in the current series, somewhat larger numbers, wider indications, use of intravenous busulphan and inclusion of matched unrelated volunteer donors. Of relevance is that, at least in siblings, further immunosuppression is not needed after ex vivo T-cell depletion and this translates to financial cost saving with possibly a decrease in morbidity. It therefore follows that even when alternative graft sources are used, the relatively high initial costs are clearly offset by the potential for cure and so justify the maintenance and indeed ongoing development of such a therapeutic option. This situation differs significantly from regimens using unmanipulated grafts which would then typically include cyclosporine A, short-course methotrexate and often corticosteroids as necessary to control rejection and blunt acute as well as chronic graft-versus-host disease. To accommodate these variables identification of teams that fully and consistently meet standards, of which the center-effect necessitating a minimal number of procedures to comply with agreed activity, is mandatory to prevent this important treatment option becoming discredited as a result of inadequate performance. Whether a mechanism for national scrutiny and registration can be established is currently conceivable but whether it would ever become acceptable in the wider world remains moot. Currently at least compliance with the approved guidelines from The North American Foundation for the Accreditation of Hematopoietic Stem Cell Therapy\textsuperscript{24} as well as the Joint Accreditation Committee of the International Society for Hematopoietic Therapy and Graft Engineering in Europe and the European Group for Blood and Marrow Transplantation\textsuperscript{4} would be a desirable starting point. In this context there is also the crucial balance between

Hematol Oncol Stem Cell Ther 1(2) April 2008 hematolstem.cellmedge.com
the undoubted need and funding provided by managed health care required to allow private sector programs to match state activities with the latter having a reciprocal obligation to provide for individuals with limited resources. In these circumstances utilization of these procedures should be shared on the basis of resource availability for individual patient groups.

Thirdly is the crucial caveat that only peer-reviewed protocols, having undergone scrutiny by Ethics and Research Committees coupled with institutional Review Board endorsement, are supported. These need, in a single center by definition, to have the expertise and flexibility to accommodate appropriate patient categories and to do so irrespective of age. Given the constant revision of the role that such interventions generate an acute awareness of shifting entry indications is vital. For example there is now appropriate and decreasing referral in acute myeloid leukemia when the presence of specific, or good risk, cytogenetic markers show equal outcome with optimum chemotherapy. Furthermore, the competing role of small molecules such as retinoic acid and arsenic in progranulocytic tumors on the one hand and signal transduction inhibition in chronic granulocytic leukemia using imatinib on the other, alter the previously automatic inclusion of stem cell transplantation in treatment algorithms. There needs to be a consciousness that these expensive but potentially curative interventions retain a role in Hodgkin and other lymphomas, but outside clinical trials, preferably international, raise serious reservations about uncritical and random usage. Concerns focus on small numbers of cases in unregistered practice by occasional therapists not reporting results. Implicit in such ongoing scrutiny is an obligation for unit or team recognition based upon outcome analysis and peer review accountability raising the spectre of there being some sensible restriction to preferred providers or designated units. These need to be defined by published survival data and, most certainly, not the alternative, but convenient choice of only cost as the defining factor for so-called preferred providers.

Fourthly, among the areas of expanding interest are the solid tumors. The present data are too small for interpretation and only establish technical feasibility. The continuation of this commitment, perhaps more so than in conventional usage, should not be restricted but rather encouraged, within the context of thoughtful, registered and multicenter trials.

CONCLUSION
This interim analysis of ongoing studies presents outcomes consistent with international standards of practice and supports the appropriateness of continuing to provide immunohematopoietic stem cell transplantation to properly selected cases throughout South Africa. This sub-Saharan stance could serve as a model for other under-resourced countries worldwide. Predictably no difference in results could be found between those from this private academic center or a state hospital emphasizing that allocation of transplantation should be shared as dictated by availability of resources in each sector. Furthermore, since these are uniform irrespective of age, separate pediatric units are difficult to justify in the face of a limited and ever deteriorating economic climate. Whilst acknowledging substantial financial costs and morbidity and mortality, these are offset by the curative potential of this form of treatment and, accordingly, they remain an obligation, but should be provided, and fully supported, only in those centers that meet stringent international criteria, including regular audit, and consequently enjoy ongoing accreditation by major registries worldwide.

Acknowledgments
We thank our courageous patients and their families for participation in this programme, colleagues for referrals, and we appreciate the excellent nursing provided in the Department of Haematology including the Clinic, Apheresis Unit, Sunflower ward and the Bone Marrow Transplantation Unit. Additionally the invaluable supervision of nutrition by Mrs Sue Vincent and physiotherapy by Miss Lee Anne Dave and staff. Cardiology consultation was provided by Dr Chris Hugo-Hamman and Dr Philip Barlow Mills. Infectious disease monitoring by Professor Arderne A Forder together with Dr Carol de Gouvia at the Pathcare Laboratory.

Histocompatibility testing was through Professor Ernette Du Toit and technologists of the Provincial Laboratory for Tissue Immunology. The matching was through the South African Marrow Donor Registry and search for unrelated volunteers internationally by the Anthony Nolan, Australian, German and Leiden Groups as well as The American National Donor Program.

Mrs. Christine Dölling for providing invaluable bibliographic assistance. Mrs Sharon Griffin prepared and impeccably typed drafts including the final manuscript.

original research report

**Immunohematopoietic stem cell transplantation in Cape Town: a ten-year outcome analysis in adults**

Lucille Wood, Jonathan Haveman, June Juritz, Herman Waldmann, Geoffrey Hale, Peter Jacobs

*BACKGROUND AND OBJECTIVES:* Immunohematopoietic stem cell transplantation has curative potential in selected hematologic disorders. Stem cell transplantation was introduced into South Africa in 1970 as a structured experimental and clinical program. In this report, we summarize the demography and outcome by disease category, gender, and type of procedure in patients older than 18 years of age who were seen from April 1995 to December 2002.

*PATIENTS AND METHODS:* This retrospective analysis included 247 individuals over 18 years of age for whom complete data were available. These patients received grafts mostly from peripheral blood with the appropriate stem cell population recovered by apheresis.

*RESULTS:* Patient ages ranged from 20 to 65 years with a median age of 42 years. There were 101 females and 146 males. There were no withdrawals and 63% survived to the end of the study. At 96 months of follow-up, a stable plateau was reached for each disease category. Median survival was 3.3 years (n=26, 14.6%) for acute lymphoblastic anemia, 3.1 years (n=44, 18%) for acute myeloid leukemia, 2.8 years (n=47, 19%) for chronic granulocytic leukemia, 2.8 years (n=21, 29%) for lymphoma, 1.5 years (n=23, 9%) for myeloma, 1.43 years (n=10, 4%) for aplasia, and 1.4 years (n=38, 15%) for a miscellaneous group comprising less than 10 examples each. Multivariate analysis showed that only diagnosis and age had a significant impact on survival, but these two variables might be interrelated. There was no significant difference in outcome by source of graft.

*CONCLUSION:* The results confirm that procedures carried out in a properly constituted and dedicated unit, which meets established criteria and strictly observes treatment protocols, generate results comparable to those in a First World referral center. Low rates of transplant-related mortality, rejection and graft-versus-host disease are confirmed, but the benefits cannot be extrapolated outside of academically oriented and supervised facilities.

---

**Traditional allogeneic bone marrow transplantation, introduced primarily for correction of irreversible aplasia whether congenital or acquired, may also be life saving in other defects exemplified by immunodeficiency disorders and metabolic diseases.** It is currently accepted as having a place in treating acute1 and chronic leukemia,1 Hodgkin’s or indolent2 as well as aggressive lymphoma3 in addition to myeloma. The scope increasingly extends to a number of solid tumours amongst which are breast cancer4 and, in selected cases, acquired lesions including paroxysmal nocturnal haemoglobinuria3 or myeloproliferative syndromes amongst which is idiopathic myelofibrosis.13

Outcome continues to benefit from more precise matching at both major4 and minor13 histocompatibility loci, using DNA-based or molecular techniques, which also make possible definition of chimerism16 or quantification of minimal residual disease.17 Nevertheless problems persist amongst which are rejection18 and acute15 or chronic graft-versus-host disease.20 These are offset by better utilisation of immunosuppressive regimens for conditioning21 as well as in the post-procedure period with corticosteroids, methotrexate,22 cyclosporin,21 tacrolimus24 and mycophenolate mofetil.28 Concurrently
there is greater attention being given to supportive care, with proactive evaluation and maintenance of nutrition underpinned by strong psychosocial networks. Against the background of this therapeutic option was introduced into South Africa in 1970 via an animal allotransplant graft program with active research and ongoing clinical development sustained by the original international team. On this basis it was possible to provide a forty-year perspective in which four separate developmental, albeit overlapping, periods can be identified with the appreciation that such distinction is somewhat artificial.

Firstly was a need to pioneer the use of apheresis in this country so replacing the obstructed delivery of blood products in bottles and, applied initially, to explore a place for granulocyte transfusions. There was subsequent permeation of the technology into commercial blood banks where, in the course of the last 30 years, it has entirely appropriately become a well-established routine. Concomitantly to expand the use in processing bone marrow after collection whilst, latterly, to directly harvest the corresponding population after mobilisation with stimulatory peptides into the peripheral blood. The latter resulted in a substantially shortened time to engraftment, a low incidence of relapse in acute myeloid leukemia, but reappearance of cytomegaloviral infections.

Secondly were preliminary cooperative studies with Jeanne Borel at Sandoz in Basel showing that cyclosporin A, at least in experimental animals, decreased both the incidence and severity of acute graft-versus-host disease. Follow-up in the clinic, however, revealed that while these benefits could be reproduced in patients, prevention was only partial and did not abrogate recurrence.

Thirdly there followed collaborative research initially in Cambridge and with the same group continuing these investigations latterly in Oxford that defined a role for T-lymphocyte depletion using Campath monoclonal antibodies in vivo by adding them to the graft in the bag. One consequence was recognition of an altered expression or forme fruste of immunologically mediated acute graft-versus-host disease that appeared later, was typically limited to skin and usually responsive to topical steroids although on occasions systemic administration was unavoidable.

This syndrome is not considered chronic in the accepted sense either to time of onset or more importantly having a quite different clinical spectrum and remains distinct being conceptually regarded as reflecting modulation by the antibody used in this particular way. Such an approach remains firmly established as local, and much wider, practice. It also forms part of the broader ongoing participation and reporting of results to the Campath users group. The original lytic IgM protein was subsequently replaced by an epoic equivalent and more recently shifted to a chimeric humanised version designated Campath 1H. In all these studies engraftment remains uniform and rejection infrequent. This applies even when extended to include family members and matched unrelated volunteer donors identified through the South African Bone Marrow Registry interacting with corresponding European Centers and the American National Donor Program.

Fourthly, appreciating that peer review was crucial to maintaining standards, but unfortunately non-existent in this country or anywhere in sub-Saharan Africa, every patient, from inception, has been reported to the International and then Autologous Bone Marrow Transplant Registries for scrutiny and audit. After more than twenty years of refinement and consolidation, our original program was transferred, in 1995, to an academic Department in the private sector. Maintenance of this active surveillance mechanism, now to the Center for International Blood and Bone Marrow Transplant Research, has sustained unbroken reaccreditation to the present time. Concurrently the original group remain designated as a Transplant, Harvest and Donor Center within European Bone Marrow Transplant Registry and concurrently with participation and approval for transplant placement as well as and as harvesting by the American National Donor Program.

After 30 years it is appropriate that this single team experience be updated to allow comparison, particularly in the last decade, to other private and state services in this country, but, more critically, to be measured against results on a worldwide basis.

It is mandatory in South Africa, as in other emerging, developing or under-resourced areas, that a clear and reliable statement of what can be expected is available. Such statistically analysed data provides perspective against which to evaluate changes that continue to occur as a result of the ever-shifting landscape of managed care for the insured patients. This is especially relevant as government seeks to focus on costs in private hospitals whilst medical aids seek to define preferred providers, not as one would expect on cost-effective benefits, but primarily using financial or incentive-driven criteria. Scientifically, academically and intellectually, it is argued that such monetary focus is inappropriate and should defer to the identification of high-performing multidisciplinary units that can meet the requirements for the widely acknowledged center effects. Corresponding information for those under 18 years of age is the subject of a separate publication.

To definitely document the introduction and subse-
original research report

quent development the comprehensive experience in this country has recently been reviewed.48

Also the wider place of these interventions from introduction at the University of Cape Town and Groote Schuur Hospital in 1970 with establishment in the private sector with continued development over the last 15 years is in preparation for the History of Medicine Series.49

Accordingly, we detail, from this academic unit in Cape Town, statistically analysed results and define projected basic as well as clinical research that will focus on immunologic reconstitution.50 The latter is anticipated to correlate laboratory findings with patient response to viral, parasitic and bacterial infections in the context of reverse isolation and emerging multi-drug resistance.51

The particular relevance is that this program will explore immunosuppression by only ex vivo T-cell depletion that is distinctly different from many more conventional approaches where a range of agents are administered for periods of time after engraftment for control of rejection and graft versus host disease. Additionally, so better document commitment to quality-of-life assessment with psychosocial counselling in conjunction with liaison psychiatry. There already emerges a strong argument to restrict these costly treatments to active teams that have a clear record of meeting first world performance judged by published outcome, attract sufficient volume to sustain the advantages of the well-recognised center-effect.52-53 and, in developing or under-resourced areas, meet criteria for international acceptance via endorsement as full participating membership in appropriate registries.54 Indeed it has recently been proposed that these activities be collected and analysed by establishing a repository within the South African Bone Marrow Registry to match the ongoing survey by European Bone Marrow Transplant Group.55 The latter focuses on cord blood but draws attention to the widely recognised argument to require reporting of all procedures while leaving the way open for local groups to assign resources regionally. These are not exclusive but can readily be revised to include survival analysis in the future.

METHODS

Diagnosis

Following comprehensive clinical assessment agreed definitions were used for aplasia, acute and chronic leukemia, Hodgkin's or other lymphomas and myeloma.56 Morphologic features on bone marrow aspiration were supplemented by appropriate cytochemistry,57 flow cytometry,58 karyotyping and molecular genetics documented.59 Immunohistochemistry was used as necessary on tissue and trephine biopsies.59

Radiology

Conventional films were complemented by computerized axial tomography including determination of bone mineral density.60 Skeletal involvement was recorded and changes graded according to locally developed criteria (unpublished). The preferred PET-CT was not routinely available during this time.

Biochemistry

Renal and hepatic profiles, serum protein electrophoresis, immunoglobulin quantitation and markers of tumour activity included sensitive C-reactive protein and S2 microglobulin.

Staging

Where relevant this was according to the Cotswold modification of the Rye system or, preferably, the international prognostic index.61

Pre-transplant phase

Physical facility

Management was in reverse isolation where each two-roomed suite had dedicated shower and toilet. There was a particular focus on patient information and interactive counselling offered to help maintain optimum quality of life.62-63 In addition details of local bone marrow transplant unit were provided in two specially written information brochures.64-65

Nutritional status

Selective decontamination of the bowel relied on oral levofloxacin.66 A low microbial diet was provided with daily review of weight, caloric status and vitamin as well as trace metal balance. All patients were in the routine care of a trained academic dietician.

Where targets were not achieved placement of a nasojejunal, as opposed to nasogastric, fine bore feeding tube was used and this remains a subject of evaluation (Wood, Schloss, O'Keefe, Jacobs - study in progress).

PATIENTS

Three hundred and twenty consecutive individuals, over 18 years of age, eligible for immunohematopoietic stem cell transplantation were registered from April 1993 to December 2002, a number of which were included in a recent audit by the Center for International Blood and Marrow Transplant Research and retrospectively analysed. After the data was cleaned to implement age restriction a total of 247 cases qualified as the basis for this report.
Total parenteral nutrition was infrequently needed and then largely in the paediatric age group.

Nausea and vomiting
These symptoms were anticipated and recipients received 72 hours of oral phenobarbitone, metoclopramide or serotonin antagonists prior to admission. This was switched to intravenous route at the time of conditioning and dosage titrated to proactively prevent such side effects with this regimen supplemented by paracetamol, dexamethasone or valoid orally or by suppository as needed. More recently neurokinin-1 antagonists and second-generation 5-hydroxytryptamine antagonists have become available and, together with motility-controlling drugs, were used when indicated. Clostridium difficile was treated with oral metronidazole or, if resistant, vancomycin by the same route.

Neutropenic fever and viral infections
Pyrexia, defined as 38°C, when confirmed at 60 minutes, required repeated cultures of blood, urine and stool followed by empiric single agent ceftazidime or tazocin with the beta-lactams given as 24-hour continuous intravenous infusion. Isolation of pathogens was the basis of switching to in vitro sensitivity directed regimens and typically with 2 drugs synergistic in vitro for persisting fever.

Culture-negative cases were managed with 1 mg/kg of amphotericin in 200 ml 5% dextrose water given, as a continuous 24-hour infusion since side effects, and particularly nephrotoxicity, were abrogated. Cyto megalovirus was monitored by serology and more recently routinely screened for by the PP65 and PP67 assay with polymerase chain reaction when leukocyte counts were below 1x10^9/L. Pre-emptive treatment was by intravenous gancyclovir or valganciclovir and switched to the latter agent orally for a further two weeks once the virus was no longer detectable. It is notable that, at least in solid organ transplants related to the pharmacokinetics and pharmacodynamics, both agents can result in drop in white count and delay recovery in neutrophil and monocyte levels.

Transfusion policy
Neutropenia, particularly when associated with fever, of less than 0.5x10^9/L granulocytes received 300g GCSF intravenously until this level was stable above 1x10^9/L and temperature again normal. Packed red cells were administered on a standard regimen for symptom-relief with haemoglobin arbitrarily kept above 100 g/L. Platelets were used in those at risk from bleeding to maintain counts greater than 30x10^9/L with single-donor apheresis units concurrently with 500 mg of cydokapron orally or intravenously every 8 hours. These were collected initially from a dedicated volunteer panel and with quality control to meet safety standards.

Surveillance
Data analysis was on a moment-to-moment basis. All decisions were updated daily at morning report and included planning for nutrition, psychosocial counselling, liaison psychiatry, physiotherapy with review of medication by haematology pharmacists.

Central venous access
This was secured using a double-lumen Brovic catheter inserted under general anaesthetic following the Hickman technique. The position was checked on recovery to confirm that return of muscle tone did not dislocate the tip, ideally positioned 1 cm above the junction of the superior vena cava with the right atrium. Low dose warfarin, with the INR in the normal range, was employed to reduce the risk of venous thromboembolism.

Counselling and liaison psychiatry
At diagnosis a family conference was convened that included introduction to nursing and paramedical staff, dietician and physiotherapist. Previous cytotoxic drug treatment and irradiation was documented and the risks, as well as potential benefits, of the procedure explained and brochures describing the organisation of the department and the unit provided. Once all issues had been fully discussed the informed consent was signed by patient or, in the case of minors, by parents or responsible guardians.

Prior treatment protocols

Donor selection
Histocompatibility was confirmed by standard methods via the South African Bone Marrow Registry where appropriate searches extended to include British, Australian, Dutch and American participating centres; further consultation was with the Leiden Group. These activities were part of a worldwide research project with certification through the International Immunogenetics Group.

Acute lymphoblastic leukemia (n=14: 6%)
Treatment was standardised to the Berlin-Frankfurt-Munster or BFM programs.
**Acute myeloid leukemia (n=44; 18%)**

Initially the combination of cytosine arabinoside, an anthracycline antibiotic with an epipodophyllotoxin, was used. More recently this was extended to the British Medical Research Council AML 15 program. In some instances managed health care organisations, on advice of their local consultants, have unfortunately restricted access to these regimens despite clear evidence of benefit from adding gemtuzumab ozogamicin to this drug regimen.

**Chronic granulocytic leukemia (n=47; 19%)**

Disease control was rapidly achieved using hydroxyurea and latterly imatinib mesylate. Transplantation was offered to fully matched recipients particularly with the escape from the tyrosine kinase, if cytogenetic abnormalities developed or this was patient’s choice.

**Hodgkin and other lymphomas (n=71; 29%)**

Current protocols parallel those used by the European Organization for Research and Treatment in Cancer (EORTC) or the German Hodgkin and Lymphoma Study Group.

**Myeloma (n=23; 9%)**

Stratification was by comorbidity and risk factors using guidelines from the International Myeloma Working Group. VECD comprising vincristine, epirubicin, cyclophosphamide and dexamethasone were preferred. Here the target was greater than seventy-five percent reduction in both paraprotein level and plasma cell infiltrate of marrow trephine biopsy to qualify for autologous immunohaematopoietic stem cell grafting. Thalidomide was not approved by local third party funders during these studies. In appropriate cases maintenance depended on negotiating for this agent with bortezomib still not being available. Alternatives were pulsed melphalan and methylprednisolone or salvage with dexamethasone and vincristine.

**Aplasia (n=10; 4%)**

Intensive support included limiting blood and other components as far as possible. Where suitable sibling donors were available this remained the preferred treatment. In other instances immunosuppressive regimens including high dose methylprednisolone and antilymphocyte globulin were standard.

In keeping with established practice, including this country, irreversible bone marrow failure was a prime indication for one or other form of immunohaematopoietic stem cell allografting either matched sibling, unrelated or minimally mismatched family donors.

**Miscellaneous group (n=38; 15%)**

This varied by subtype. In hairy cell leukemia 2-chlorodeoxyadenosine was largely successful and so seldom needed grafting. Cutaneous lymphomas, including mycosis fungoides or Sézary syndrome, received appropriate superficial irradiation. Gemcitabine or alemtuzumab for tumours of T-lineage and individualised therapy in B-lymphocyte neoplasms appropriate for risk category. Individuals received pulsed chlorambucil or combinations of rituximab, fludarabine and cyclophosphamide; latterly the anti-CD20 monoclonal antibody Campath or alemtuzumab. In selected refractory instances allografting was an option.

**Special projects**

A number of prospective investigations are actively evaluating changes in pulmonary, skeletal, gastrointestinal, renal and cardiovascular status as an integral part of management and incurred new costs. Immunologic reconstitution is to become a major focus of the program to explore the importance of side effects better now described as survivorship.

**Transplantation phase: conditioning regimens**

Two myeloablative options were used. In none of these patients was this primarily immunosuppressive-alternatively described as reduced intensity.

**Radiotherapy**

12 gray fractionated whole body irradiation on days -7/-6/-5 is followed by 60 mg/kg of cyclophosphamide intravenously on days -4 and -3, and 6 gray fractionated total nodal irradiation on days -2 and -1. The graft is infused on day 0.
Chemotherapy
Bisulfan combined with cyclophosphamide, used originally in the four-day regimen has been replaced by two-day alternative: the former being intravenous as opposed to oral.\textsuperscript{134,135} In selected individuals, where this agent was contraindicated, fludarabine was used. Additionally in over eighty percent of our cases the first choice was the BEAM preparative regimen.\textsuperscript{136}

Re-transplantation
With primary or secondary graft failure preparation was with fludarabine\textsuperscript{137} antilymphocyte globulin and cyclophosphamide.\textsuperscript{138}

Mobilization and quality control
Granulocyte-colony stimulating factor was commenced subcutaneously on Day 5 at a flat dose of 300\textsuperscript{132}mg with the last injection at 04h00 on the day of first large volume apheresis harvest. CD34 population were noted but not specifically used to time these collections.\textsuperscript{12}

Autografts
Cyropreservation was undertaken as previously described.\textsuperscript{139}

Allogeneic transplants
Histocompatible siblings received only the ex vivo T-cell depleted product after exposure to Campath 1H in-the-bag.\textsuperscript{130} Alternative family members and matched unrelated volunteer donors - exclusively - received cyclosporin at full therapeutic dose for six months with a fifty percent reduction at three months and the remaining three months at twenty five percent optimum dose.

Infusion techniques
Premedication, given half an hour before the graft containing the monoclonal antibody, consisted of 100 mg of hydrocortisone, 12.5 mg of promethazine hydrochloride intravenously and 500 mg paracetamol orally. Continuing non-invasive cardiovascular and respiratory monitoring was sustained until vital signs were stable. Oxygen desaturation necessitated rate adjustment of this infusion and this occurred in less than five percent of the procedures. In approximately thirty percent pyrogenic reactions with abdominal discomfort were attributed to the immunoglobulin. There were no lasting side effects. In autografts transient fever was initially attributed to presence of DMSO and recently ascribed to contaminating granulocytes in the apheresis product.\textsuperscript{140}

Product manipulation
Bone marrow, although no longer routinely used, continued to accommodate matched unrelated volunteer programs predicated on requirements of the coordinating center from different parts of the world. Here the harvest was modified using the standard apheresis technology: vide supra.\textsuperscript{139} once greater than ninety-five percent of the mononuclear cells have been recovered the residual blood was infused to the donor or discarded. The immunohaematopoietic stem and progenitor concentrate had the standard ex vivo addition of 20 mg of Campath 1H, incubated at 37° for half an hour and infused.\textsuperscript{141}
Post-transplant surveillance
Immunosuppression was not used in histocompatible siblings. Conversely, in family members and matched unrelated donors, the recipients received cyclosporin maintaining therapeutic levels of 1500 ng/mL on the C2 assay. In the dose was cut to fifty percent at six months, twenty five percent at nine months and discontinued at twelve months protocol included 200 mL of stabilised human serum weekly in addition to 500 mg of valaciclovir twice daily for viral prophylaxis for three months and co-trimoxazole comprising trimethoprim 80 mg and co-trimoxazole 400 mg daily for one year.

Statistical analysis
Data was examined using the Kaplan-Meier product limited estimator, Cox proportional hazard based on initially fitting each risk factor, multivariate analysis and Pearson Chi squared contingency tables for independence testing.

RESULTS
Age and gender
Median and mean age were both 42 years with a range from 19.45 to 65.0 (Figure 1). At transplantation, mean age for females was 41.3 years and for males 42.7 years. Most were between 40 and 50 years with a much-reduced number between 60 and 70. There were 101 female and 146 males. Gender was balanced in the middle but at the other end of the spectrum roughly double the number of males were present. Survival decreased with age (Figure 2) but despite difference between the groups, it is notable that the estimate of survival function is roughly the same. This suggests that once the initial transplant-related mortality is past, there is equal benefit from the procedure. There are no gender differences evident (Figure 3).

Influence of transplantation procedure
When subdivided by those having peripheral blood stem cell autologous or allogeneic transplants and further into groups were the graft source was from bone marrow or peripheral blood treated respectively with the of opsonic monoclonal antibody Campath IG or the humanised variant designated IH survival appears unaffected by the immunoglobulin (Figure 4). There was no statistical difference between control patients receiving peripheral blood stem cell autografts (n=101) when ex vivo t-cell depletion is carried out with the Campath IG bone marrow (n=14) or blood (n=36). Similarly, when humanized monoclonal antibody IH was used in-the-bag on the mononuclear
cells driven by apheresis from the circulation (n=96) outcome was comparable.

Outcome by diagnosis
The majority of the patients were referred with non-Hodgkin lymphoma followed by chronic granulocytic and acute myeloid leukemia (Figure 5).

Analysis of survival on this basis (Figure 6) (Table 1) shows substantial differences with superiority for the acute leukemias followed by lymphoma although these are not stratified for Hodgkin and other variants with approximately equal outcome for the remaining cases with aplasia and myeloma.

Cause of death
The majority were multifactorial having a final common pathway of severe inflammatory response syndrome culminating in multiple organ dysfunction. Where separation and assignment to particular predominant explanation was possible, relapse, followed by respiratory failure accounted for most of the remainder with small numbers probably artificially attributed to sepsicaemia and cerebral events (Figure 7).

DISCUSSION
The introduction initially as conventional transplantation of bone marrow and subsequent development in South Africa over the ensuing 35 years has, in the last decade, started to raise questions about sustainability of these often life saving, albeit costly, endeavours. Unquestionably they require a substantial investment of resources in providing tertiary or even quaternary level physical facilities originally based in state supported University teaching units but increasingly re-deployed at privately funded hospitals or clinics. Both areas depend for continued effective function on retaining a stable complement of highly trained and experienced doctors with nurses as well as paramedicals that make up the indispensable multidisciplinary team. Here arises the first problem, and it is as acute as serious, with severe understaffing becoming ever more critical at all levels reflecting a steadily accelerating exodus from South Africa of these professionals. Secondly, in monetary terms, there is inevitable competition with other health care priorities most strikingly in sub-Sahara by those created in the wake of an escalating acquired immunodeficiency disease pandemic.

Sharp focus is given to these sobering realities by an analysis describing such activities in Europe coupled with a recent survey for the first time documenting the current local situation. Accordingly the time was judged appropriate to set out the way in which the latter point had been reached with a further intention of offering perspective for the future of immunohaematopoietic stem cell grafting in a Third World country seeking to objectively balance need against capacity. Such a repository has a number of potential benefits. It will allow government or other licensing authorities to look at the way regional activities are distributed. Secondly to ensure equitable accessibility to state funded programs and for all centers, particularly those in the private sector, to show effectiveness in adults and children, determined objectively by outcome analysis. Such impartiality facilitates scrutiny by managed healthcare organisations and medical aids of results from individual teams and so shifts the responsibility...

It is crucial to ensuring that potentially incentive-driven financing is replaced by supporting preferred providers where audit and accountability take into consideration the all-important center effect.

In an endeavor to provide this type of non-partisan information consecutive admissions over a seven-year period were analyzed from an academic center based in the private sector. The facility was specifically created to recapitulate the standard University style department. Interestingly, the same investigators that designed and commissioned the prototype and custom-built bone marrow transplant unit in the Groote Schuur Hospital have extended this experience over 35 years.46

Thus with the relocation of the Jean Porter apheresis unit and many of the professional nurses it has been possible to continue reporting consecutive recipients to the Center for International Bone Marrow Transplantation Research. This has ensured that their scheduled audits continue with accreditation: a status, which has remained intact for more than three decades.

Using this database the paediatric results could be compared to earlier experience from the State Hospital and document, apart from a more active private program, essentially the same results.47

The parallel experience in our adult cohort supports five conclusions.

Firstly, given a suitable physical facility and adherence to management protocols that are commensurate with international standards of care, an environment could be created to meet and then sustain established criteria for international standards of care whilst continuing to develop and introduce new research topics as appropriate. The cardinal consideration was a focus on the all-important haematology co-ordina-
tor managing a multidisciplinary management team made up of long stay nursing and paramedical professionals including academic dieticians and skilled janitorial support staff with constant interaction between infectious disease, cardiology, nephrology and gastroenterology consultants. Such a comprehensive unit emerges as the indispensable key to provision of unquestionably costly, albeit sophisticated, interventions with the all-important appreciation that this is an entirely realistic undertaking even in an under-resourced area of the globe.

Secondly, under these circumstances, outcome analysis is seen to approximate that from recognized reference centers in the field. This applies in the first three months with mortality largely related to the procedure itself. Then also, and of note, given the vagaries of southern Africa with migrant populations and civil unrest, the opportunity of serially observing these individuals for more than 35 years to provide a reliable long term reference point for overall cost effectiveness.

Thirdly, in the specific context of ex vivo T-cell depletion is the seminal observation that survival curves are stable and do not have late and previously unrecognized sequelae that differ from those generated in recipients exposed to conventionally used post-transplant immunosuppressive regimens. Thus there is no apparent impact of this unique immunosuppressive regimen on developing myelodysplasia or predisposing to chronic infections such as pulmonary tuberculosis so rampant in sub-Saharan Africa. It remains to be determined whether the slightly higher incidence of cytomegaloviral infections translates into any clinically important requirements other than the need for prompt recognition and proactive antiviral therapy. It is also momentarily unclear as to whether the impact of retroviral infections can be altered in the face of appropriate combination active retroviral therapy and this is the subject of ongoing study.45 Currently the quality-of-life with the low incidence of graft versus host disease, in its various forms, is gratifying.

Fourthly veno-occlusive disease has not been seen despite the use of intravenous busulphan. Furthermore peripheral blood stem cell mobilization with G-CSF has been efficient with only relatively minor side effects of backache and bone pain in some donors. No difference can be seen when bone marrow is compared to peripheral blood as source of the graft. Also, and of relevance, is that no serious adverse reactions46 have thus far been noted in donors despite which informed consent has been altered to include extended surveillance both among siblings and matched unrelated volunteers.
through each referring registry.²,¹²⁷

Fifteenth, immunohaematopoietic stem cell grafting including collaboration on a worldwide basis is entirely realistic in this country given that donations can be imported or exported with due observance to rules on moving human tissue between countries.²,¹²⁷ This, in turn, is relevant and underlines the importance of our having established the South African Bone Marrow Registry²⁰⁴ that functions interchangeably with others throughout the world including in the United Kingdom, Europe¹⁰⁹ and the American National Marrow Donor Program.¹⁰⁸ Logically such a network can provide an impartial repository to monitor country-wide activity with the further attraction of a database upon which to plan national protocols, co-operative clinical trials and research studies.

Conclusion

These procedures carried out in a properly constituted and dedicated unit continues to generate results that are comparable to those from established first world reference centres. The low transplant related mortality, rejection rate and graft-versus-host disease, previously reported are confirmed. The benefits of what is clearly a center effect cannot necessarily be extrapolated to similar interventions performed outside designated and monitored academically orientated facilities. In Third World countries, given current parlous financial climate and rampant retroviral epidemics, allocation of restricted resources for this purpose is rationally most sensible when limited to established, audited and accredited teams. Such a stance rests heavily on publication of outcome to justify ongoing support. It will also direct focus to actual achievement in contrast to the currently favoured incentive-driven preferred providers.

Acknowledgments

We recognise the courage of our patients and their families. Thanks to the staff in the Joanne Porter Apheresis and Bone Marrow transplant units, the Sunflower Haematology ward and the outpatient clinic for their high level of professionalism and care.

Supported by the Haematological Research and Education Trust and Chairman’s Fund of the Anglo-American Corporation with grants from The Anthony Taberer, Louis Shill and Margaret Ward Foundations (Lucille Wood and Peter Jacobs): Manufacture of the Campath antibodies was supported by the UK Medical Research Council, the EP Abrahams Trust, Millennium Pharmaceuticals Inc (formerly LeukoSite Inc) and TolerRx Inc. Thanks are due to all members of the team at the Therapeutic Antibody Centre Oxford, notably Pru Bird, Patrick Harrison, Eleanor Berrie, Emma Belam and Tony Gallagher. Tissue typing was via the South Africa Bone Marrow Registry and we recognise the excellence of that internationally accredited immunogenetics group.

Some of the work referred to in this thesis was an Honours project for BSc in Actuarial Science awarded to Jonathan Haveman.

We thank Mr Pedro Abrunhosa for help with the graphics. Christine Dolling for the bibliographic review and Natasha Trueman typed the manuscript: we record appreciation and thanks to our research staff.

CHAPTER 8

CONCLUSION

THE PAST – PRESENT – AND FUTURE
Orientation

The analysis and reporting of this long-running research project is considered, with every possible humility, as but one additional step in continuing to import relevant knowledge into our country as a basis for further development of an established, clinically applicable and multidisciplinary technology. In reaching this point each of the four goals originally identified have been largely realised. Specifically creating a suitable experimental environment to set-up the haematology laboratory, then transferring the methods to relevant and standardised clinical protocols, penultimately ensuring participation in scientific advances exploring innovative therapies and, finally, maintaining accepted international academic and intellectual standards to comply with registry participation and accreditation.

Concerns were expressed in the Lancet this year, on the behalf of the Academy of Science of South Africa, about clinical research in our country\(^2\rightarrow7\). For this reason a compelling argument can be mounted to invigorate immunohaematopoietic stem cell transplantation by capitalising on sustained local achievement some of which carries with it strong worldwide recognition and collaboration.

To give credence to such a stance it is instructive to look back over the voluminous records meticulously collected and catalogued. The data is found to fall quite naturally into three interlocking, albeit consequential, segments.

The past dates from the mid to late 1960s recognising a need to introduce bone marrow transplantation into our country. This was realised by drawing on experience from many parts of the globe in defining technology and building the necessary infrastructure essential for a credible scientific programme. Much time and effort was invested in the animal model as well as establishing entirely new techniques including clonogenic assays. Inevitably there was a steep learning curve linking many different disciplines through an unusual esprit de corps best described as remaining perpetual students. International interaction anchored this growth with guidance offered from numerous other lands culminating in emergence of the first South African transplant centre.
The **present** accounts for most of these years given to constantly forging a multidisciplinary basic science and clinical research facility. The resulting matrix was sufficiently productive of good quality published and presented outcome studies to be allocated specific topics for investigation within major cooperative scientific groups. These included the innovative new method for immunosuppression with cyclosporine A and benchmark exploration of the Campath series of monoclonal antibodies leading to description of *ex vivo* use or in-the-bag technique. A distinct achievement rests on accountability for every consecutive procedure leading to more than three decades of unbroken accreditation by major registries worldwide. A further significant challenge was relocation of almost the entire prototype team from the University of Cape Town in Groote Schuur Hospital to a newly developed academic centre in the private sector accompanied by seamless transfer of all the long-standing links so carefully established within the worldwide transplantation community. Ever sensitive to the importance of designation at teaching hospital level was the privileged opportunity to qualify for satellite status in the Division of Clinical Haematology - Health Sciences Faculty at Stellenbosch University.

The **future** is projected along three interrelated axes. One is to consolidate status as a reference centre for new facilities being developed throughout this under resourced part of the world. The second to sustain intergroup contact to constantly upgrade and enhance local science and clinical treatment protocols. The third to bring clear focus to the spectrum of disturbed immunologic integrity that occurs during post-transplant reconstitution and the all-important concept of survivorship. Such phenomena are overshadowed by the acquired immunodeficiency disease in sub Sahara adding an undefined new dimension to the role of these therapies in unique lymphoproliferative and myelodysplastic disorders.

**Organisation of research data**

Using this time-frame as the template only carefully selected publications have been grouped by dominant topic into consecutive chapters. Within each, as well as throughout the summary of the work in its entirety, contribution from local colleagues is readily and gratefully acknowledged. Also recognition is unhesitatingly given, with considerable appreciation, to the still active participation in a number of international study groups.
The weight of direct involvement in any publication identified by asterisk where the investigator not included in writing committee but interactive with the registry or group to variable extent.

Similarly, although in a slightly more personal way, to identify those who continue to make up The Haem Team ranging from janitorial and clerical staff through research typists and librarians to medical or nursing and other paramedical colleagues. The citation of published work is not exhaustive but rather critically chosen to keep within the confines of the research theme. The conclusion then briefly recapitulates the major positive findings allowing a strong closing statement to place in perspective new contributions outlined in this work as an anchor upon which to build in the future.

The stimulus to study and introduce bone marrow transplantation in South Africa

In keeping with long established European traditions haematology was based in University Pathology Departments contrasting with the alternative acceptance of a vital clinical component pioneered largely in North America. Change was as spectacular as it was acute following the first human heart transplant by Professor Christian Neethling Barnard and his team. Tissue typing and the immunobiology of tissue and organ transfer created opportunities at the University of Cape Town that coincided with exposure to immunohaematopoietic stem cell allografting during Fellowship at the University of Washington in Seattle. With the honour of appointment as Professorial Head of the new autonomous Department of Haematology at this prestigious Institution the direction was established with the future clinical base to be in Groote Schuur Hospital.

Experimental haematology

Although much of the experience worldwide was based in a mouse model an alternative approach, using inbred strains of rabbits, was made possible through collaborative studies with Swiss scientists. All the methodology needed to harvest bone marrow and create a monocellular suspension that would be required in the human procedures meticulously standardised. From this point it was possible to move into the clinical programs.
Development of laboratory and clinical infrastructure

Once recovered the starting material was characterised in terms of cell numbers and immunophenotypic composition with flow cytometry in parallel with repopulating capacity using in vitro culture or clonogenic assays. Apart from internal quality control split sample studies were cross-checked at European and Canadian reference laboratories.

The necessary granulocyte and platelet infusions, neither available in South Africa at that time, predicated introduction of apheresis technology and establishment of dedicated donor panels initially from staff in our Department. The next step was to apply the methodology to separation of stem and progenitor cells from marrow-rich blood and extending this to recovery of the same population from peripheral circulation following parenteral stimulatory peptides. It now became pertinent to create a cryobiology section providing further options to the available range of graft sources. Harvest techniques in the human were refined in a number of cadaver exercises. Once all the requirements had been identified compliance needed to initiate the first procedure obtained from the Hospital and University Ethics and Research Committee.

Initially at new Groote Schuur a dedicated facility was engineered in association with experts from the Fred Hutchinson Cancer Institute in Seattle and built into the newly developed State Hospital and subsequently duplicated first in Wynberg and then in Constantiaberg Medi-Clinic. Implicit in such a transplant unit was committed involvement to all the specialities needed to effectively operate multidisciplinary, often daily, consultation from infectious disease, pulmonology, gastroenterology, dermatology and very particularly professional nurses and paramedical professionals including academic dieticians, psychologists and psychiatrists – the morning report. Central to effective coordination, data capture and maintaining records was establishment of a career structure for a Chief Professional Nurse designated as Haematology Coordinator and filled with great distinction by Sister Lucille Wood – in her own right a registered medical natural scientist. This interactive approach, introduced first at the University of Cape Town, continues as the standard being upgraded and refined. Interestingly the structure has recently been duplicated elsewhere in the country.
Acknowledging the benefits of constant education has been the creation of an exchange program with the University of Omaha in Nebraska for senior residents and, most notably, established investigators from the nursing Department.

Audit with registry participation and accreditation
In addition to case-by-case review of the initial patients transplanted it was immediately appreciated that such, if free standing, would be inadequate for acceptance into the international transplantation community. Accordingly, after a probationary period, every consecutive procedure was reported to the International and then the Autologous registries. This continues to the current day with all these activities consolidated in the Centre for International Bone Marrow Transplant Registration. Additional information is provided to The European Group for Blood and Bone Marrow Transplantation. On this basis and as result of random ongoing audit the original team continues with an uninterrupted record of accreditation extending beyond three decades and currently still active.

Cyclosporin A studies
With accumulating experience, confirmed from within all the participating groups, remained dual and very real problems of rejection and graft-versus-host disease as paramount side-effects to overcome. Collaboratively this unique undecapeptide of fungal origin was tested and found to be effective. However it did not abrogate either acute or chronic variants of reverse rejection. Current usage is limited to histoincompatible pairs and the subject of ongoing study.

Campath monoclonal antibodies and in-the- bag technique described
In an extension of endeavouring to blunt post-transplant side-effects the opportunity arose to collaborate with colleagues originally in Cambridge and subsequently relocated to the Dunn School of Pathology in Oxford. These ongoing studies are noted regularly by the Campath users group. Of particular significance is the generally accepted landmark study in which, as a result of experimental endeavours in our Department, these antibodies were used not in vivo to the patient but exposed to the incoming graft ex vivo or in-the-bag.
There resulted effective decrease in typical graft-versus-host disease which has been replaced by a *forme frust*. This variant is readily responsive to topical corticosteroids and, notably, not accompanied by any significant increase in cytomegaloviral infections or leukaemic relapse.

**Standardised protocol with reporting of adult and paediatric outcome**

Coordinated management has made possible, on the still active and continuing basis, declaration of outcome in respect of all results at two levels. Firstly freestanding scientific reports from this team in first-line and peer-reviewed journals. Notable here the survival curves approximate those occurring in major first world reference centres. Secondly acknowledgement for inclusion of relevant contributions in publications and presentations from international collaborators being particularly the Centre for International Bone Marrow Transplant Registration and the European Bone Marrow Transplant Registry.

**Designation as an international transplant, harvest and donor centre**

In addition to individual case reporting the overall status of the team, measured by stringent worldwide criteria, maintains approval and designation in each of these categories by registering authorities worldwide. Furthermore, in recognising the need as well as local difficulties in finding allograft donors where siblings are not available, initiated the concept and the successful establishment of the South African Bone Marrow Registry. This laboratory has now been registered for immunogenetics and enjoys regular interaction with reference centres including long running consultation with colleagues in Leiden.

**Focus on immunologic reconstitution and the concept of survivorship**

Considerable spin off is constantly becoming available from the main line treatment protocol with the established research programmes both locally and internationally. One of these is to focus on the immunologic aspects of these procedures and such is to be undertaken jointly with Professor Patrick Bouic in his Department at Stellenbosch University. The second, having benefited from the high profile at the recent South African Lymphoma Study Group meeting jointly with the German Hodgkin counterparts, drew crisp attention to the largely under represented and poorly reported, albeit sometimes subtle, side-effects.
These increase with time both quantitatively and qualitatively. Accordingly, to focus particular attention on this very important aspect of the whole range of such interventions, a formal study is now in progress with a PhD student registered at Stellenbosch University.

**Achievement as a basis for future direction in an under resourced South Africa**

Ripple effects from this research endeavour are seen in a number of actively expanding arenas.

Of major importance for resource allocation on a national basis is the concept of developing closer interaction between private and public sector. Although the impact of a national health insurance remains to be determined this may further compromise such future interaction. Whilst neutrality is important there is nevertheless a sense of responsibility to protect this important segment of medicine.

Secondly the repository of a secure and internationally accredited team is self-evident from the way in which a number of practices throughout the country are increasingly embarking on these procedures in one or other form.

Thirdly, and in this latter regard, is the strong encouragement for all such practitioners to seek accreditation - preferably international - with the understanding that this could perhaps be offered nationally. This type of advance could take into account changes that are likely to arise in legislation affecting the human tissues act and impacting on the broad ambit of transplantation with special focus as regenerative applications extend to exploring reparative options.

Fourthly, neither should the capacity to use these techniques in properly selected cases of solid tumour oncology and a range of autoimmune diseases be glossed over but here there would be strong emphasis for developing national coordinating programs.

Fifthly, while a modest leadership role has already been taken in documenting activity between the different centres it would, with deference, be hoped that such a common sense approach will receive the necessary endorsement from licensing authorities including the Department of Health.
Sixthly, and not to be overlooked, are alternative graft sources ranging from umbilical blood or cord transplants to amniotic fluid with thought needing to be given to centring this on National venture rather than random unsupervised, growing by default, in the private sector.

Penultimately there is a high priority to understand the impact of human immune deficiency virus infections, as they will certainly influence a whole new spectrum of lymphoproliferative disorders.

Finally many of these activities are seen as precedent creating important growth points that are best sustained in Fellowship training programs as have proven so successful in other parts of the world. Examples already demonstrable are gene rearrangement studies offering better insight and particular application to further document differences in geographical haematopathology. A positive step is interaction with Nebraska Medical School in Omaha extending the long-running lymphoma reclassification project.

It has been a pleasure and an enormous privilege to associate with a very wide range of local and international colleagues - all fellow students - over these many decades. Few could have asked for greater scientific, academic or intellectual fulfilment. Add to this the examples daily provided by patients and families one is left with an indelible legacy of what little has been possible and how much remains to be done.

A fitting quote on which to bring all this experience together might therefore be:

*Tot Faciendum Parum Factum*

So much to do - so little done.
health system and its people if the government were to continue on its previous path. We hope that this Series and the accompanying comments will serve as the basis for serious discussion and ultimately decisive action to improve health outcomes for South Africans.

It is encouraging that the new Health Minister, Aaron Motsoaledi, a physician with long experience in provincial politics, touched on many of these fundamental issues in his budget speech on June 30. He will need to show financial and political commitment in the face of the international economic crisis and additional destabilising effects, such as an HIV epidemic and the effects of climate change. A strong, stable, and equitable South African health system with tangible outcomes should be the most important legacy of this new government.

Three new strategies are needed to form the basis for change. First, to establish a dedicated and strengthened—in skills and numbers—health workforce for the public sector. Second, to ensure sustainable and equitable access to health services for all through the introduction of an affordable national health insurance system. And third, to give leadership and managerial positions to those who are most competent and who are not afraid of being held accountable. There is no place for corruption, nepotism, or misguided political correctness. Only after these changes have been implemented can the real work begin and the current downward trajectory be reversed.

The South African people have shown extraordinary resilience during difficult times. The current leaders have survived apartheid, and often imprisonment, to fight for the future of their country. Civil society, with its strong voice, has brought about many important changes in health. South Africa is a young democracy with pride and hope, and above all with high expectations for a fair, equitable, and peaceful society. Its people deserve a healthy future.

academically active, to inject their expertise into the service sectors, and to influence health delivery policies.3

As a result, many clinical researchers have been left with no option but to turn to the drug industry for the funding of those clinical trials in which the companies concerned have an interest, or to international donors who undertake large-scale but short-term to medium-term projects in South Africa, with local researchers drawn into international teams.4 Drug-industry investment is aimed predominantly at profitable areas, such as chronic diseases of lifestyle, mental illness, and allergy, whereas most of the external donor funding is directed at the local HIV and tuberculosis epidemics.

The serious decline in clinical research activity and capacity has prompted the Academy of Science of South Africa (ASSAf)4 to launch a consensus study designed to make recommendations on reinvigoration of clinical research in the country. An additional stimulus is the emphasis by the government in its 10-year science and technology plan on the development of new medicines and other biologically useful agents (“farmer to pharma”).4 A 14-member panel chaired by Bongani Mayosi of the University of Cape Town is expected to release an independently peer-reviewed report later this year.

Scholarly publication and the accompanying targeted dissemination of new information is an important, measurable indicator of activity in particular research areas.5 South Africa is one of many developing countries that produce only a tiny fraction of the world’s health research literature.6 Despite this shortage, the country dominates sub-Saharan Africa in terms of number of publications, and was for some time particularly productive, in world terms, in clinical medicine. Since the 1960s, health-related research has accounted for the largest proportion of South African literature in the indexed Thomson Reuters ISI Web of Knowledge system. An exhaustive study of South African research articles included in this system showed that 50% were in the medical and life sciences (the analogous figure for Africa overall was no less than 61%).7 Groote Schuur Hospital in Cape Town alone achieved a greater number of the 1% most-cited papers in the ISI system during 1981–91 than did all but two of South Africa’s higher education institutions.8

More recently, however, the share of total ISI-indexed papers from South Africa in clinical medicine has fallen by almost a fifth, from 0.59% in 1990–94 to 0.48% in 1996–2000, mostly caused by a failure to keep up with the rapidly growing total number of publications.9 Most South African ISI-indexed papers in clinical medicine are now published in international (foreign) specialty journals; the number of reports published in local journals, ISI-indexed or not, has substantially decreased in recent years. Articles describing randomised trials in the local flagship South African Medical Journal numbered 195 between 1976 and 1987, but only 92 between 1988 and 1997.10

The capacity to continue to publish articles in leading international specialty journals depends on survival mechanisms under conditions of public disinvestment. There are still a few South African groups with high standards in design and execution of clinical research projects, international collaborations, and effective training programmes. The lack of purposeful and coordinated planning and support makes them fragile and limits their number, however. The recent success of the national Department of Science and Technology in mobilising funding from the National Treasury for Centres of Excellence, research chairs, and major new equipment has been associated mainly with the natural sciences and engineering, which are the preserve of the National Research Foundation, itself controlled by the Department of Science and Technology. The Medical Research Council, which falls under the Department of Health, has failed so far to link itself to these important and highly effective investments. The Department of Health has also been unable to achieve its declared targets of spending on health research.11 Dysfunctional
Otamixaban in acute coronary syndromes

Anticoagulants are widely used to prevent recurrent ischaemic events in patients with acute coronary syndromes. For those who are managed medically, low-molecular-weight heparin (LMWH) or fondaparinux are often used instead of heparin because of the convenience of subcutaneous administration once or twice daily. By contrast, intravenous heparin or bivalirudin is preferred for patients with acute coronary syndromes who are undergoing percutaneous coronary intervention (PCI) because these agents have a rapid onset of action and a short half-life, and the dose can be titrated with point-of-care coagulation monitoring.

Otamixaban is a new direct-acting parenteral factor Xa inhibitor. Like heparin and bivalirudin, otamixaban has a rapid onset of action and a short half-life (table). Otamixaban produces a predictable anticoagulant effect, which obviates the need for routine coagulation monitoring, and unlike heparin or LMWH, the drug does not cause heparin-induced thrombocytopenia. Finally, with less than a quarter of the drug cleared by the kidneys, dose modifications are unlikely to be required in patients with mild or moderate renal impairment. On the basis of these characteristics, otamixaban has the potential to replace heparin in patients with acute coronary syndromes who are undergoing PCI.²

In The Lancet today, Marc Sabatine and colleagues report the results of the Study Program to Evaluate the Prevention of Ischemia with direct Anti-Xa inhibition in Acute Coronary Syndromes 1—Thrombolysis in Myocardial Infarction 42 (SEPIA-ACS1 TIMI 42). In this phase 2 dose-finding study, the investigators compared five doses of otamixaban (0.08 mg/kg bolus followed by infusions of 0.035, 0.07, 0.105, 0.14, or 0.175 mg/kg per h) with the combination of heparin plus eptifibatide for the prevention of major cardiovascular events in more than 3200 patients with non-ST-elevation acute coronary syndromes. More than 98% of patients received concomitant therapy with aspirin and clopidogrel, 99% had coronary angiography, and 63% had PCI. During the first 7 days, the rates of the primary efficacy outcome, a composite of death, myocardial infarction, urgent revascularisation, or bail-out glycoprotein IIb/IIIa use, were not significantly different across the five doses of otamixaban or with any of the otamixaban doses compared with heparin plus eptifibatide. However, the group who received the lowest dose of otamixaban was stopped early, and with this dose and the next lowest dose of otamixaban, the rates of thrombotic complications or use of bail-out glycoprotein IIb/IIIa inhibitor during PCI were at least two-fold higher than...
CHAPTER 9

SELECTED BIBLIOGRAPHY
Criteria for publications selected

In each of the sections, as noted on page 8 – Objectives – Title and Scope - quoted works fall into two broad categories. In the first – identified by an asterisk – the investigator had access to restricted protocols, privileged reports and ongoing trial data from registries but where citation is deemed relevant to this research project. No immediate role is claimed but rather acknowledges advice, help and collegial scientific as well as academic interchange.

In the second, all the remainder, project planning, direct participation, data analysis and full involvement in all stages is compliant with authorship and thus the criterion for inclusion.

The entire bibliography is sequential and tracks advances occurring throughout the world in the different and evolving aspects of immunohaematopoietic stem cell transplantation. Thus the arrangement is along these time lines, not segregated by geographical or methodological consideration such as graft source. The listing therefore documents the prospective evolution of the project over this thirty year period.

Chapter 1 – Explanatory Introduction

CHAPTER 10

SUPPORTING CURRICULUM VITAE
ABRIDGED CURRICULUM VITAE - 2010

PROFESSOR PETER JACOBS

PERSONAL DETAILS
ID Number: 3403215045082
Date of Birth: 21 March 1934
Place of Birth: Pretoria, South Africa

EDUCATION
1948: Matriculation - Prince Edward School
      Salisbury, Southern Rhodesia (now Harare, Zimbabwe)

TECHNOLOGY EXPERIENCE
1949-1953: Chief Medical Laboratory Technologist
          The Pasteur Institute & Blaine Laboratories
          Salisbury, Southern Rhodesia (now Harare, Zimbabwe)

GRADUATION RECORD
1954-1959: M.B., B.Ch., University of the Witwatersrand, Johannesburg

1960:
      Internship
      Professorial Departments of Medicine and Surgery
      University of the Witwatersrand and Johannesburg General Hospital

1966:
      MD, University of the Witwatersrand, Johannesburg

1974:
      PhD, University of the Witwatersrand, Johannesburg

2010:
      DSc (Medical Science)
      University of Stellenbosch, Cape Town
      Thesis entitled "Immunohaematopoietic stem and progenitor cell transplantation – a thirty year prospective and systematic research investigation."
REGISTRATION

1959: Medical Practitioner
      South African Medical and Dental Council

1960: Physician
      South African Medical and Dental Council

1961: Medical Practitioner
      General Medical Council: United Kingdom

1996: Pathologist - Haematology as Speciality
      General Medical Council: United Kingdom

1998: Clinical Haematologist
      Health Professions Council of South Africa

RESEARCH BURSARIES AND FELLOWSHIP

1961-1963: Senior Research Bursar,
            CSIR Iron and Red Cell Metabolism Unit, Department of Medicine,
            University of the Witwatersrand, Johannesburg

1967-1969: Senior Research Fellow in Haematology,
            Department of Medicine, University of Washington, Seattle,
            Washington

PROFESSIONAL QUALIFICATIONS - COLLEGES

1960  Membership, British Medical Association
1966  Fellowship, The College of Physicians, Surgeons and Gynaecologists of
      South Africa
      The College of Medicine of South Africa
      Fellowship, The Royal Society of Medicine, UK
1967  Membership, International Society of Haematology
1973  Membership, The American Society of Hematology
1974  Membership, New York Academy of Sciences
1977  Membership, The International Society of Experimental Hematology
      Fellowship, The American College of Physicians
      Membership, The Royal Society of South Africa
1978  Membership, The American Association for Cancer Research
1979  Membership, The American Society of Clinical Oncologists
      President-Elect, The Southern African Society of Haematology
58          The European Bone Marrow Transplantation Group
1982  Fellowship, The Royal College of Pathologists, UK
1983  Membership, The Scientific Advisory Board, Immunology and
      Haematology Research
      Membership, The Council of Biology Editors
      Membership, International Society of Thrombosis and Haemostasis
      Honorary Advisor, International Division, The American Biographical
      Institute
      Membership, The New York Academy of Sciences
      Membership, The Southern African Transplantation Society
      Membership, The European Bone Marrow Transplantation Group
      Membership, The European Society for Haemapheresis
Director, African and Asian Chapter, The European Society for Haemapheresis
Membership, Biological Standardisation Committee, Medicines Control Council

1985 - Membership, The College of American Pathologists
1986 - Foundation Member, South African Society of Medical Oncology
1986 - Fellowship, The Royal Society
Fellowship, International Research into Science and Technology
Counsellor, European and African Division
Board of the Council, International Society of Haematology
Fellowship, American Society of Clinical Pathologists
Director, Board of Directors for America, African Countries, Asia and Pacific Countries, European Society for Haemapheresis

1987 - Membership, World Apheresis Association
1991 - Foundation Member, South African Society of Medical Oncology
1991 - Fellow, International Biographical Association
1992 - Foundation Member, South African Lymphoma Study Group
1992 - Foundation Member, South African Bone Marrow Registry
1994 - Fellowship, Academy of Haemostasis and Thrombosis
1994 - District Counsellor for Africa on the 1994-1996 WAA Board of Directors
1995 - Tygerberg Comprehensive Lymphoma Study Group
2006 - Sub-Saharan Africa Lymphoma Consortium
2006 - Life Fellowship, The Royal Society of Medicine
2008 - International Fellow, American Society of Clinical Pathologists
2008 - Emeritus Member, American Society of Haematology
2008 - Emeritus Member, European Society for Haemapheresis and Haemotherapy
2008 - Emeritus Member, International Academy of Clinical and Applied Thrombosis/Haemostasis
2008 - Emeritus Member, International Society for Interferon and Cytokine Research
2009 - Emeritus Member, The Royal College of Pathologists
2009 - Emeritus Member, The Royal College of Physicians Edinburgh
2009 - Emeritus Member, American Society for Blood and Marrow Transplantation
2009 - Emeritus International Fellow, The College of American Pathologists

POSTGRADUATE EXPERIENCE

1961-1963: Part-time Casualty Officer,
Senior Research Bursar, CSIR, Iron and Red Cell Metabolism Unit,
Department of Medicine, University of the Witwatersrand, Johannesburg

1963-1967: Clinical Tutorial Registrar
Department of Medicine, Johannesburg General Hospital and
University of Witwatersrand

1967-1969: Senior Research Fellow in Haematology
Instructor in Medicine
University of Washington
Director, Division of Haematology, Department of Laboratory Medicine,
University Hospital and King County Medical Centre
University of Washington,

University of the Witwatersrand and Johannesburg General Hospital.
1972-2010: Chief Specialist – Groote Schuur Hospital Teachings Group
1995 - 2010: Consultant Physician and Haematologist – Constantiaberg Medi-Clinic

**ACADEMIC APPOINTMENTS**

1972-1994: Foundation Professor of Haematology, University of Cape Town
Chief Specialist and Consultant Haematologist, Groote Schuur Hospital Teaching Group, Cape Town
Director, University of Cape Town Leukaemia Centre
Rotating Chairman, Division of Pathology, University of Cape Town

1995-2010: Emeritus Professor of Haematology
University of Cape Town
Honorary Consultant
Groote Schuur Hospital Teaching Group

1996-2003: Honorary Professor of Haematology
University of Stellenbosch
and
Tygerberg Academic Hospital

2001-2010: Professor of Internal Medicine, College of Medicine,
University of Nebraska Medical Centre

2003-2010: Foundation Professor and Head, Division of Clinical Haematology –
the Department of Internal Medicine
Stellenbosch University and Tygerberg Academic Hospital

2010: Honorary Professor, Division of Haematopathology –
the Department of Pathology
Stellenbosch University and Tygerberg Academic Hospital

2010: Honorary Professor, Department of Internal Medicine

**CONCURRENT APPOINTMENTS**

1995-1997: Director
Haematology Clinic and Bone Marrow Transplant Centre
Wynberg Hospital, Cape Town

1998-2010: Director and Head
Department of Haematology and Bone Marrow Transplant Unit
Constantiaberg Medi-Clinic, Plumstead, Cape Town
incorporating
The Searll Research Laboratory for Cellular and Molecular Biology

**INTERNATIONAL APPOINTMENTS**

1984: The European Society of Haemapheresis

2000: The Scientific Advisory Board for Immunology and Haematology Research
2008: Honorary Consultant: Stem Cell and Immunotherapy Unit, Barbados West Indies “The Peter Jacobs Stem Cell Suite”

AWARDS AND PRIZES INCLUDE

1956-1958: Ernest Oppenheimer Memorial Travelling Scholar
1956-1958: Chalarick Solomon Memorial Scholar
1959: David Lurie Memorial Prize in Surgery
       Medical Graduates Prize in Medicine
1967-1968: Eli Lilly International Fellowship
1968-1969: The University of Washington Research Fellowship
1970: S.L. Sive Memorial Travelling Fellowship
1990: The first 500, The International Biographical Centre Cambridge, England
1991: Andries Blignault Memorial Medal
       Glaxo Research Award
2009: Centenary Medal, Die Suid-Afrikaanse Akademie vir Wetenskapp en Kuns

ACADEMIC HONOURS INCLUDE – FROM 1970

Counsellor, European and African Division Board of the Council

Director, African and Asian Chapter, The European Society for Haemopheresis

Director, Board of Directors for the Americas, African Countries, Asia

District Councillor for Africa 1994-1996 WAA Board of Directors

Fellow, International Biographical Association

Honorary Advisor, International Division, the American Biographical Institute

President, Southern African Society of Haematology

Fellowship, International Research into Science and Technology

Visiting Professor to many prestigious academic institutions in Europe and the United States of America

Chairmanship to major haematologic and research meetings

Invitations to deliver plenary sessions, seminars and lectures at international meetings

INVITED INTERNATIONAL PAPERS, FACULTY LECTURES & SEMINARS

Over 100 original research presentations
29 Organised symposia and congresses (1978-2002)
12 Non-medical lectures (1976-1994)
INTERNATIONAL RESEARCH COLLABORATION

Study of C. parvum immunotherapy in acute leukaemia (Wellcome Research Laboratory)
Epipodophyllotoxin VP16-213 as an anti-cancer agent (Swiss and American Research Groups)
Polycythemia Vera Study Group
SASIB Breast Cancer Study Group
International Acute Aplastic Anemia Study Group
CIBMTR – Center for International Blood and Marrow Transplant Research
NMDP – National Marrow Donor Program
IMWG – International Myeloma Working Group
Autologous Bone Marrow Transplantation Registry
European Group for Blood and Marrow Transplantation Registry
International Study Group for Interferon in Chronic Granulocytic Leukemia
AML Collaborative Group, Oxford
ALL Group, Oxford
Campath Users’ Group, Oxford
World Apheresis Association
The Non-Hodgkin’s Lymphoma Classification Project

EXAMINER

15 Post-doctoral theses
15 Research theses supervised

EDITORIAL BOARDS

Experimental Hematology
Journal of Clinical Apheresis
Medicine International – Overseas Adviser
Immunology and Hematology Research
Bone Marrow Transplantation
Editor-at-large in the field of Haematology for Marcel Dekker
Apheresis Transfusion Science
Hematology – Associate Editor
Clinical Lymphoma
Hematology/Oncology and Stem Cell Therapy

BIBLIOGRAPHY INCLUDES

2 Theses – MD and PhD
3 Medical books
30 Non-medical books and diaries
44 Chapters in books and encyclopaedias
244 Original scientific publications in peer-reviewed journals
109 Major publications from international collaborative study groups reviewed journals
100 Preliminary communications and letters
327 Abstracts in reviewed journals & presentations at scientific meetings
213 Full length reviews and editorials
8 Miscellaneous publications
Presently in press are numerous research publications and abstracts
CURRENT INTERESTS OUTSIDE MEDICINE INCLUDE

Golf, tennis, gym fitness programs, motor mechanics, photography, hiking
