A second and unique immunological problem may arise once the graft has become established. Thus, donor lymphocytes recognize the recipient's antigens as foreign and this gives rise to a variable clinical pattern of graft-versus-host disease, with the burden of the damage being borne by the skin, the gastro-intestinal tract and the liver. This phenomenon will occur in approximately two-thirds of patients with HLA identity and no reactivity in the mixed lymphocyte reaction, suggesting the importance of other less clearly defined histocompatibility antigens. The precise genetic basis for this phenomenon is presently controversial, but its severity is clearly correlated with sex mismatch of the donor and the presence of refractoriness to random donor platelets at the time of transplantation.

Aplastic anaemia without available donor poses a special problem. In the first instance patients with some residual haematopoiesis, selected on ferrokinetic studies and stem cell growth patterns in vitro, may
benefit from treatment with lithium or etiocholanone. The anabolic androgens are unlikely to be of benefit in severe acute aplastic anaemia but, in contrast, some response may be achieved when hypoplasia of lesser degrees is present. However, those forms of treatment need to be critically evaluated against the possibility that immunosuppressive therapy, with or without marrow infusion, may result in remission. Furthermore, if the macrophage is centrally involved in the genesis of graft-versus-host disease, then selective attacks upon those cells with liposomes or platelets loaded with cytotoxic agents may offer a realistic approach to control of this immunological entity, which remains the major limiting factor in the use of marginally mismatched grafts.

The role of bone marrow transplantation in cases of acute leukaemia is undergoing critical review. Initially, the procedure was reserved for patients who had failed to achieve complete remission or who had recurrent disease. The poor results achieved with this approach initiated attempts to reduce the leukaemic body burden of patients before conditioning them for transplantation. While there is a small number of long-term survivors of these programmes, the median survival is not markedly different from that which can be achieved with modern chemotherapy and immunotherapy programmes. Analysis of recent information has identified three distinct periods following transplantation. The first 120 days are characterized by high patient mortality from advanced disease, graft-versus-host disease and associated infection, while recurrent leukaemia is a relatively insignificant problem. In a second period, from 120 days to 2 years, recurrent leukaemia causes additional mortality. Approximately 15% of the original patient group are now in a third period which has extended to 64 years, and in which leukaemia has not recurred. It would therefore be reasonable to conclude that bone marrow transplantation is curative for some patients, even, apparently, in the end-stage of the disease.

Clearly, bone marrow transplantation has an important role to play in the management of the patient with leukaemia, and the next step must be to define the most appropriate way of realizing the potential of this procedure to prolong the quantity and quality of life in patients afflicted with this disease. The fact that long survival is possible, although recurrent leukaemia remains a problem, suggests that effort should now be directed at evaluating bone marrow transplantation in the first complete remission rather than after relapse. One additional modification which must be considered is the storage of bone marrow collected at this time in anticipation of autograft support in the event of subsequent relapse. There are good reasons for serious consideration of this approach. Firstly, treatment will be given at a time when the body burden of tumour cell is low, and the selection of these patients should take into account all laboratory studies designed to recognize minimal residual disease. Secondly, the patient will be in good condition and therefore better able to tolerate the transplantation regimen. Thirdly, and importantly, the leukaemic clone will not have become resistant to therapeutic modalities. It may therefore be concluded that bone marrow transplantation from a monozygotic twin or from an HLA identical and MLC non-reactive sibling is the treatment of choice for patients with severe combined immunodeficiency disease or acute aplastic anaemia. In these situations the prognosis is so poor, and alternative approaches so unsatisfactory that, in the absence of a compatible sibling, there is a clear need for the extension of donor matching to a national scale, or for the development of collaboration with other countries. The question of acute leukaemia poses two problems. The first is the management of patients who have drug-resistant disease, or who have relapsed, and whose prognosis is poor. Since some of these individuals can be salvaged by transplantation, and have long disease-free periods, this approach remains a rational form of management. However, in view of the generally unsatisfactory median survival of the latter group of patients, it may be preferable to use this valuable resource in those who are achieving their first complete remission. Finally, advances in the immunobiology of bone marrow transplantation are such that it should soon extend to lethal genetic disorders of other marrow elements such as homoygous thalassaemia, sickle-cell disease and qualitative defects in white cells.

and
*The Department of Haematology, University College Hospital, London.

THE NURSE — A CENTRAL FIGURE

The well-trained nurse is the central figure in the efficient operation of the Cell Support Unit. This individual is responsible for the safety of those undergoing the procedures, whether they be volunteer donors or patients and has as a prerequisite thorough training and competence in intensive nursing care.

To this basic requirement must be added a minimum of three months in an accredited training centre to become familiar with the operation of the cell separator in order that malfunction of the instrument and complications arising in donor or patient may be recognised immediately and appropriate corrective steps taken. This new breed of professional nurse reflects in part the introduction of sophisticated technology and in part the increasing role played by nurses at the forefront of health care.

THE UNIT

The Cell Support Unit consists of expensive sophisticated machines called blood fraction separators. These may be of different types but the one used at Groote Schuur Hospital (figure 1) is the NCI-IBM 2997 model which uses disposable pre-sterilised plastic tubing and a separation band (figure 2) which is assembled, inserted into the machine and all air flushed out with physiological saline. The machine function, integrity of the tubing, and the alarm systems are tested before the subject is started on the procedure.

Each cell separator is operated by one full-time professional nurse who never leaves her station at any stage during the procedure. The machine can be used for different purposes including white cell collection, known as leucopheresis, platelet harvesting, known as plateletapheresis, plasma exchange or plasmapheresis, and red cell exchange. The different techniques are collectively known as apheresis.

The Cell Support Unit is ideally an integral part of the Department of Haematology, where it fulfils the function of providing white cells and platelets for the leukaemia and transplantation programme, collections of haematopoietic stem cells for bone marrow grafting, and a wide range of emergency procedures not only for haematology patients but for those in the remainder of the hospital.
Fig. 1 Blood fraction separator.

These include replacement of abnormal red cells in patients with sickle cell disease during crisis, plasma exchange for life-threatening antibody-mediated diseases such as myasthenia gravis and Goodpasture syndrome, or removal of immune complexes in rapidly progressive glomerulonephritis.

After the introduction and development of separators in university departments, they are being slowly introduced into blood transfusion services for more efficient collection of platelets; here as well, the professional nurse should be in control of the procedure.

APHERESIS TECHNIQUES

The technique is relatively simple. Intravenous cannulae are introduced into the brachial vein in the forearm. Blood enters the specially designed band in the machine where it is separated into components based on differences in their specific gravities by means of circumferential centrifugation. Any of the components can then be selectively removed by means of roller pumps and the remaining blood returned to donor or patient by intravenous infusion into the opposite arm. In exchange procedures, large volumes of red cells or plasma can be separated and discarded and blood volume and composition retained by appropriate infusion into the return line.

Many safety devices are incorporated into the equipment to minimise hazards to the subject arising from instrument dysfunction. No technology, however, can safely be left to operate without continuous supervision by a highly trained and thoroughly experienced nursing sister.

Fig. 2 Separation band.
Leucopheresis

Leucopheresis is the collection of white cells and with appropriate adjustment in technique this may be largely lymphocytes or, more usually, predominantly granulocytes.

Lymphocyte depletion may be used as a form of immunosuppressive therapy and is being investigated in the treatment of autoimmune and immunologically-mediated diseases. Granulocyte transfusion plays a vital role in patients with neutropenia, as seen in severe acute aplastic anaemia, following bone marrow transplantation, and after cytotoxic chemotherapy in leukaemic patients.

In each of these situations the peripheral blood granulocyte count should be less than 0.5 × 10⁹/l, the patient to have a sustained fever greater than 38.5°C, and having failed to respond to adequate courses of appropriate intravenous antibiotic therapy for 48 hours. Once granulocyte transfusions are commenced, they are continued until the count is greater than 0.5 × 10⁹/l, the infection controlled, and the temperature normal for 48 hours.

The procedure time for white cell collection is approximately two hours and depends upon the donor's white cell count. It is useful to administer 48 mg of methylprednisolone six to eight hours before commencing the collection to raise the white cell count. Under these circumstances, a 250 ml volume will contain between 2 and 4 × 10⁹ leukocytes which are morphologically and functionally normal.

During the procedure a concentrated citrate solution is infused as an anticoagulant in the ratio of 13:1 to the whole blood to ensure that clotting does not occur once blood is in the machine. A sedimenting agent in the form of 500 ml of hydroxyethyl starch is also added to the blood in the separator to improve granulocyte separation. The donors are always ABO and Rh group compatible with the recipients.

Plateletpheresis

Plateletpheresis is undertaken for bleeding when the platelet count is below 20 × 10⁹/l, particularly following chemotherapy for cancer. It is important that donors do not take any tablets containing aspirin or other antiplatelet drugs prior to donation since, although the numbers may be normal, their function may be suboptimal.

A similar situation is found in patients with myeloproliferative syndrome and when such individuals require surgery additional platelets may be needed despite normal numbers.

The procedure time is ninety minutes to collect 250 ml of plasma containing between 3 and 5 × 10¹¹ platelets. It is useful, following platelet infusion, to monitor the rise in platelet count which should be approximately 50 × 10⁹/l/m² for a single such pack and indications for further infusions can be gauged by documenting platelet survival. The latter measurement is simply carried out by twice daily platelet counts.

Plasmapheresis

Plasmapheresis refers to the separation and removal of plasma and its replacement with an appropriate fluid which may be either fresh, frozen plasma, fractionated serum, or plasmalyte B and albumin. A practical exchange is approximately four litres but will vary with the individual's plasma volume.

Flow rates between 30 and 50 ml/minute are achieved using acid citrate dextrose as an anticoagulant at a ratio of approximately 1:11 with the blood. Specimens are collected before and after the procedure to monitor the white cell count differential, platelet count, biochemical profile, and changes in clotting factor. Serum samples are stored to measure the level of the product removed, such as cholesterol, antibodies or immunoglobulin.

A wide variety of indications exist for plasma exchange. Firstly, the hyperviscosity syndromes, as in Waldenström's macroglobulinaemia, in multiple myeloma, and in cryoglobulinaemia where abnormal proteins are precipitated in the cold.

Secondly are antibody-related diseases where the procedure is carried out in conjunction with immunosuppressive therapy using prednisone, cyclophosphamide, or azathioprine and aimed at removing the antibody giving rise to the disease. Examples would include Goodpasture syndrome where renal failure and haemoptysis characterise the clinical syndrome, myasthenia gravis where weakness and paralysis are prominent clinical findings, and less frequently in haemophilia associated with antibodies to factor VIII, in diabetes with anti-insulin antibodies, in rheus sensitisation where anti-D causes haemolytic disease of the newborn, and in both immune thrombocytopenia and haemolytic anaemia.

Similarly, immune complexes formed between foreign antigen and antibody may produce life-threatening symptoms in systemic lupus erythematosus and fulminating glomerulonephritis.

Thirdly there is a group of miscellaneous conditions where plasma exchange may be used to remove poisons or drugs taken in overdose, removal of biologically active substances in hypercholesterolaemia, in liver disease, porphyria, thyrotoxic crisis, and even to remove blood group antibodies where incompatibility exists between donor and recipient prior to bone marrow transplantation.

Other indications

Continuous-flow red cell exchange is an efficient and practical way of removing abnormal haemoglobin (HbS) in patients with sickle cell anaemia and replacing this with normal adult haemoglobin (HbA). This may be done prophylactically where patients require surgery or therapeutically when patients present with sickle cell crises.

In addition, therapeutic leucopheresis may be done where very high white cell counts may interfere with blood flow, as in acute and chronic leukaemia, while platelets may be removed by means of therapeutic plateletpheresis in individuals at risk from thrombotic episodes due to thrombocythaemia.

JUNE 1984
ROLE OF THE NURSE

In all of these sophisticated and relatively complex techniques, the role played by the professional nurse cannot be overstated and falls into two broad groups. Firstly, the thorough competence with all aspects of machine operation including the recognition of hazards and complications associated with the procedures. Secondly, the important role of donor recruitment.

Machine operation and patient observation

Hazards may be associated with the machine. Thus, air embolism may result from incorrect priming, extracorporeal clamping may reflect insufficient anticoagulant, while haemolysis may be due to a failure to recognise abnormal pressure changes occurring in the circuit.

Anticoagulants, particularly the acid citrate dextrose solution used in the procedures, may lead to side effects including citrate toxicity in which reduction of ionized calcium, due to binding, produces symptoms. The latter may be slight with numbness and tingling in the lips and around the mouth or the extremities, while priapism may be embarrassing. Failure to immediately recognise and correct citrate overdosage may lead to more severe side effects such as nausea and vomiting, subternal chest pain with changes in the electrocardiograph and even cardiac arrest. While correction is easy and involves reduction in flow rate, failure to obtain immediate reversal may require the intravenous administration of 10 ml of 10% calcium gluconate over the course of 10 minutes.

The sedimenting agent, hydroxyethyl starch, may result in urticaria, skin irritation with no visible changes which may last for many days, or headache due to plasma expansion. The replacement fluid, particularly when this is fresh, frozen plasma, may cause allergic reactions, fever, chills, urticaria, and hypotension.

Finally, the individual undergoing the procedure may present difficulties because of poor venous access, or anxiety, usually during the first procedure. This can be overcome by a confident operator, reassurance to the patient, and careful step-by-step explanation.

Syncope or fainting may occur. Haematoma may occur at the site of intravenous cannulation, particularly in the hands of inexperienced or poor operators and, similarly, blood may infiltrate the return site.

In each of these situations it is imperative that the professional nurse be able to recognise and separate anxiety from changes in plasma calcium level due to citrate intoxication or dilutional effects. Only experience will help the nurse to recognise more severe reactions that may occur during the course of these procedures and which may correlate with the underlying disease.

It is completely unacceptable to have a sister nominally present or in charge of such a unit. The only arrangement appropriate for an academic institution is to have a senior member of the nursing faculty positively and directly in charge of all aspects of the procedure and responsible for the supervision and in-service training of her more junior staff.

Donor recruitment

Neither should the question of donor recruitment, which lies within the ambit of the professional nurse, be underestimated. While in many situations families of patients come forward as volunteer donors, the demands of a busy unit require considerable support from the community and this can be elicited most efficiently by word of mouth in which one donor brings friends. To be efficient, such a system implies a happy unit competently staffed and with which the donor panel clearly identifies. Additional sources of donor recruitment are the media including the press, radio, television and illustrated short talks to large firms and factories.

Donor selection itself is important since each individual establishes a personal relationship with the nursing staff of the Cell Support Unit. It is the moral responsibility of the staff to fully explain the procedure to all donors, including the use of drugs, and then to obtain fully informed consent.

Initial screening includes blood and rhesus grouping, screening for hepatitis, malaria, and venereal disease, and excluding underlying serious illness. Donor age is not critical, lying anywhere between 18 and 55 years. A suitably large panel, meticulous control of rotation and a philosophy never to store products but to collect components only as the specific need arises will mean that donors are used about once every four months for white cell collections but monthly for platelet donation. Following bone marrow grafting, the donor may undergo apheresis daily for five days to collect haematopoietic stem cells.

CONCLUSION

It is concluded that the professional nurse plays a vital role in the Cell Support Unit. The services range from collection of white cells and platelets through continuous-flow red cell, white cell, and platelet exchange to plasmapheresis. In each of the procedures sophisticated equipment with numerous fail-safe devices is used.

Nevertheless, it remains the cardinal principle that safety rests solely on the shoulders of the professional nurse in charge of the procedure. Only thorough familiarity with every aspect of the instrument and the procedure is compatible with patient safety and there is no excuse for leaving an instrument unattended at any stage of its operation. These prerequisites for donor and patient safety emphasise the everexpanding role of the professional nurse as an equal partner with the doctor in delivery of modern health care services.

ACKNOWLEDGEMENTS

The cell support system was established at Groote Schuur Hospital by the Department of Hospital Services with the support of the Teaching Hospitals Central Advisory Committee. We record our appreciation for encouragement and strong continuous support from both bodies and we acknowledge with pleasure the role played by dedicated and outstanding nursing staff. We thank the Medical Superintendent of Groote Schuur Hospital for permission to publish.
Review Article

Trephine biopsy of the bone marrow

A. R. BIRD, P. JACOBS

Techniques of trephine biopsy

Many methods of trephining the bone marrow have been described. The Vim-Silverman needle was the first device to be used regularly. This was followed by the introduction of the Westerman-Jensen needle, a modification of the Vim-Silverman needle, which is still used in many centres. The technique is excellently illustrated by Ellis et al. More recently, the Jamshidi needle was introduced and is now probably the most widely used device. Other coring techniques using the Border trephine, Gidlund's instrument, the Radner needle, the Gardner and the Sacker-Nordin needle have been described. Larger specimens may be obtained with Burkhardt and Notter-Labhart needles or by open surgical biopsy. These procedures are, however, time-consuming and therefore unsuitable if serial biopsies are required.

Our preference is to use the Jamshidi needle. The technique of coring is outlined by Jamshidi and Swaim and is well known to most haematologists. We have also had extensive experience with the Westerman-Jensen needle but now prefer the Jamshidi needle for the following reasons: (a) there is little disturbance in the architecture of the core obtained by the Jamshidi needle; (b) it requires less maintenance than the Westerman-Jensen needle since sharpening and replacement of cutting blades are avoided; (c) larger cores are obtained; and (d) it is our experience that patients tolerate trephining with the Jamshidi needle better than with the Westerman-Jensen needle.

Certain points, however, should be noted. Firstly, the cutting tip of the Jamshidi needle should be sharpened regularly and the tip should be kept acutely angled to reduce the incidence of 'lost cores'. Secondly, we have experienced difficulty in obtaining specimens from very osteoporotic patients using large-gauge Jamshidi needles. In these circumstances, the Westerman-Jensen needle is often preferable. Thirdly, the anatomy of the pelvis must obviously be considered when performing a trephine biopsy. The posterior iliac crest (the most convenient and probably the safest site for marrow biopsy) is usually easily palpable with the patient lying prone. The sacro-iliac joint lies perpendicularly below the posterior crest. The wing of the ilium slopes laterally and it is in this direction that the biopsy needle should be aimed.

We routinely perform marrow aspiration just prior to biopsy. We do not aspirate with the same needle but prefer to use the Klein or similar needle. As long as the needle is directed away from the site of the proposed biopsy, there is no distortion on the subsequent trephine sections.

It is well known that aspiration of marrow can cause sharp pain. Trephining of the marrow, with few exceptions, seems to cause less discomfort. Unallayed anxiety, inadequate local anaesthesia and poor technique are factors which may make the procedure unacceptable. Physicians inexperienced in the technique of trephine biopsy usually provide inadequate specimens and therefore the procedure has to be repeated. In our hospital, therefore, all patients requiring bone marrow examination are referred to the Haematology Department. The marrow aspirates and trephine biopsies are then performed by the residents.
Preparation of the specimen for examination

Fixation

Once an adequate core (> 2.0 cm) has been obtained, it is fixed for a minimum of 4 hours in Zenker’s fixative, with constant agitation. It is washed overnight to remove the dextranate and the following morning is placed in Formal/Decal solution for 4 hours to decalciﬁy the bone using a roller mixed to ensure even exposure of the core to solution. After washing for 15 minutes, it is then processed and embedded in Paraplast according to standard methods.

Poor-quality sections are often the result of one or more of three problems involving fixation: (i) inadequate time allowed for proper ﬁxation — we have run a number of trials to assess optimum ﬁxation time, and 4 hours is the absolute minimum using Zenker’s ﬁxative; (ii) using a Zenker’s stock solution older than 2 weeks; (iii) ﬁxative prepared too far in advance of the biopsy procedure; it should be prepared just prior to biopsy.

Preparation of sections

The preparation of good sections ensures accurate identiﬁcation of the haematopoietic cells. Ideally, serial sections should be examined. We recommend that at least three sections taken at different levels should be studied. If properly decalciﬁed and ﬁxed, sections can be cut at 4 µm. By using a methacrylate embedding process, sections as thin as 1 µm can be prepared.17 This allows for very accurate identiﬁcation of haematopoietic cells. The major disadvantage of this technique is the time required for preparation of the blocks, usually a minimum of 4 days.

Staining procedures

At least three sections from each core biopsy specimen should be stained with haematoxylin and eosin, and one section for reticulin. Romanovsky stains have been recommended2 but in our experience add little diagnostic information. Iron stores are best evaluated on the aspirate smears using Perl’s reaction, but if smears are not obtainable, sections may also be stained for assessment of iron stores. Loss of iron from the section, however, may occur during ﬁxation and we do not recommend core biopsies for the assessment of iron stores. Special stains for fungi or tubercle bacilli may be indicated in the presence of granulomas, although these stains, too, may be affected during the ﬁxation processes.

Indications for trephine biopsy

In the following section we outline what we consider to be absolute indications. In these situations, failure to do a trephine biopsy may result in a missed or delayed diagnosis.

Failure to aspirate marrow

Three failed aspirations from different puncture sites should be regarded as a ‘dry tap’. In these cases, material for cytological assessment may still be obtained by performing a touch preparation with the trephine biopsy.

Myeloproliferative syndrome (Fig. 1)

This is probably the commonest condition leading to failed aspiration. The appearance of the marrow is pathognomonic,14 although in the early cellular phase of polycythaemia vera the diagnosis may not be obvious. A stain for reticulin is mandatory, however, as even in polycythaemia vera the typical pattern of increased marrow reticulin is seen.

Metastatic neoplasia (Fig. 2)

‘Dry taps’ in patients with cancer metastatic to the marrow are not infrequent. A review of 74 marrow aspirates and trephine specimens obtained over a 2-year period (January 1973 – December 1974) from patients with non-haematological malignant disease showed the presence of metastatic tumour in 18 (24%). In 7 of these tumour was found in both the aspirate and the trephine specimen, while 5 were ‘dry taps’. In only 1, a child with metastatic retinoblastoma, was the aspirate positive in the face of a negative trephine specimen (A. R. Bird and P. Jacobs — unpublished observations).

Fig. 1. Silver stain showing dense parallel strands of reticulin in a patient who presented with pancytopenia and splenic enlargement. Myelofibrosis was diagnosed.

Fig. 2. Metastatic carcinoma with intense desmoplastic reaction and blood vessel invasion in a patient with fever and weight loss who was eventually found to have a 8.5 cm primary carcinoma of the proximal colon.

In a study by Savage et al.4 utilizing a Jamshidi needle for biopsy and aspiration, a correlation between biopsy and aspiration results was shown in 75% of cases positive for metastatic cancer. In only 1 instance was the aspirate positive and the trephine biopsy negative. The remaining discrepancies were all due to biopsy-positive, aspirate-negative specimens. Other studies also attest to the efficacy of the trephine biopsy in increasing the yield of positive specimens.11,38 Performing bilateral tre
phine biopsies further increases the yield of positive specimens.26
Garrett et al.,21 however, reviewed 291 patients with non-
haematological malignancies and found 39 positive for metastatic
tumour. The biopsy was positive in 3 patients with a negative
aspirate, and in 3 others the aspirate was positive with a negative
biopsy. They attributed their high rate of tumour detection in
the aspirate to a thorough initial screening by technologists; this
process, however, sometimes occupied several hours in scanning
many smears.

The yield of positive marrow specimens may be increased if
biopsies are performed at sites of local tenderness or in a
suspicuous area as depicted on the radiograph or bone scan.
However, needle biopsies can be performed safely only from the
anterior or posterior iliac crests, or occasionally from the verte-
bral spines. Negative radiographic studies or bone scans do not
mitigate against the performance of a marrow biopsy, as positive
marrow specimens may be obtained in the case of a negative
skeletal survey or scan.22

Concurrent aspiration and trephine biopsy from the posterior
iliac crest, bilaterally if possible and aided by radiographic stu-
dies and a bone scan, should therefore ensure the best possible
yield of positive specimens from the marrow in the diagnosis of
metastatic tumours.

Acute leukaemia
Although aspirate smears are indicated for the cytological
diagnosis of acute leukaemia, the marked increase in reticulin
sometimes seen in both acute lymphoblastic and acute myelo-
blastic variants may lead to a 'dry tap'. A recent study has shown
that the presence of this reticulin does not appear to be related to
the prognosis,23 although there has been a report to the con-
trary.24 Induction of remission in patients with increased mar-
row reticulin results in a distinct reduction in the reticulin.
Recurrence of increased reticulin may herald the onset of a
relapse of the leukaemia.25,26

In the follow-up of patients with acute leukaemia, and particu-
larly in the post-induction period of hypoplasia, marrow biopsy
allows for a more comprehensive assessment of marrow reserve
than the scanty particles obtained on aspiration alone.

Leukaemic reticulo-endotheliosis
This rare but well-described condition mainly affects adults,
and patients with pancytopenia and splenomegaly. The diag-
nosis is usually made from the peripheral blood smear where the
diagnostic 'hairy' cells are seen.27 These cells show a characteris-
tic positive acid phosphatase reaction which is resistant to tar-
rate pretreatment.28 Attempted marrow aspiration is invariably
non-productive and a marrow biopsy is required. Sections show
the characteristic infiltrate with a dense reticulin pattern.

Staging and follow-up of patients with
lymphoma
Hodgkin's disease (HD) (Fig. 3)

Marrow specimens positive for HD show disruption of the
normal marrow architecture by fibrosis, necrosis, and a cellular
infiltrate of lymphocytes, plasma cells, eosinophils and histio-
cyes, even in the absence of Reed-Sternberg cells. The pattern
of infiltration may be diffuse or focal.27 Marrow aspiration alone
is of limited value in the detection of marrow involvement by
HD. This is not unexpected, in view of the often focal nature of
the infiltrate and the high incidence of accompanying fibrosis. A
review of 53 trephine biopsies and aspirate smears from patients
with HD during a 2-year period from January 1973 to December
1974 revealed 19 positive specimens. Of these 4 were 'dry taps',
while the remainder were all biopsy-positive and aspirate-
negative (authors' unpublished data).

Positive bone marrow biopsy specimens from untreated
patients have not been reported in patients initially clinically
classified as stage I and II A. However, up to 25% of patients
thought to have stage III disease may be reclassified as stage IV
as a result of a positive core biopsy.29,30 Occasionally, marrow
infiltration may be the only evidence of stage IV disease. Bilat-
eral biopsies have been shown to increase the yield of positive
specimens.31

The diagnosis of HD on the basis of marrow infiltration alone
in patients without peripheral lymphadenopathy presents many
difficulties. Neiman et al.26 described a group of 13 patients with
lymphocyte-depleted HD. The patients had fever, pancytopenia,
and abnormal liver function, but there was no striking peripheral
lymphadenopathy. The outcome was consistently fatal, usually
within a short period. In 5 patients the marrow sections were
diagnostic, and in 3 of these were the sole criterion for the
diagnosis.

The occurrence of granulomatous lesions in tissues involved
by HD is well recognized.31 The significance of isolated non-
caseating granulomas in otherwise uninvolved tissues, however,
is less clear. Kadin et al.32 reviewed tissue obtained from 185
patients with HD prior to treatment and noted isolated granulo-
mas in the liver and spleen. Further extensive sectioning of these
tissues failed in many instances to reveal a diagnostic infiltrate of
HD. In some, however, the granulomas were intimately associa-
ted with an HD infiltrate. It was concluded that the discovery of
isolated epithelioid cell granulomas in HD should not influence
the staging criteria.

Another phenomenon occasionally encountered is the pre-
sence of extensive lymphoid aggregates in otherwise normal
biopsy specimens from patients with HD. The significance of
this remains uncertain.

Non-Hodgkin's lymphoma

Proper histopathological classification and clinicopathological
staging are now regularly employed in the non-Hodgkin's lym-
phomas: (i) to define patterns of disease better; (ii) to correlate
these patterns with the clinical course and response to treatment;
and (iii) for selection of the appropriate therapy.

Although aspiration smears or sections of aspirated particles
have been used in the detection of marrow involvement by
lymphoma, several reviews testify to the trephine biopsy as the
best method for detection of marrow lymphoma. By performing bilateral posterior iliac crest biopsies the yield of positive specimens is increased by 10–20%. Marrow biopsy often influences the staging of patients with non-Hodgkin’s lymphoma. It has been shown that 50–65% of patients thought to be in stage I–II may be reclassified as stage IV as a result of a marrow biopsy. A normal full blood count does not exclude infiltration of the marrow.

One of the major problems in the diagnosis of marrow lymphoma is the distinction between benign lymphoid aggregates and lymphoma. Studies of the prevalence of lymphoid follicles in marrow biopsies and clot sections obtained in vitro show a wide variation. Although most biopsy studies (including our unpublished data) report an incidence of 1–9%, much higher figures, up to 47%, are reported when clot sections are used. These benign lymphoid nodules are commoner in older patients and in many cases constitute a normal finding without any known clinical significance. Yet infrequently, however, we have found it difficult to decide whether the marrow was involved by a lymphoproliferative disorder, both in patients with known lymphoma and in those without evidence of lymphoma elsewhere. The following features have been described as suggestive of early lymphomatous infiltration: (i) size of aggregates; (ii) aggregate covering more than 25% of a 40 high-power field is suspect; (iii) cytological atypicality; (iv) multiplicity of aggregates; (v) infiltration into surrounding normal marrow; and (vi) paratrabecular location.

These criteria must be viewed critically, however, as we have seen several marrow specimens with many of the above features in patients in whom subsequent follow-up revealed no evidence of lymphoma. Moreover, nodular lymphoid hyperplasia of the marrow is a well-described entity. Recent reports of this syndrome have emphasized that caution must be exercised before a definitive diagnosis of lymphoma is made. In a study by Ryvlin et al., 10 patients with lymphoid hyperplasia of the marrow were noted. In 5 of these, follow-up was possible. During a 2–4-year period, none of these patients developed signs or symptoms suggestive of a lymphoproliferative disorder. Careful follow-up of patients in whom the isolated finding of lymphoid hyperplasia of the marrow is made is therefore preferable to treating them as cases of early lymphoma.

Diagnosis of the hypoplastic anaemias

Marrow trephine biopsy, preferably from more than one site, is an essential procedure in the diagnosis of hypoplasia. Although this is important diagnostically, no correlation between estimations of cellularity and prognosis has been shown.

Granulomatous disorders (Figs 4 and 5)

Granulomas represent a host inflammatory response which may be the result of a wide variety of stimuli. In an extensive study by Pease of 150 patients with granulomatous lesions in sections of aspirated marrow particles, the commonest underlying disorders were tuberculosis, histoplasmosis, infectious mononucleosis, sarcoidosis, brucellosis, and Hodgkin’s and non-Hodgkin’s lymphoma. Marrow granulomas were also found in a wide variety of other disorders, some of which are not ordinarily associated with granulomatous change. Okun et al. have described the presence of marrow granulomas in a patient with Q fever. Unless a specific organism can be identified by special stains or bacteriological culture, there are no diagnostic features of the granulomatous disorder; although prominent caseous necrosis favours the diagnosis of tuberculosis.

Granulomas may very occasionally be seen in aspirate smears, but the yield is considerably increased by sectioning particles of material. Although no adequately controlled studies are available, biopsy will presumably further increase the yield owing to its ability to reach more deep-seated tissue.

Although marrow aspiration and biopsy are complementary to other investigations, marrow examination and culture may sometimes succeed in establishing the diagnosis of a granulomatous disorder when other tests have failed to do so.

Chronic lymphocytic leukaemia (CLL)

Bone marrow histological patterns and their relationship to prognosis in chronic lymphocytic leukaemia have been evaluated by some authors. Gray et al. studied 115 patients and showed that those with diffuse marrow infiltration had a poorer prognosis than those presenting with a nodular or mixed (nodular and diffuse) pattern. Rozman et al. studied 63 patients with CLL and described 4 different histological patterns: (i) interstitial (lymphoid infiltration without displacement of fat cells); (ii) nodular (abnormal lymphoid nodules without interstitial infiltration); (iii) mixed (combination of the first two patterns); and (iv) diffuse (replacement of both haematopoietic and fat cells by lymphoid infiltration). Statistical analysis of actuarial curves showed a significant difference of survival probability according to the marrow infiltration patterns. In patients with interstitial or nodular patterns life expectancy is significantly less than in those with mixed or diffuse patterns. They also noted a significant degree of correlation between bone marrow infiltration patterns and the various methods of clinical staging.
Miscellaneous

Bone disease. Bone trabeculae can easily be studied in marrow trephine sections and thus provide a simple method for the diagnosis of bone disease, such as may accompany chronic renal failure, intestinal malabsorption, and other disorders.

Lead poisoning. Bone is a primary site of lead storage and core biopsies may therefore be used to estimate stored lead levels. A recent study of skeletal lead concentrations in Americans has documented the presence of plumbism in polluted environments and underlines the value of this investigation in such epidemiological studies.

Contraindications to marrow trephine biopsy

These are all associated with a tendency to increased bleeding. Thrombocytopenic bleeding (Fig. 6) has never been a problem in our experience, provided adequate compression has been applied to the biopsy site on completion of the procedure. In the face of disseminated intravascular coagulation, haemorrhage following a trephine can be catastrophic, and marrow biopsy is therefore contraindicated in the presence of this disorder. In patients with hereditary coagulation factor deficiencies, marrow biopsy should be performed only with adequate cover by the approximate component. For patients on anticoagulant therapy, cessation of therapy is indicated until adequate haemostatic status has been regained.

Fig. 6. Megakaryocytic hyperplasia in an otherwise normal bone marrow specimen from a patient who presented with purpuric bleeding and a platelet count of 5 x 10^9/l. Auto-immune thrombocytopenic purpura was diagnosed.

Complications

The problem of post-biopsy bleeding has been discussed above. The only other complication we have experienced is infection. Our incidence of infection is less than 1%. Infection has occurred only in immunocompromised patients on cytotoxic drugs. We therefore use a strict aseptic technique and wear surgical masks and gloves when biopsying these patients.

Diagnostic pitfalls

Besides some of the diagnostic problems that have already been mentioned, we should like to emphasize a few other problems of interpretation occasionally encountered.

Megaloblastic anaemia

The cellular and apparently blastic appearance of the marrow tissue on sections stained with haematoxylin and eosin may lead to an erroneous diagnosis of leukaemia or lymphoma. The marrow aspirate should obviously lead to the correct diagnosis, but the trephine biopsy may still be misinterpreted by the inexperienced, especially if examined in isolation.

Angio-immunoblastic lymphadenopathy

This unusual hyperimmune disorder of B-lymphocyte origin may involve the marrow. The characteristic morphological features of immunoblastic and plasma cell infiltrates, amorphous acidophilic interstitial material and vascular proliferation may closely resemble HD. The diagnosis is usually made on clinical grounds in conjunction with a lymph node biopsy.

Eosinophilic fibrohistiocytic lesions

These lesions were described by Rywin et al. in 1972. They consist of spindle cells, numerous eosinophils, some plasma cells and occasional mast cells. In Rywin et al.'s series, some of the patients were anaemic and all of them were taking numerous medications. Withdrawal of the drugs led to an improvement in the anaemia and disappearance of the eosinophilic lesions. We have noted a similar lesion in a patient with urticaria pigmentosa.

Post-induction therapy for leukaemia

A trephine biopsy is indicated in the follow-up of patients with acute leukaemia after intensive cytotoxic therapy for the induction of a remission. This applies particularly to acute myeloblastic leukaemia. The trephine biopsy ensures good assessment of: (i) the extent of residual disease, if present; and (ii) the extent of haematopoietic reserve and early signs of regeneration of normal haematopoietic tissue.

Occasionally, diagnostic problems may be encountered in the assessment of biopsy specimens when clusters of blasts are present — is this a sign of residual disease or of regeneration? It is our experience that these sections should be interpreted with caution. Very often these blasts are part of a regenerative process and do not represent residual leukaemia.

We have also noted some unusual regenerative phenomena in classic myeloid leukaemias following induction therapy, e.g. megakaryocytic hyperplasia.

Comment

Needle biopsy of the bone marrow has for some time been the accepted method for obtaining a specimen of bone marrow for examination when aspiration has resulted in a "dry tap". It is only in the last decade, however, that it has become clear that biopsy is superior to aspiration in the detection of Hodgkin's and non-Hodgkin's lymphomas and metastatic malignant tumours. Some authors have advocated the use of sections of aspirated material and have demonstrated their superiority to aspirate smears in the detection of granulomas, metastatic tumours and lymphomas. A comparative study by Dee et al. indicated a distinct superiority of the biopsy specimen when this was compared with the aspirate and sections of aspirated particles in the diagnosis of HD. In non-Hodgkin's lymphomas, biopsy was also the most sensitive diagnostic procedure, particularly with follicular lymphomas, although there were several positive clot sections in the presence of negative biopsies. On the basis of a study performed on 30 cadavers, Rywin concluded that aspirated marrow par-
ticles which were concentrated before sectioning yielded larger areas of marrow for examination than needle biopsy sections. This may be misleading, as 10 ml of marrow was aspirated in each case and this is not always possible in vivo. It is nevertheless clear that the various techniques are complementary. In practice, however, we have found it simpler to obtain and process biopsy specimens as described earlier. Moreover, in contrast to Ryvlin, we are able to obtain equally as good cytological detail in our trephine sections as in the particle sections. It is rare to obtain inadequate specimens, whereas with aspiration inadequate sections for examination may be obtained in as many as 10% of cases. 7

We should like to re-emphasize the importance of proper fixation and preparation of sections. We have frequently received slides which are difficult to interpret owing to poor fixation and thick sections. To obtain good trephine sections is an art which requires some practice and it is therefore preferable to refer patients requiring marrow trephines to centres where biopsies are regularly performed and the specimens examined, rather than submit an inadequate specimen for opinion. This often leads to the patient having to undergo the procedure a second time.

Bone marrow sections should be interpreted by a pathologist or hematologist in conjunction with a thorough examination of the smear preparations. The practice of examining marrow sections in isolation is not recommended and may lead to misdiagnosis.

In summary, therefore, it is our experience that bone marrow biopsy sections with concurrent marrow aspiration smears are complementary, and together allow for a thorough assessment of the bone marrow. The morbidity is minimal and the procedure can be performed on outpatients. The few contraindications to biopsy are those associated with a severe bleeding tendency as a result of depletion of coagulation factors.

CHOICE OF NEEDLE FOR BONE MARROW TREPHINE BIPSY

PEETER JACOBS
Professor and Head, The University of Cape Town Leukaemia Centre and the Department of Haematology, Groote Schuur Hospital, Observatory, Cape, South Africa
(Received 12 February, 1994)

Optimal examination of the bone marrow combines cytology on aspirated material with histopathology, as reflected in the trephine biopsy, where architectural relationships are preserved, with this procedure most usually being carried out using the Westernman-Jensen or Jamshidi needles. Experience with these two has been compared to the recently introduced Islam system and in 50 consecutive studies superior results were obtained with the latter and in no instance was a biopsy of less than 3 cm, devoid of crush artifact, obtained. It is concluded that this latest instrument has advantages over its predecessors and is recommended for routine use.

KEY WORDS: Trephine marrow biopsy, Islam system, Technical aspects.

INTRODUCTION

Simple aspiration, introduced in 1929, is adequate for diagnostic purposes where cells are easily obtained and distinctive cytology exists. In selected cases of nutritional deficiency and the acute or chronic leukaemias, this may be all that is necessary, particularly as it provides a convenient way of obtaining material for immunophenotyping and cytogentic studies.

Conversely, when the marrow cavity is hypercellular and increased reticulin or collagenous fibrosis is present a dry tap results so that trephine biopsy becomes invaluable. Furthermore, there are specific instances where no realistic alternative exists to the latter procedure, exemplified by the need to quantitatively evaluate haematopoiesis in aplastic anaemia, document regeneration following cytotoxic chemotherapy, where questions arise about infiltrative conditions such as the malignant lymphomas and myeloma or in the search for granulomata, as might be found in tuberculosis.

Historically, the first approaches were surgical, but these became outmoded with the introduction of the Vim-Silverman needle and the popular Westernman-Jensen modification. An entirely new method was the Jamshidi tapered device, which has dominated recent practice, although other options exist, including the Gidlund's.
PATIENTS AND TECHNIQUES

Fifty consecutive individuals scheduled for routine diagnostic bone marrow examination, having a wide range of underlying conditions and indications, had the experimental nature of multiple biopsies explained to them and gave informed consent.

Following infiltration of the skin and the tissues overlying the posterior superior iliac spine with local anaesthetic, aspirations were compared using the Turkel and Islam needles. For practical purposes, there was no difference in the quality of material obtained, and in the three patients where the procedure failed it did so using both approaches, and the reason was subsequently shown to be the presence of dense myelofibrosis.

Since it has been suggested that aspiration produces an artifact in subsequent trephine biopsies, this point was examined and our own experience accords with the opposite viewpoint that a one-step combination technique works well and the use of two sites on the iliac crest is therefore not considered necessary.

The technique for biopsy was standardised, and despite a small skin incision having been advocated by some, this was shown to be unnecessary from the first report and in our three decades of experience we would endorse the original opinion. Similarly, whilst the left lateral position was initially advocated and is, indeed, entirely practical, it is easier if the patient is relaxed and prone in a warm procedure area. Interestingly, background music and relaxation exercises are both judged to be significant adjunctive manoeuvres, but their individual benefits have not been objectively documented.

Once the tip of the obturator was firmly anchored in the outer cortex, the needle was advanced, with gentle pressure, on a plane carefully directed towards the ipsilateral anterior superior iliac spine. On penetrating the marrow cavity, generally easily perceptible with even minimum experience, the obturator was withdrawn and a minimum of 3 cm core obtained; anything less than this was designated a failed procedure.

When using the Westerman-Jensen needle, the cutting blades were advanced, with steady pressure, until the desired depth had been reached. At this point, the outer case was rotated until the biopsy was free; this motion was well tolerated if gently carried out and was associated with loss of the least number of cores.

In the case of the Jamshidi needle, it was advanced with a rotating and pronating action through approximately 45 degrees until the required depth was achieved. It was then rotated two or three times in a complete circle in both directions and gradually withdrawn. The modification, said to improve the technique, was not examined in this study. The core was gently delivered through the back of the needle, paying particular attention to the introduction of a correctly sized, solid metal probe supplied for this purpose.

An essentially identical technique was used with the Islam system. Although it has been suggested that the rotation employed for the Jamshidi needle is unnecessary, this causes no discomfort to the patient, favours optimum penetration, achieves a smooth cut to the edges of the biopsy and universal retention of the core.
RESULTS

The Westerman-Jensen Needle

Based on our previous experience\textsuperscript{2}, we have largely overcome technical failure, although in this series of 50 patients adequate material was not obtained in four individuals. In two, this was because the bones were virtually impenetrable due to osteosclerosis, and in two, unacceptably small traumatised cores were obtained in the face of dense myelofibrosis. Despite care in carrying out the procedure, the cutting blades were widely splayed in all four of these patients and in two were effectively destroyed.

Maintenance of this instrument is relatively time-consuming and requires that the cutting surfaces be gently rubbed with the finest possible water paper to ensure a sharp edge after every two or three procedures. Any distortion of the delicate blades renders biopsies difficult and leads to an immediate increase in crush artifact. However, with meticulous attention to detail and as experience accumulates, these needles have a long life and our record with one set now exceeds 300 biopsies.

The Jamshidi Needle

This resulted in the core being unobtainable on the first try in seven patients, and in five this failed on two further attempts. In contrast to the Westerman-Jensen needle, the biopsies were recovered in patients with sclerosis and fibrosis, but were lost in three who had profound osteoporosis and in an additional two where the bone was soft and gelatinous due to myelomatous infiltration.

The maintenance of the angled cutting edge is crucial. However, inevitably, and even with precision engineering, there is loss of the taper and gradual gaping of the mouth; from this point, biopsies are readily lost, particularly with soft marrow. In our experience, the life of the Jamshidi needle, with optimal care, is somewhere between 100 and 150 procedures, with minimal resharpening being needed about every 10 to 15 biopsies.

The Islam Needle

In all 50 patients, adequate biopsies were obtained. A learning curve of only two or three procedures was needed, and even these were easy to carry out and suitable samples obtained. Of particular note was the fact that biopsies were readily straightforward with dense myelofibrosis at one end of the spectrum and tumour replacement with myeloma and serous atrophy or gelatinous necrosis at the other.

To date, we have little experience in maintaining the serrated cutting edge, with the current recommendation being to return these to the factory for sharpening. Having deliberately used a single needle for all these procedures, absolutely no loss of quality or increase in crush artifact has been noted. It would appear as though somewhere between 100 and 200 biopsies should be achievable before resharpening is necessary, and it may well be that in many areas this can be carried out locally and at relatively low cost.
DISCUSSION

Routine diagnostic aspiration from the posterior iliac crest or the sternum was judged to be no different using the Turkel or the particular Islam needle designed for this purpose. Some concern does, however, exist about the use of the latter for the sternum, where the guard is held in position with a simple screw as opposed to the more secure threaded system available on some of the alternatives. This argument does not apply to aspiration from the posterior iliac crest, but here neither the volume nor the quality obtained differed from instruments used in the comparison.

With regard to biopsies, the Westerman-Jensen needle, although well tried and compared to the Jamshidi systems, is limited by the pliability of the blades, and in anything other than marrow of near normal texture these tend to become distorted and on occasions impossible to restraighten. Furthermore, crush artifact is relatively frequently encountered, even when the needles are maintained in excellent condition by sharpening them regularly with fine grain water paper. Of the three needles tested, this is the easiest one to introduce and engages the cortex most readily, so that sliding or shifting in the first part of the procedure is not a problem. Despite shortcomings, it is excellent for soft or gelatinous medullary contents, but has a significant failure rate in the presence of fibrosis or dense infiltrative lesions.

The Jamshidi needle, which has been popular for some years now, bears many similarities to the Islam system. It does, however, have two limitations. The first of these is that the maintenance of its cutting edges is difficult, and even with polishing or minimal resharpening the taper is gradually lost, so that the obturator fits less well and cores are increasingly left behind in the patient as the mouth of the needle widens.

However when new or little used they are easy to employ and produce good biopsies in most instances, although retention of very soft or necrotic cores is a definite problem, requiring repeat procedures.

The Islam system has been uniformly more versatile and has the highest success rate of the three. No cores were lost, crush artifact was, for the most part, nonexistent, and neither soft nor hard medullary contents posed the problems seen with the alternatives. The extent to which maintenance of the serrated cutting edge will create difficulties is presently unknown. In practical terms, the recommendation by the suppliers that these be returned to the factory for precision engineering after approximately 100 procedures remains an issue for clarification.

CONCLUSION

Aspiration with the Islam needles for cytormorphology is equivalent to standard and established techniques; its additional cost does not appear justifiable in these circumstances. In contrast, the trephine biopsy system was more flexible and gave consistently superior results in this study when compared to the older Westerman-Jensen and Jamshidi counterparts, with crush artifact and loss of cores not being encountered.

The technique for the use of these needles proved easy to impart to residents in training. Based on this small but direct comparative study, this system can be recommended as that of choice for routine diagnostic laboratories. It is safe and efficient, with skills not being lost, even when procedures are infrequently carried out. In services performing large numbers of biopsies, as with the Westerman-Jensen and Jamshidi needles, it is
mandatory to maintain a clean and sharp cutting edge. We are able to comment on whether this could be achieved by local engineers or would require recycling to the factory, probably after 100 to 200 procedures.

Summary

10-20 μmol/L carminomycin produced more severe acute heart failure than equimolar concentrations of daunomycin (P<0.04) in the isolated perfused working rat heart. Coenzyme Q10 (Q10), which is an obligatory coenzyme of oxidative phosphorylation, was unable to restore control cardiac output although Q10 restored (P<0.001) ATP depletion which was associated with anthracycline administration. We therefore concluded that heart failure was not due to ATP depletion. Reversal of heart failure (P<0.0001) by 2.5 mM to 5.0 mM change in the perfusate calcium concentration suggested that anthracycline acute cardiotoxicity might be on the basis of calcium channel antagonism. Lack of lactate dehydrogenase release into the medium suggested that myocardial cell membrane damage did not occur.

Cardiotoxicity limits the use of anthracyclines, which are potent antimitotic agents, used to treat solid tumours and leukaemias (2,3,13). Impaired myocardial metabolism (14,17) or altered calcium channel activity (1) has been proposed to explain anthracycline cardiotoxicity. In addition to comparing equimolar concentrations of a new analogue, carminomycin to daunomycin on the isolated perfused working rat heart model, we studied the possible role of calcium channel activity by manipulating the perfusate calcium concentration.

Myocardial metabolism was evaluated directly by measuring tissue adenine triphosphate (ATP) of the hearts and indirectly by administration of a mitochondrial extract Q10. Release of lactate dehydrogenase (LDH) into the medium was taken as a non-specific index of cell membrane damage (5,6,7).

Materials and Methods

Hearts, excised from Long-Evans male rats and rapidly arrested in Krebs-Henseleit buffer at 4°C, were preperfused via the aorta by the Langendorff method at a hydrostatic pressure of 65 cm H2O while the pulmonary veins were cannulated. After 15 minutes of Langendorff perfusion, hearts were perfused by the left atrial method (10) for 75 minutes at a filling pressure of 10 cm H2O, working against a hydrostatic pressure of 100 cm. The perfusate was a Krebs-Henseleit (9) bicarbonate medium equilibrated with 5% CO2, 5% O2, with 11 mM glucose as external substrate, with an ionic composition of NaCl 128.5 mM, KCl 4.7 mM, CaCl2 2.5 mM, K2HPO4 1.19 mM, MgSO4 1.19 mM and NaHCO3 25 mM. 5.0 mM CaCl2 perfusate was obtained by doubling the CaCl2 added to the solution. Release of LDH from the heart was measured as the arteriovenous difference.

Solutions prepared from the mannitol-stabilized powder of daunomycin HCl and carminomycin HCl, were added to the atrial perfusion at 20 min. of the working heart. 10 μg/kg of vehicle-free Q10 was administered via the tail vein at 2 hours and at half an hour before sacrifice, in equally divided doses.

At the end of experiments, hearts were freeze-clamped by aluminium tongs (16),
cooled to the temperature of liquid nitrogen and analyzed for ATP and phosphocreatine (PCR) (11) expressed in terms of fresh weight.

Results were expressed as means ± standard error of the mean, with P values calculated from Student's t test and values greater than 0.05 were considered not significant.

N = 8 for all groups
a P<0.04 carminomycin vs equimolar daunomycin
b P<0.0003 vs control
c P<0.003 vs control
d P<0.001 vs 17.5 μmol/l carminomycin

In Table 1 10-20 μmol/l of daunomycin and carminomycin produced time and concentration dependent mechanical failure as measured by cardiac output. In equimolar concentrations carminomycin was more cardiotoxic than daunomycin (P <0.04). Q10 did not influence mechanical function of hearts treated with 17.5 μmol/l carminomycin.

17.5 μmol/l of daunomycin and carminomycin significantly (P <0.003) reduced ATP values from control values. ATP, depleted by 17.5 μmol/l carminomycin was significantly (P <0.001) restored in hearts that were pretreated with Q10.

In figure 1 the reduction of cardiac output produced by carminomycin was much less (P <0.0001) when the perfusate calcium ion concentration was doubled. The protection lasted throughout the experiment. Daunomycin was not tested at the higher calcium ion concentration.

Data in figure 1 has been included in a detailed manuscript prepared for Cancer Research, Saman, Opie, Jacobs (1982).

The reduction of cardiac output when 17.5 μmol/l CMH was added, was much less for 5.0 mM Ca^{2+} concentration.

Discussion

The proposal that anthracyclines produce acute heart failure by inhibiting the synthesis of high energy phosphates (12,14) is unlikely in our preparation because firstly, phosphocreatine was preserved and, secondly, Q10 was unable to reverse acute heart failure by restoring ATP depleted by the anthracyclines. In another study of the isolated rat heart, high energy phosphates were preserved even though heart failure occurred (4).

Our study also does not support the possibility that anthracyclines produced heart failure by chelating extracellular calcium ions (8). Calculation reveals that in our experiments each anthracyclines molecule would have to bind approximately 70 calcium ions to reduce the perfusing medium (intracellular) calcium ion concentration by half.

It is more likely that anthracyclines produced acute heart failure by blocking
slow calcium channels. Support for this hypothesis stems from: firstly, our finding that increase in the calcium ion concentration of the perfusing medium protected against anthracyclines heart failure; secondly, recent evidence that high doses of anthracyclines blocked the slow response action potential (1); and thirdly, evidence that pretreatment of rats with digoxin protected the isolated perfused heart from daunomycin cardiotoxicity (4).

Heart failure in our study was unaccompanied by myocardial enzyme release suggesting that myocardial membrane damage did not occur.

In equimolar concentrations, the new analogue, carminomycin, proved to be more cardiotoxic than daunomycin. However, if it is confirmed that carminomycin has a better antimitotic efficacy at a lower concentration, then the true chemotherapeutic dose might be less.

In conclusion we propose that either calcium ion infusion or digoxin pretreatment (4) might be of value in preventing acute anthracycline cardiotoxicity.

Mechanism of Acute Anthracycline Cardiotoxicity in Isolated Rat Hearts: Carminomycin versus Daunomycin

Selva Saman, Peter Jacobs, and Lionel H. Opie

ABSTRACT

Cardiotoxicity limits the use of anthracyclines which are potent antitumor agents. In the isolated rat heart, we investigated the mechanism of acute anthracycline cardiotoxicity and compared a new anthracycline, carminomycin, with daunomycin which is in established use. Daunomycin 1.75 × 10^{-9} M produced a fall in cardiac output (36 ± 2 versus 58 ± 1 ml/min; p < 0.01), left ventricular power production (9 ± 0.7 versus 16 ± 0.3 mJ/sec/g; p < 0.01), and efficiency of heart work (3.3 ± 0.2 versus 6.3 ± 0.2 mJ/sec/ml O_2; p < 0.01; mean ± S.E. 40 min after daunomycin). Carminomycin (1.75 × 10^{-8} M) produced a greater fall in cardiac output than equimolar daunomycin (26 ± 2 versus 36 ± 2 ml/min; p < 0.01). Daunomycin did not reduce coronary flow rate, heart rate, or oxygen consumption. From the preceding data, we inferred that, since afterload and preload were constant in this model, heart failure was due to a depressed inotropic state. Procedures that increased cytosolic calcium relieved heart failure namely, pretreatment with digoxin (62.4 μg), isoproterenol (10^{-8} M), and increased perfusate Ca^{2+} (5 mm versus 2.5 mm) all prevented carminomycin-induced fall in cardiac output (41 ± 1, 47 ± 5, and 52 ± 1, respectively, versus 26 ± 2 ml/min; p < 0.01). Acute anthracycline contractile failure was also associated with a fall in high-energy phosphate compounds which could also have contributed to the decreased inotropic state. We conclude that carminomycin is more cardiotoxic than daunomycin in equimolar concentrations and that a lowered cytosolic calcium and decreased energy stores might cause the contractile failure. The cytosolic calcium and high-energy phosphate compounds were lowered by separate mechanisms.

INTRODUCTION

Anthracyclines are potent antitumor agents (29). Their use may be limited by cardiotoxicity of which 2 types have been identified. (a) Acute clinical cardiotoxicity with a fall of ejection fraction can be found within 4 to 24 hr of administration of anthracyclines in patients (3, 26). (b) With cumulative doses of anthracycline, a chronic toxic cardiomyopathy may occur (17). There may be a common mechanism for the acute and chronic cardiotoxicity because the myocardial lesions were similar in one study (31). This paper investigates the mechanism of acute contractile failure in an isolated heart model. We also compare daunomycin with equimolar concentrations of carminomycin (6), a new analogue reported to be less cardiotoxic (7).

Previously contractile failure in blood perfused hearts has been explained by a decreased coronary flow rate (19). However, the finding of ATP depletion in cultured cells exposed to Adriamycin (25) argues against a simple effect on coronary flow and suggests a direct toxic effect on energy production (10). Another hypothesis is that anthracyclines might cause myocardial cell membrane damage and thereby cause enzyme release (9, 22). Another possible hypothesis is that there is a decreased availability of cytosolic calcium, because anthracyclines may block membrane Na^{+}/Ca^{2+} exchange (5) or antagonize calcium-dependent slow-response action potentials (1). Cardiac glycosides are reported to prevent acute contractile failure caused by anthracyclines (4, 33), although they neither compete with anthracyclines for membrane binding sites (27) nor prevent myocardial uptake of anthracyclines (2). Because cardiac glycosides are thought to increase cytosolic calcium (14, 20) indirectly, these observations support the proposed role of a decreased cytosolic calcium in acute contractile failure.

We explored the mechanism of acute anthracycline cardiotoxicity by the following procedures: (a) the role of coronary flow was studied by relating coronary flow rates to myocardial mechanical performance; (b) the possible role of myocardial energy metabolism was evaluated by measuring the tissue content of high-energy phosphates and of cyclic AMP; (c) the possible toxic effect of anthracycline on mitochondria was indirectly studied by observing the effects of coenzyme Q_{10}, an agent thought to stabilize the mitochondrial membrane (18); (d) release of lactate dehydrogenase into the perfusing medium was used as a non-specific index of cell membrane damage; and (e) the possible role of calcium ions was studied by altering the perfusate calcium concentration or by administration of isoproterenol or digoxin.

MATERIALS AND METHODS

Isolated Working Heart. Hearts (exsised from male Long-Evans rats; weight, 250 to 300 g) were rapidly arrested in Krebs-Henseleit buffer at 4 °C. The hearts were preperfused via the aorta by the Langendorff method at a hydrostatic pressure of 65 cm H_{2}O for 15 min and were thereafter perfused by the left atrium (21) for a further 75 min at a filling pressure of 10 cm H_{2}O, working against a hydrostatic pressure of 100 cm; 100 ml of perfusing medium were recirculated. The perfusate was a Krebs-Henseleit (16) bicarbonate buffer equilibrated with 95% O_{2} and 5% CO_{2}, with 11 mmol glucose as external substrate, and with an ionic composition of NaCl, 115.5 mm; KCl, 4.7 mm; CaCl_{2}, 2.50 mm; KH_{2}PO_{4}, 1.19 mm; MgSO_{4}, 1.19 mm; and NaHCO_{3}, 25 mm. CaCl_{2} (5.0 mm) was obtained by doubling the CaCl_{2} added to the solution.

Aortic pressure was measured by a Statham P23DB pressure transducer and monitored on a Device M2 direct writer, Welwyn Garden City, Hertfordshire, United Kingdom. Heart work (W) or power production (13) was measured as the sum of pressure and kinetic power by:

\[ \text{Pressure power} = W_p = 0.002222 \times P \times CO \]

\[ \text{Kinetic power} = W_k = \frac{1}{432 \times 10^5} \times \frac{a(CO)^3}{A^2} \times \left( \frac{I}{T_0} \right)^2 \]

CANCER RESEARCH Vol. 44, 1984
where $P_s$ is pressure power, $P_o$ is peak systolic pressure, $CO$ is cardiac output, $W_k$ is kinetic power, $d$ is density of perfusate; $A$ is internal cross-sectional area of aortic cannula, $T$ is cycle time, and $Te$ is ejection time. Units are milliwatts (mW/sec) for kinetic power, mm Hg for pressure power, ml/min for cardiac output, g/cm for density, and sq cm for area. The perfusate density was taken as 1 g/cm³.

The efficiency of mechanical work was the total power production (pressure plus kinetic) divided by the oxygen uptake.

Release of lactate dehydrogenase from the heart was measured as the arteriovenous difference (AV) at 5, 15, 30, and 60 min of left atrial perfusion.

The required concentrations of daunomycin and carminomycin (1 × 10⁻⁴ M and 1.75 × 10⁻⁵ M) were obtained in the perfusate by addition of a solution to the arterial perfusion at 20 min of working heart. Solutions were prepared from the mannitol-stabilized powder of daunomycin HCl and carminomycin HCl. In one series, rats were pretreated with coenzyms 

Drugs. Daunomycin and carminomycin were obtained from Maybaker, Port Elizabeth, South Africa, and Bristol-Myers Co., New York, NY, respectively.

Statistical Analysis. Results were expressed as mean ± S.E. Statistical analysis was by one-way analysis of variance or 2-way analysis of variance as indicated; p values greater than 0.05 were considered not significant.

RESULTS

Control Working Heart. In control hearts, cardiac output and coronary flow rates were stable during the 75-min perfusion period that hearts were made to work (Chart 1). At 60 min, left ventricular power production and efficiency were the same as 15-min values (Chart 2). Heart rate was 244 ± 5 at 5 min but stabilized at between 220 and 230/min at 15 min. Left ventricular stroke volume was 0.24 ± 0.01 ml at 5 min and stabilized at 0.26 ± 0.01 ml at 15 min. Peak aortic systolic pressure was not changed for the duration that hearts worked. Oxygen consumption was 185 ± 4, 164 ± 6, and 153 ± 4 units/g/min at 15, 30, and 60 min. Phosphocreatine, ATP, and cyclic AMP values were 5.1 ± 0.8 μmol/g, 4.7 ± 0.2 μmol/g, and 0.40 ± 0.02 nmol/g, respectively (Table 1), at the end of the perfusion period (75 min).

Effect of Daunomycin and Carminomycin. Daunomycin and carminomycin, which were added 20 min after the onset of heart work, produced mechanical heart failure which was concentration related (Chart 1). Fifty-five minutes after daunomycin and carminomycin (1.75 × 10⁻⁵ M), cardiac output was reduced by 44 and 56% respectively. Left ventricular stroke volume was reduced by 42 and 56%, and peak aortic systolic pressure was reduced by 12 and 16%, respectively (Table 1). Heart rate did not fall, so that the decreased cardiac output was caused by a fall in the stroke volume. At 2 equimolar concentrations, carminomycin produced greater fall in cardiac output (p < 0.01) than daunomycin. Coronary flow rates were not reduced. Left ventricular power production and efficiency of work were reduced by addition of Anthracycline

Chart 3. Protection by higher perfusate Ca<sup>2+</sup> (5 mm versus 2.5 mm) (n = 8), isoproterenol (n = 5), and digoxin (n = 6) against the fall of cardiac output produced by camomycin (2) (n = 16). Calcium concentration other than as indicated was 2.5 mm. Control, n = 14. Coenzyme Q<sub>0</sub> series, n = 7. * p < 0.01 versus camomycin 1.75 × 10<sup>-6</sup> µ alone.

48 and 42%, respectively, after added daunomycin (40 min; Chart 2). Similarly, camomycin reduced power and efficiency by 64 and 61%, respectively. However, the oxygen consumption was not altered by either daunomycin or camomycin (Table 2). Fifty-five min after added daunomycin or camomycin, the fall in ATP was 34 or 38%, and the fall in phosphocreatine was 37 or 10% (not significant), respectively.

Effect of Interventions. The following interventions were tested: (a) a higher perfusate calcium ion concentration (5 mm versus 2.5 mm); (b) addition of isoproterenol to the perfusate; and (c) pretreatment of rats with either digoxin or coenzyme Q<sub>10</sub>. The aim was to prevent the fall in cardiac output caused by camomycin (1.75 × 10<sup>-6</sup> µ, p < 0.01 versus camomycin 1.75 × 10<sup>-6</sup> µ alone).

Chart 4. Effect of 5 mm perfusate Ca<sup>2+</sup> (n = 8) on fall of left ventricular power production (Prod.) (top) and efficiency of heart work (bottom) produced by camomycin 1.75 × 10<sup>-3</sup> µ (n = 14). Control (n = 14) perfusate Ca<sup>2+</sup> was 2.5 mm, * p < 0.01 versus camomycin 1.75 × 10<sup>-6</sup> µ alone.
whereas digoxin pretreatment gave 74% of the control. The high calcium treatment also partially prevented the fall in left ventricular power production and efficiency of work caused by cami-
nomycin (Chart 4).

Release of Lactate Dehydrogenase. Low levels of enzyme release were found at 60 to 75 min after the onset of atrial perfusion; higher values in the first 15 min were probably related to the trauma of excision and mounting of the hearts (8). Neither daunomycin nor camininomycin increased enzyme release over the whole time course of perfusion; results at 75 min are shown in Table 1.

DISCUSSION

An early hypothesis for the acute myocardial contractile failure caused by anthracyclines was that of coronary vasoconstriction. Mhatre et al. (19) proposed that an anthracycline metabolite, which required blood for its production, was responsible for contractile failure. Yet, when their isolated hearts were perfused with a blood-free solution, the coronary perfusion pressure did not change. In our hearts perfused by an artificial medium, there was contractile failure even though the coronary flow did not fall (Chart 1). Since the preload (left atrial pressure) and afterload (height of perfusion column) were unchanged, and heart rate did not fall (Table 1), the acute heart failure could be ascribed to a reduced inotropic state rather than to any coronary vasocstriction.

A disturbance of cellular energy stores could play a role, as suggested by recent studies with nuclear magnetic resonance in isolated rabbit hearts (12). Anthracyclines might impair the production of high-energy components by acting on the mitochondria (24). In our hearts, the contractile failure produced by treatment with anthracyclines was associated with a fall in ATP, but it is unlikely that fall in ATP was the only factor causing the contractile failure, since coenzyme Q_10 restored the high-energy phosphate compounds toward normal but did not improve mechanical function (Table 1).

Anthracyclines may depress the inotropic state by modulating the cytosolic calcium concentration. This hypothesis was supported by our finding that procedures which increased cytosolic calcium relieved heart failure, namely, higher perfusate calcium, isoproterenol, or digoxin. A higher perfusate calcium could increase the inward flux of calcium and thereby elevate the cytosolic calcium ion concentration. Isoproterenol might do this by enhancing calcium entry by the slow inward current (28), whereas digoxin might achieve the same effect by inhibiting the sarcoplasmic Na^+K^-ATPase (2, 11, 32). The negative inotropic effect of acute anthracycline administration has also been reported in in vitro preparations studying contractile force (1, 15, 19, 32). The mechanism could be that anthracyclines either sequester calcium at intracellular sites (24) or interfere with the transmembrane flux of calcium ions (5). It is unlikely that anthra-
cyclines altered calcium flux by modulating cyclic AMP, because the myocardial levels of the latter were unchanged.

We conclude that, in our model, anthracyclines lowered cyto-
solic calcium ion concentration and impaired the production of high-energy phosphates by separate mechanisms. It must be emphasized that our conclusions, based on the acute effects of anthracyclines on an in vitro heart preparation, may not neces-
sarily be relevant to the situation in patients receiving anthracy-
clines.

NEW PLATELET MEASUREMENTS

To the Editor: The critical reassessment of old, well-established haematological methods has, inevitably, followed the introduction of dynamic measurements into the study of blood and its diseases. An important benefit of reviewing old concepts in the light of new data is the opportunity of assigning a more meaningful interpretation to the same observations, so that a clearer understanding of the disturbed pathophysiology emerges than may be appreciated from casual or superficial examination.

Perhaps the classic example of this approach is the way in which the ordinary reticulocyte count may be more meaningfully expressed. Thus, by taking into consideration the degree of anaemia and prolonged maturation of these cells in the circulation, a reticulocyte index can be derived, and this correlates well with red cell production. The revised measurement reliably reflects effective erythropoiesis, making possible a distinction between hypo-proliferative anaemia and that due to accelerated loss of mature cells from the circulation, and this without recourse to the more complex and less readily available kinetic measurements.

An analogous situation in which a simple laboratory test can yield a wealth of additional information once its full potential is realized, holds true for the platelet. Thus, functional and morphological heterogeneity have been clearly demonstrated, with young platelets at one end of the spectrum being indistinguishable by their larger size and greater volume. The latter, now known as megathrombocytes, account for roughly 10% of the number normally present on the stained smear: when this number increases, a correlation with stimulated thrombopoiesis and accelerated platelet production is demonstrable.

Since the megathrombocytes have a characteristic appearance on the stained blood film, a routine laboratory technique is readily available for the assessment of platelet production without necessarily subjecting the patients to the inconvenience of full isotopic thrombokinetic study. A further simple refinement, also readily available, is evaluation of platelet volume with electronic sizing equipment, and this will add a confirmatory dimension to simple examination of the stained smear.

The clearer appreciation of the benefits that may be derived from critical examination of platelet morphology and size is reflected in the examination of the patient with thrombocytopenia. In this situation it should be possible to divide the individuals into two broad groups, one on the basis of a production defect where these platelet parameters will be normal, and a second where accelerated peripheral removal with an intact marrow will be identified by an increased number of large platelets.

We have recently examined a series of such individuals, and our results are essentially in agreement with those described by Garg, Lackner and Karpatic, who demonstrated significant increase in megathrombocytes in patients with systemic lupus erythematosus (68%, of 41 patients), chronic auto-immune thrombocytopenic purpura in apparent remission (47% of 14 patients), disseminated intravascular coagulation (52% of 10 patients), individuals with rheumatic heart disease (48% of 19 patients) and those with prothrombotic heart valves and rheumatic heart disease (20% of 25 patients). The significance of these findings serves to emphasise the earlier report from Harker and Schlichter, who demonstrated a much shorter bleeding time in thrombocytopenic patients when this occurred on the basis of accelerated turnover, than when low platelet counts reflected impaired production. The logical extension of this latter observation is the prediction that clinical deterioration characterised by increased numbers of megathrombocytes, which could easily be identified by examination of the blood film, would indicate a predisposition to a thrombotic state.

While it is logical to incorporate the increased number of circulating megathrombocytes in clinical situations associated with clotting abnormalities, and to seek such at-risk patients with screening procedures, a degree of caution should be injected into an unqualified approach, since it is not yet proved that such a correlation is absolute.

In an attempt to define those situations where the more sophisticated tests are needed, prospective studies are in progress to relate platelet size and volume to accelerated turnover in patients who have had prosthetic cardiac valves inserted. In addition to further clarifying this relationship, such observations must be applied to examining the hypothesis that drugs known to interfere with platelet function will return the disturbed platelet homeostasis towards normal and, therefore, provide a rational basis for the selection and use of different anticoagulant regimens in this group of patients.

Obviously, then, the time has come when routine haematology laboratories should be extracting considerably more information from the platelet count and morphology than may have been general practice to date, and this would be particularly true in the elucidation of bleeding and clotting problems. Equally clearly, such observations need to be coupled with more refined measurements of thrombopoiesis in order that the limitations of the former, in characterizing dynamic pathophysiological processes, may be more precisely appreciated.

Finally, in general terms, the need clearly exists constantly to re-examine tests in routine use with more sophisticated measurements so that, with the reticuloocyte count and platelet morphology, optimal interpretation of otherwise static measurements can be made available by the laboratory to the clinical staff.

DRUGS IN OBESITY

ERRATUM

To the Editor: We refer to our letter on drugs in obesity, which was published in the SAMJ on 10 May 1975. We should like to point out a small but important error. The fourth paragraph should start: 'Of the 32 subjects who completed the trial, I complained of insomnia and headache 1 of nausea and 1 of agitation — side-effects which did not necessitate discontinuation of the drug'.

A practical method for ensuring long-term venous access

Professor Peter Jacobs MRCPath FACP
Jack Jacobson MB FRCS
University of Cape Town Leukaemia Centre and
Departments of Haematology, Clinical Science
and Immunology, Groote Schuur Hospital,
Observatory, Cape 7925, South Africa

Reliable venous access is of critical importance in the management of the chronically ill and debilitated patient. It is also indispensable during the period when cytotoxic chemotherapy is infused for induction of remission in patients with acute leukaemia and following bone marrow transplantation, when the patients may depend upon intravenous therapy continuously for 6 weeks or more. In these circumstances, consideration must be given to the risks of introducing infection that follow repeated venepunctures in immunocompromised patients, while movement for nursing procedures and physiotherapy inevitably disturb the safety of a peripherally-located venous line.

In an attempt to resolve these problems a technique was developed based on earlier studies in a rabbit model (Jacobs 1973, Jacobs & Adriaenssens 1970) where an entirely subcutaneous plastic system had been implanted; the reservoir remained available for intermittent sampling and provided intravenous access over a 3-month period. The same method is equally applicable to man, but we have recently modified this because, following irradiation and bone marrow transplantation, continuous as opposed to intermittent venous access is mandatory.

1 Accepted 2 June 1978

© 1979 The Royal Society of Medicine
On the basis of our first 30 procedures, we report a simple technique that has been found helpful in this regard since it leaves the arms free, does not expose the patient to the risks of repeated venepunctures, and is suitable both for intravenous infusion and blood sampling over a long period of time. In contrast to percutaneous subclavian catheterization this approach has been totally free of any complications.

**Technique**
The venous line can be placed under either general or local anaesthetic. A 10-gauge silastic paediatric nasogastric tube with a rounded solid tip and two side holes has been found to be most suitable.

A 1 cm incision is made diagonally across the deltopectoral groove at the junction of its upper and middle third. To locate the groove the flat hand is placed on the anterior chest wall and moved laterally over the pectoralis major, when the tips of the fingers will palpate the medial fibres of the deltoid as a ridge. This manoeuvre identifies the position of the cephalic vein (Figure 1). It should be remembered that this groove harbours not only the cephalic vein but also the vessels from the acromiothoracic trunk which lies deep to the vein in that situation (Figure 2). The catheter is introduced subcutaneously through a small stab wound 3 cm lateral to the skin incision and enters the subclavian vein via a small incision in its cephalic tributary (Figure 3). In rare circumstances the basilic vein may have to be used instead of the cephalic, but the principle remains the same. The catheter is directed to lie with its tip 1 cm above the right atrium using radiologic control and is then secured in this position and the skin wound closed. The wound is sutured with 4 O Dexon and the whole site sealed with a single strip of Opsite which does not require to be changed until the wound has healed.

The proximal end of the catheter is connected to a three-way tap which allows continuous intravenous infusion and monitoring of central venous pressure. Blood for a variety of investigations may be collected from the tap, and the technique employed is to precede specimen collection by the withdrawal of 20 ml of blood and to return this to the patient before recommencing the infusion.

**Discussion**
This simple technique provides practical and reliable venous access for periods in excess of 6 weeks and necessitates a minor surgical procedure for introduction of the catheter. The operation requires an experienced surgeon and approximately one hour for its completion and has a high degree of patient acceptability, particularly when compared to the alternative of multiple venepuncture. Furthermore, it avoids the hazards associated with repeatedly breaching the skin, thus reducing the risk of introducing exogenous organisms into the circulation with the development of septicaemia in the chronically ill and immunocompromised patient. This method offers substantial advantages over percutaneous introduction of a central venous line where thrombocytopenia may result in haemothorax: 2 recent patients
required platelet transfusion and pleural aspiration for this complication. Because of the position of the catheter the patient's arms are free for physiotherapy and for any manoeuvres that the individuals may wish to perform for themselves. For these reasons we consider that the investment of time, with the benefits for patient management, is more than justified.

In those individuals where continued intravenous manipulation is anticipated, the simultaneous creation of an arteriovenous fistula or insertion of a plastic prosthesis under the same general anaesthetic has become our recent routine practice, and markedly reduces the difficulties experienced with venous access in subsequent management.

Maintenance of the line is of paramount importance and, provided the catheter is flushed through with 5 ml of physiological saline every 4 hours, no problem in maintaining patency has been encountered. The development of infected thrombi at the end of the tubing and occlusion have not yet been encountered, even on removal of the catheter. In the experimental situation, thrombus in the catheter can be gently aspirated or lysed using low-dose infusion of streptokinase. One thousand units of heparin in each 1000 ml fluid should further reduce the risk of clot formation, and while we have used this regimen its efficacy has not been tested under controlled circumstances.

A point of particular importance is the ability to sample blood directly from the centrally-placed catheter. While it might be anticipated that differences would occur between blood collected from this plastic line and from clean puncture of a peripheral vessel, numerous comparisons of electrolytes, biochemical profiles, haematologic tests and blood cultures have consistently failed to show any difference between samples obtained from the two sites. The ability to avoid repeated venepunctures is considered a major benefit by patients who have personally experienced both approaches. It is unlikely that this procedure is new, but we feel that its redescription is justified at a time when an increasing number of patients are undergoing intensive chemotherapy and bone marrow transplantation, and are thus dependent upon reliable venous access for long periods of time.

Summary
A simple method of creating dependable long-term venous access is described. This method is suitable both for infusion and repeated blood sampling. Complications have thus far not been encountered.

Acknowledgment: We are grateful to Jeanne Walker for the illustrations.

INTRODUCTION

Bone marrow transplantation is the preferred form of treatment for patients with severe acute aplastic anaemia\(^1\) and immunodeficiency disease\(^2\). The procedure has also been used in the treatment of patients with refractory or relapsed acute leukaemia and may result in further disease-free periods in excess of two years in approximately 15% of such individuals\(^3\). On the basis of the latter experience bone marrow transplantation is now being evaluated in patients with acute leukaemia who have achieved their first complete remission. Preliminary data both for lymphoblastic\(^4\) and myeloblastic\(^5\) variants suggest that such an approach may hold advantages over cytotoxic maintenance programmes. Other possible indications for this procedure, while still controversial, include lethal genetically transmitted diseases such as thalassaemia major, constitutional or familial bone marrow failure, and chronic granulocytic leukaemia. Understandably, the morbidity and mortality that currently attend marrow transplantation are factors limiting its wider clinical use.

Two immunologic barriers influence the outcome of any transplantation procedure. The first of these is the satisfactory acceptance of the graft; failure to engraft is designated rejection. Best results are obtained by matching donor and recipient at the major histocompatibility complex. Despite HLA compatibility and mixed lymphocyte culture non-reactivity, problems may arise because of isoinmunisation of the recipient by prior administration of blood products. It is for this reason that transfusions should be minimised, ideally by early referral of patients. To encourage engraftment, the immunologic competence of the recipient is suppressed by drugs, such as cyclophosphamide, with or without whole-body radiotherapy. This preparative treatment is associated with destruction of residual haematopoietic tissue and thus contributes to the pancytopenia that characterises the post-transplantation period, when severe infection and thrombocytopenic bleeding are common problems.

Secondly, morbidity and mortality may result from graft-versus-host disease or reverse rejection. Here, an inflammatory reaction is directed predominantly against the cells of the gastrointestinal tract, the liver, and the skin, but its pathogenesis is controversial\(^6\). Because it is rare in identical twins or syngeneic transplants, importance is attached to optimal matching of donor and recipient. Nevertheless, the clinical syndrome, which may be either acute or chronic, occurs in up to 70% of apparently perfectly matched transplantation pairs. A prominent component of this syndrome is infection, where allogeneic granulocyte support may be life-saving.

The steady improvement in results of bone marrow transplantation must take into account the importance of specialised nursing and, particularly, the role of an efficient cell support section. The latter is needed to provide, on a moment-
to-moment basis, adequate numbers of functionally viable white cells and platelets. It is this facet of the programme that is illustrated by experience derived from five recently transplanted patients.

CASE REPORTS

Case No 1

POOR PROGNOSIS ACUTE LYMPHOBlastic LEUKAEMIA

A 10-year-old boy presented with a 12-day history of fever and headache, undue fatigue, and petechiae in the 24 hours before admission. Physical findings were limited to firm enlarged lymph nodes in the neck, axilla, and groin, and 4 cm hepatosplenomegaly. Initial haematology showed a haemoglobin of 9.8 g/dl; total white cell count of 114 x 10⁹/l, all lymphoblasts; and a platelet count of 60 x 10⁹/l. The biochemical profile was normal. Bone marrow examination confirmed the diagnosis of acute lymphoblastic leukaemia (FAB type L1). Lumbar puncture revealed the presence of numerous lymphoblasts in the cerebrospinal fluid. Radiology of the dorsal spine showed mild osteoporosis and vertebral collapse without positive evidence of leukaemic infiltration.

Complete remission was achieved successfully with a combination of vincristine, prednisone, 6-asparaginase and Adriamycin. The central nervous system was cleared of leukaemic blasts with twice weekly alternating intrathecal cytosine arabinoside (30 mg/m²) and methotrexate (12 mg/m²). Two courses of consolidation chemotherapy were given using the four induction drugs. Standard craniospinal therapy was given without complication.

In view of the bad prognosis predicted by the high circulating blast count and the presence of central nervous system disease, the patient and his family were offered bone marrow transplantation in this first complete remission. An HLA identical and MLC non-reactive 12-year-old brother acted as donor after informed consent had been obtained.

Following placement of a central venous catheter the patient was prepared with cyclophosphamide, 60 mg/kg, administered by intravenous infusion on two consecutive days with attention to fluid balance and electrolyte status. Following a 24-hour rest period total body irradiation was given to a mid-plane dose of 1.000 rads; the skull was shielded at 500 rads to compensate for previous administration of 3.200 rads cranial irradiation.

Under general anaesthetic 440 ml of marrow was collected from the donor by multiple percutaneous punctures from the sternum and both iliac crests. 2.3 x 10⁸ nucleated cell/kg were infused into the recipient. The adequacy of the donor marrow was confirmed by in vitro bone marrow culture. The donor was discharged from hospital 24 hours after marrow donation.

In the post-transplantation period the patient received daily parenteral intravenous alimentation. For five days following infusion of the marrow the donor buffy layer was infused providing both white cells (mean of 2.2 x 10⁹; range 0.7 — 4.0 x 10⁹), and platelets (mean of 0.4 x 10¹¹; range 0.2 — 0.8 x 10¹¹).

Because the patient remained pyrexial despite an intravenous antibiotic regimen of cephaloradin, aminoglycoside and metronidazole, allogeneric white cell support was continued until day 14 when the temperature returned to normal.

Successful engraftment was confirmed by a rising peripheral platelet and granulocyte count on day 12. Trephine biopsy was hypocellular but all lines were represented.

Comments

The immediate post-transplantation course in this patient was characterised by mild to moderate graft-versus-host disease with persisting skin rash and transient diarrhoea requiring intravenous hyperalimentation and corticosteroids. There are residual Cushingoid striae but no measurable endocrine abnormalities. The osteoporosis, perhaps due to leukaemic infiltration, has resolved with calcium and vitamin D supplementation.

A transient period of jaundice was unexplained and may have been the result of viral infection from transfusion therapy, a reflection of graft-versus-host disease, or incidental infectious hepatitis. One year from transplantation the patient again had elevation in liver enzymes and mild conjugated hyperbilirubinemia. There were no demonstrable antibodies against hepatitis A or B, and the possibility of intermittent biliary tract obstruction was considered but not proven.

The patient has remained immunocompromised with hyperglobulinaemia and has received parenteral gammaglobulin. In addition, he has had an episode of staphylococcal septicaemia requiring six weeks of intravenous antibiotics. Recovery was uneventful. One year after being transplanted, he developed an acute abdomen requiring emergency laparotomy. Pigment gallstones obstructing the common bile duct were found. The patient handled wound healing and his surgery without difficulties.

At the present time, one and a half years after successful bone marrow transplantation and despite a variety of complications, he is disease-free and has mild (Grade I — II) but steady resolving graft-versus-host disease.

Case No 2

POOR PROGNOSIS ACUTE UNDIFFERENTIATED LEUKAEMIA

A 22-year-old student presented with a one week history of anaemia and bleeding from his gum margins. Physical examination was negative apart from 1 cm hepatosplenomegaly. Initial haematology showed a haemoglobin of 12.5 g/dl; total white cell count of 35 x 10⁹/l; 11% neutrophils, 5% eosinophils, 1% basophils, 38% lymphocytes (many of which were atypical), 6% monocytes, 3% promyelocytes, 5% myelocytes, 31% metamyelocytes; platelet count was 146 x 10⁹/l. The biochemical profile was normal. Bone marrow examination showed marked hypercellularity and many ringed sideroblasts. The marrow was extensively involved with undifferentiated acute leukaemia.

Initial attempts to induce remission in the patient with a combination of an anthracycline antibiotic, MARCH 1983
cytosine arabinoside and the epipo-
dophyllotoxin VP 16-213 were un-
successful. Remission was subse-
sequently achieved with the combina-
tion of vincristine, prednisone, e-
asparaginase and adriamycin. Fol-
lowing two courses of consolidation the 
patient was offered bone 
marrow transplantation in view of 
the poor prognosis associated with 
acute undifferentiated leukaemia. 
Conditioning was with the stan-
dard regimen of cyclophosphamide 
and total body irradiation12. He 
received 4 x 10⁸ nucleated cells/kg 
from an HLA identical MLC non-
reactive brother. The adequacy of 
the donor marrow was confirmed by 
_in vitro_ bone marrow culture. 
Post-transplantation stem cell boost-
ing was provided with adminis-
tration of buffy layer for five days. 
Mean white cell yield 3.4 x 10¹⁰ 
(range 1.7 - 3.8 x 10¹⁰). Mean 
platelet yield 6 x 10¹⁰ (range 0.5 
- 1.2 x 10¹¹). No further cell support 
was needed.

Comments 
Mild to moderate graft-versus-host 
disease developed which responded 
dramatically to 1.5 mg/kg 
parenteral prednisone/24 hours and did 
not reappear when the cortico-
steroid was withdrawn. The patient 
developed an acute abdomen with 
radiologic and ultrasonographic evi-
dence of acute biliary tract obstruc-
tion. He rapidly developed fulmi-
nating sepsicaemia and died before 
surgery could be undertaken.

At post mortem biliary obstruc-
tion had occurred as a result of a 
mucosal cast having impacted and 
totally obstructed the common bile 
duct. No residual evidence of leu-
kaemia was demonstrated and bone 
marrow engraftment was con-
firmned.

Case No 3

**SEVERE ACUTE APLASTIC ANAEMIA**

A 35-year-old woman was referred in 
extremis after having been ill for 
six weeks. There had been bruising 
and minor trauma with severe head-
ache and vaginal bleeding for four 
weeks. Examination showed ecchym-
moses around both eyes and exten-
sive purpura was present. There 
was marked neck stiffness and the 
patient was stuporous although 
moving all her limbs. Pupils were 
equal and responsive. No other 
focal or neurologic signs were pres-
ent. Lumbar puncture showed 
bloodstained cerebrospinal fluid.

Initial haematology showed a 
haemoglobin of 2.7 g/dl; white cell 
count of less than 1 x 10⁸/l and platelets less than 10 x 10⁹/l. Only 
lymphocytes were circulating in the 
peripheral blood. The biochemical 
profile was normal. Bone marrow 
aspiration and the trephine biopsy 
showed aplasia.

The patient was initially managed 
conservatively from the standpoint 
of her sub-arachnoid haemorrhage 
with irradiated allogeneic platelet 
transfusions. She responded well to 
this management and once fully 
conscious and able to make deci-
sions accepted bone marrow trans-
plantation. A central venous line 
was placed and conditioning under-
taken with a standard regimen of 
cyclophosphamide. Total body ir-
radiation was not used.

The patient was uneventfully 
transplanted from her HLA identi-
cal and MLC non-reactive sister, re-
ceiving 3.8 x 10⁸ nucleated cells/kg 
and the graft viability was estab-
lished by _in vitro_ marrow culture.

The patient received five days 
post-transplantation buffy layer to 
supplement haematopoietic stem 
cells; mean white cell yield 1.2 x 10¹⁰ 
(range 0.5 - 2.3 x 10¹⁰) and pla-

teelets with a mean of 1.0 x 10¹¹ 
(range 0.5 - 1.9 x 10¹¹). Engraft-
ment was demonstrated by rising 
peripheral count confirmed by tre-
phine biopsy on the 12th post-trans-
plant day.

On the 11th post-transplant day, 
after buffy layer had been discon-
tinued, the patient was again pyre-
xial and had an episode of fresh 
rectal bleeding. Allogeneic white 
cells and platelets were recom-
mented and the patient was unex-
pectedly found dead in bed on the 
17th post-transplantation day.

Comments 
The pyrexial episode was investi-
gated with blood cultures which 
failed to grow an organism. Never-
theless, the standard antibiotic regi-
men of cephalosporin, aminoglyco-
side and metronidazole were com-
menced and because the fever per-
sisted allogeneic white cells were 
infused.

The cause for the rectal bleed-
ing was never established and the 
patient remained thrombocytopeni-
at this stage and there was a prompt 
response to platelet infusion.

Post mortem examination failed 
to reveal the cause of death. No 
cerebral bleeding was demon-
strated. Marrow engraftment was 
confirmed.

Case No 4

**FANCONI ANAEMIA**

A diagnosis of Fanconi anaemia 
was made at the age of 12 when the 
patient was seen with easy bruising 
and thrombocytopenia. During the 
ensuing years these symptoms were 
moderately controlled on low doses 
of corticosteroids. In the year 
preceding his referral he had failed to 
respond to anabolic androgens and 
was developing an increasing blood 
transfusion requirement. On admission 
he was pale and tachylic. Scattered 
purpura and ecchymoses were 
present. He was markedly Cush-
ingoid.

Initial haemoglobin was 4.3 g/dl; 
total white cell count 4.8 x 10⁹/l 
with 22 % neutrophils; platelet 
count was 3 x 10⁹/l. Bone marrow 
showed erythroid hypoplasia with 
marked megaloblastic change, 
normal granulopoiesis, and scanty 
ogakaryocytes. In view of the 
rapid deterioration and despite the 
presence of a strong multispecific 
antibody, the patient was condi-
tioned with a standard regimen of 
cyclophosphamide and transplanted 
from an HLA identical and MLC 
non-reactive sister.

Particularly in view of previous 
sensitisation, importance was at-
tached to the buffy layer support 
which yielded a mean white cell 
count of 1.3 x 10⁹ (range 0.5 - 3.6 
x 10⁹) and a mean platelet count of 
0.5 x 10¹¹ (0.5 - 1.4 x 10¹¹).

In the two weeks following 
transplantation, most prominently etweeen days 10 and 14, the patient 
developed severe mucositis, diar-
rhoea and skin desquamation. His 
hands became swollen and deep 
bullous lesions developed over the 
knuckles. These cutaneous findins

CURATIONIS

VOL.6 NO.1
were associated with the isolated biochemical abnormality of a rising total and conjugated bilirubin.

This clinical syndrome was interpreted as being due to acute graft-versus-host disease and the patient treated with high doses of corticosteroids.

Despite the obvious progression of this immunologic syndrome, engraftment was demonstrated on the 12th post-transplant day by rising granulocyte and platelet count. Confirmation was obtained by bone marrow aspiration and trephine biopsy.

There was rapid progression of the graft-versus-host disease and by the 21st post-transplant day it was progressing to scleroderma. On the same day there was a dramatic temperature rise and the patient died from fulminating septicaemia superimposed upon his graft-versus-host disease.

Autopsy confirmed the presence of engraftment and extensive graft-versus-host disease.

**Comment**

Bone marrow transplantation in patients with constitutional anaemia, as exemplified by the Fanconi syndrome, remains controversial although successful cases have been reported. The uncertainty rests upon an inability to ensure that the donor is not also affected by the same chromosomal abnormality as the patient. In the present case appropriate studies excluded this possibility although more subtle lesions may have existed and escaped attention by available techniques.

This patient exemplifies the situation where post-transplantation stem cell boosting with buffy layer has been most encouraging. In individuals sensitised from previous exposure to blood or components there is limited evidence that immune rejection may be compensated for by buffy layer infusion. Clearly, at least in the short term, the transplantation was successful in re-establishing haematopoietic function.

The acute graft-versus-host disease is believed to represent direct transmission of sensitised lymphocytes from donor to recipient in the marrow graft. The onset and the clinical course are typical of the acute variant of graft-versus-host disease and, despite the administration of high-dose corticosteroids, the course followed by this patient is in keeping with that described by other more experienced investigators.

**Case No 5**

**SEVERE ACUTE APLASTIC ANAEMIA**

A 25-year-old female presented with a one-month history of lower abdominal pain which was diagnosed as salpingitis and treated with an unknown antibiotic by her private physician. Shortly thereafter she experienced epistaxis and menorrhagia, followed by increasing dyspnea, palpitations, and a sharp decline in effort tolerance. Apart from the antibiotics there was no history of drug ingestion. Physical examination was normal except for bilateral fundal haemorrhages.

Initial laboratory findings included a haemoglobin of 6.0 g/dl; white cell count 1.5 x 10^9/l, with 88% lymphocytes; and platelet count of 13 x 10^9/l. The biochemical profile and chest X-ray were normal. Bone marrow aspirate and trephine biopsy showed aplasia. Following conditioning with cyclophosphamide, the patient was transplanted from an HLA identical and MLC non-reactive brother, followed by five days post-transplantation buffy layer administration. The mean white cell yield was 2.5 x 10^10 (range 0.9 — 3.7 x 10^10) and mean platelets were 1.0 x 10^11 (range 0.3 — 1.8 x 10^11).

In the second week low grade fever continued despite appropriate antibiotics and in view of the pelvic inflammatory disease with which the patient presented, allogeneic granulocyte support was continued.

By day 13 the temperature had settled and engraftment confirmed by bone marrow aspirate and trephine biopsy. All support was discontinued from the end of the second post-transplantation week.

**Comment**

This patient developed rapidly increasing weakness ascribed to the administration of epsilon aminocaproic acid which she received in large amounts for her menorrhagia. Her course was further complicated by the development of septicaemia, and death resulted from sub-arachnoid haemorrhage.

**CELL SUPPORT**

The machine used for the collection of buffy layer is the NCI-IBM 2990 or, more recently, the 2997, both of which operate on the principle of differential centrifugation. The essential difference between the two machines is that the newer NCI-IBM 2997 has a disposable bowl so that risk to individuals on the machine from infection is no longer present. The blood leaves an arm vein of the donor and enters a slowly spinning centrifuge bowl where the white cells and platelets are segregated from the red cells and may be selectively removed, with all other components being returned to the donor.

In the NCI-IBM 2990 the polycarbonate bowl is primed with 1 000 ml of 0.9% saline containing 5 000 units of heparin. Following cannulation of the patient a further 5 000 units of heparin are administered as an intravenous bolus. A centrifuge speed of approximately 600 rpm is used and flow rates vary between 30 and 50 ml/minute. Under these circumstances the leucocyte and buffy layer is evident as a yellow band situated between the red cells and the plasma, and is visible through the transparent perspex deck of the centrifuge bowl. Extraction of white cells and platelets takes place at a rate between 3 and 6 ml/minute, and between 150 and 300 ml is usually collected from each donor.

Donations require informed consent and predonation full blood counts are routinely obtained on each occasion. Donor temperature, blood pressure and pulse are monitored throughout the course of the procedure. The donor, in addition to having given marrow, is routinely used in the five days immediately following transplantation with the theoretical intention of enhancing the number of haematopoietic stem cells administered to the recipient.

In those patients where fever and granulocytopenia, often associated with thrombocytopenia, are en-
countered, a further 10 to 14 days
donation of buffy layer is possible
from the same donor without either
undue difficulty or stress. If the
original volunteer is unable to con-
tinue donations while the recipient
is still dependent upon allogeneic
cells, ABO compatible relatives
and unrelated donors are used.
Under these circumstances the gra-
nuocytes are irradiated to 1500
rads to prevent proliferation of lym-
phoid cells which might produce or
enhance graft-versus-host disease.

A number of manipulations can
be used to increase the yield of
buffy layer collections, including
corticosteroid administration to the
donor and addition of hydroxyethyl
starch to the venous line supplying
blood to the bowl. The latter sub-
stance may cause headache due to
volume expansion, decrease in haem-
ogloin and platelets due to hae-
modilution in the donor, and pruri-
tis.

In contrast to differential cen-
trifugation the alternative technique
of continuous-flow filtration may be
used for granulocyte collection.
However, only centrifugation is suit-
able for buffy layer collection since
stem cells, lymphocytes, platelets,
and granulocytes are collected by
this technique.

Where filtration is used, high gra-
nulocyte yields may be obtained but
there is recent evidence that the
cells obtained are functionally and
ultrastructurally inferior to those
recovered following centrifugation.

In order to obtain cells by filtra-
tion heparinised blood is passed
over nylon filters at flow rates be-
tween 40 and 100 ml/hour. Granu-
locytes adhere to the filter and re-
covered by elution with a citrate-
containing solution. Other cellular
components do not remain in the
filter. Because a volume in excess of
10 litres needs to pass over the filter
donations usually require two
hours. A recent modification has
been the use of in-line elution but
this remains largely developmental.
It has, however, been suggested,
but not yet proven, that both cell
yield and function are significantly
improved by this approach.

During elution granulocytes can
be dislodged from the filter by per-
cussion of the casings and cells then
concentrated by centrifugation at
1600 x g for 20 minutes. The final
volume infused varies between 100
and 300 ml, and should take place
within one hour of collection.

Complications occur with both
techniques. With centrifugation
there may be a drop in haemoglobin
which requires correction by admin-
istration of fresh irradiated packed
red cell. Thrombocytopenia which is
transient occurs rarely. In a number
of patients venous access may be
difficult, requiring the use of arterio-venous shunts. Clotting
may occur in the extracorporeal cir-
culation due to insufficient use of
anticoagulant but this should not be
encountered when experienced
staff operate the machine. Similar-
ly, anxiety occurs in some donors
but can be overcome by the presen-
tce of experienced and competent
nursing and medical staff.

The complications arising from
haemofiltration also include diffi-
culties with venous access and clot-
ting. However, here an abdominal
pain syndrome is recognised which
is believed to reflect complement
activation.

BONE MARROW TRANS-
PLANTATION PROCEDURE

Donors commence oral iron and
folicate supplementation two weeks
before transplantation. One unit of
whole blood is collected in the week
before transplantation. The buffy
layer is separated and administered
to the recipient 24 hours before
commencement of the cyclophos-
phamide conditioning regimen. The
red cells from the same unit are re-
tained for re-transfusion to the
donor during the subsequent collect-
ion of bone marrow.
Donor and recipient are compat-
ible at the major loci within the
human histocompatibility complex.
Ideally, there should be no blood
group incompatibility, although re-
duction in red cell antibodies to in-
consequential levels can be effected
by means of large volume plasma
exchange4.

Twenty-four hours after adminis-
tration of the buffy layer, which
theoretically triggers immunologi-
cally competent cells in the recipi-
ent into cycle and hence renders
them maximally responsive to cyto-
toxics, cyclophosphamide condi-
toning is commenced. In patients
with severe acute aplastic anaemia,
50 mg/kg is given by intravenous
infusion over half an hour on four
consecutive days. In leukaemic
patients undergoing first remission
bone marrow transplantation a
slightly different regimen is used; 60
mg/kg of cyclophosphamide is given
for two days, following which the
patient rests for 24 hours and then,
on the day of transplantation,
undergoes 1000 total body irradia-
tion at a rate of 9 rads/minute.
The object of these conditioning regi-
mens is to destroy all immunologi-
cally competent lymphatic tissue
which may be capable of mounting
a rejection response.

Under general anaesthesia, and
with informed consent, marrow is
collected from the donor by mul-
tiple punctures of the sternum and
both iliac crests. Between 1 and 3 ml
of marrow-rich blood are aspirated
from each puncture site and a final
volume of approximately 10 ml/kg
of recipient's body weight collected.
The aspirated material is anticoagu-
lated in heparin-containing culture
medium and converted to a mono-
cellular suspension by passing it
through a series of stainless steel
screens. The graft is infused over
half an hour to the recipient. Atten-
tion is given to any discomfort in
the chest which may be associated
with multiple small fat emboli. The
arterial oxygen saturation is obser-
vated at the same time.

Apart from experiencing some
discomfort donors are usually able
to leave hospital the next day and
have little trouble in attending the
Cell Support Section to donate
buffy layer on the separator.

The recipient is nursed in iso-
lation and receives buffy layer daily
for the first five days of the post-
transplantation week. All support is
then discontinued unless the patient
is pyrexial or has significant throm-
bocytopenic bleeding. In the face of
pyrexia, antibiotics (tobramycin,
cephamandole, and metranidazole)
are commenced while awaiting ap-
propriate cultures. Failure to lyse
fever within 24 hours is an indica-
tion for allogeneic white cells, with
an arbitrary level of 1.5 granulo-
cytes x 10^10 the daily goal.
IN VITRO BONE MARROW CULTURE

Culturing haematopoietic stem cells or committed progenitors in semisolid agar in the laboratory is a useful technique which may be applied to monitoring the adequacy of the graft being infused\(^5\). In principle, the marrow is cultured in a system that provides both the nutrients and the stimulating substances necessary for the growth and proliferation of the progenitor cells. The appearance of small cell aggregates can then be counted, thereby providing an index of the number of stem cells in the graft.

In practice, the stimulating substance is a glycoprotein which is elaborated and released into the agar. The marrow from the donor is washed and suspended in a second agar layer called the overlay in a 35 mm petri dish which is then incubated in a humidified atmosphere containing a fixed amount of carbon dioxide at 37°C. The appearance of clusters and colonies are determined at days 0, 3, 7, 10 and 12. By definition, clusters contain between 3 and 49 cells, white colonies have more than 50 cells present.

Under normal circumstances the earliest evidence of in vitro marrow growth is evident between day 3 and 7, but the optimal colony cluster ratio has been recorded in our laboratory at day 10. In each of the patients discussed in the case studies normal numbers of colonies and clusters were demonstrable at this time, establishing that committed haematopoietic stem cells, at least for the monocyte macrophage line, are present in normal numbers. Experience has demonstrated that such in vitro growth patterns correlate with the supply of adequate numbers of stem cells as reflected in uniform engraftment of patients where sensitisation has not previously taken place.

DISCUSSION

Bone marrow transplantation has become increasingly successful, especially in the last decade. This improvement reflects both a better appreciation of the need to match donor and recipient at the major histocompatibility complex and a clearer understanding of the immunobiology of the procedure, particularly in providing a sufficient number of haematopoietic stem cells to bring about marrow reconstitution. Nevertheless, as these two important variables have been managed, new challenges have emerged.

It has become apparent that prior exposure to blood or blood group antigens may lead to isoinmunisation in the recipient and subsequent graft rejection. Accordingly, patients being considered for transplantation should be referred early to a transplantation centre so that this essentially iatrogenic complication may be avoided.

A second source of failure now amenable to treatment is that of thrombocytopenic haemorrhage. With the steady improvement of technique for allogeneic platelet transfusion, this complication has diminished in importance. Regrettably, this advance may be a two-edged sword in that platelet transfusions may be used indiscriminately in the short term in the hope that conservative therapy may allow spontaneous marrow recovery to occur, particularly in patients with severe acute aplastic anaemia. In this situation the problems of isoinmunisation are enormous. Platelet survival may be shortened and the option of transplantation may be lost by inadvertent stimulation of antibody production directed against donor cells.

With control of thrombocytopenic haemorrhage, infection, usually bacterial, has taken over as the major cause of morbidity and mortality in the transplant patient. Two major factors contribute to the propensity to infection. Firstly, in patients with severe acute aplastic anaemia, severe granulocytopenia is part of the disease and many of these patients reach the transplant centre with established infection, commonly of the respiratory tract. Secondly, the conditioning regimens aimed at diminishing host immune competence in order to facilitate graft acceptance superimpose immune destruction of the host upon pre-existent granulocytopenia.

Since engraftment should not be a problem in properly selected donors who have not been previously isoinmunised, it follows that carefully selected allogeneic platelet and granulocyte support occupies a crucial role in determining the success of any marrow transplantation.

The infusion of buffy layer to boost the number of stem cells given to the patient is theoretically sound. However, recent evidence suggests that this particular manoeuvre is less helpful than previously anticipated, particularly if adequate numbers of stem cells are collected in the initial graft.

Nevertheless, the provision of white cells and platelets during the first week following transplantation has notably improved the general condition of the patients. Until such time as a randomised prospective study becomes available, the advantages are sufficiently attractive for us to continue with this procedure.

Of a less controversial nature is the use of allogeneic granulocyte support in the patient who is pyrexial and pancytopenic following transplantation. Despite suggestions that the fever may be related to neutropenia per se rather than infection\(^6\), and the suggestion that prophylactic granulocyte transfusions are not helpful, our own experience has been otherwise. It remains to be determined by prospective randomised study whether the provision of adequate numbers of functionally intact granulocytes to the infected neutropenic patient following marrow transplantation can be safely omitted.

CONCLUSION

It is concluded from recent experience that transfusion of buffy layer containing granulocytes and platelets, both routinely in the week following transplantation and subsequently for the indications of fever and haemorrhage, is beneficial in the bone marrow transplant recipient. We emphasise the need to maintain rigid quality control in number and function of cells transfused, to recruit an adequate donor panel, and to maintain a highly trained nursing staff to operate an active Cell Support Section as an in-

The role of continuous-flow blood fraction separators in clinical practice

LUCILLE WOOD, P. JACOBS, D. W. DUBOVSKY, L. M. KERNOFF, K. D. GUNSTON, IRINA BOTHA, LORNA ROBERTSON

The continuous-flow blood fraction separators have the capacity to selectively exchange large volumes of plasma or red cells with minimum risk or discomfort to the patient. These procedures are effective and their use in clinical practice is increasing, as experience with 5 recent cases illustrates.

Myasthenia gravis is an antibody-mediated neuromuscular disease. Normally the locally released acetylcholine from the nerve occupies a specific receptor site on the motor end-plate, resulting in muscular contraction. In myasthenia gravis an antibody is formed and blocks the receptors so that the contractile response to a given amount of acetylcholine is suboptimal. The rationale for plasmapheresis in this condition is to reduce the quantity of the acetylcholine receptor antibody present in the circulation. Simultaneously, immunoglobulin production is decreased by administering immunosuppressive drugs. Although of greatest benefit in the short term, prolonged periods of plasma exchange may occasionally be needed.

In the pregnant woman iso-immunized to rhesus antigen, it is logical to anticipate that lowering the anti-Rho (D) titre in the maternal serum will reduce the severity of the haemolytic disease in the fetus. In those individuals who have not been given prophylactic immunoglobulin and who have become sensitized, plasmapheresis is a practical approach to resolving this problem.

Bone marrow transplantation depends upon compatibility between donor and recipient. In unusual circumstances HLA identity and MLC non-reactivity are associated with blood group incompatibility. This dilemma can be resolved by continuous-flow plasma exchange in which naturally occurring antibodies directed against the ABO system are greatly decreased. Any residual antibody is adsorbed by infusion of suitable red cell antigen prior to grafting.

Under normal circumstances adult red cells contain predominantly HbA which effectively delivers oxygen to metabolizing tissue. In sickle cell disease this HbA is replaced by an abnormal haemoglobin (HbS). The presence of HbS results in the defective red cells called sickle cells, which deform and may block the microcirculation when oxygen tension is lowered. Serious complications with tissue infarction may then arise. Since general anesthesia and major surgery may be associated with varying degrees of hypoxia, it is rational to protect the patient from these risks by pre-operative red cell exchange in which normal levels of HbA are substituted for the defective haemoglobin.

Five case reports are presented to illustrate the increasing use of continuous-flow centrifugation in current clinical practice.

Blood fraction separator procedures and laboratory techniques

Plasmapheresis

Continuous-flow exchanges were carried out using the National Cancer Institute - International Business Machine (NCI - IBM 2990) Blood Fraction Separator. A vein-to-vein technique was employed, the blood passing through a special bottle where separation of the various components takes place in response to centrifugal force. Two patients required the insertion of an arteriovenous shunt to ensure adequate vascular access. Before commencement of the procedure the 250 ml dead-space present in the lines and the centrifuge bowl was primed with a solution of physiological saline and heparin (100 mg/kg).

Effective plasma exchange is complete between 90 and 120 minutes with centrifuge speeds of 1000 rpm and blood flow rates between 25 and 50 ml/min. Ideally, exchange of 75 ml/kg or twice the estimated plasma volume is attempted, but this is influenced by many variables including patient tolerance and the kinetics of exchange...
between intravascular and extravascular spaces for the substance being removed. In the first 3 patients an exchange of 2 litres was achieved on each occasion. Priming anticoagulation was with 5000 IU heparin given as an intravenous bolus at the time of cannulation. The replacement fluid consisted of an electrolyte solution containing 20% salt-poor human albumin. During the procedure a trained nurse was present at all times.

In the patient undergoing anti-A depletion, two separate but longer procedures were employed in which 6 and subsequently 14 further litres of plasma were exchanged for ABO plasma.

**Red cell exchange**

The technique is essentially similar to that used for plasmapheresis. A volume of 2.825 ml of the patient's blood containing high concentrations of HbS was exchanged for an equivalent volume of normal red cell concentrate with a packed cell volume of 80%. The exchange procedure lasted 3½ hours and was performed at a flow rate between 10 and 15 ml/min.

**Acetylcholine receptor antibody titre determinations**

Titres of the antibody directed against the acetylcholine receptor were determined just before each plasmapheresis. An assay was used in which competition between antibody and radio-labelled α-bungarotoxin is determined for receptors present on eel cells. In this assay antibody concentration in the patient's plasma is inversely related to binding of labelled toxin to the cells.

**Estimation of rhesus (D) antibody levels**

These were determined by the indirect antihuman globulin (AHG) technique and estimations of specific anti-Rho (D) antibody concentration were made using a reference serum (National Institute for Biological Standards and Control, London).

**Estimation of anti-A titres**

Iso-agglutinin anti-A titres were determined against A+ and A- cells at 22° and 4°C. Immune anti-A was titrated against A+ cells in saline, bromelin and AHG.

**Haemoglobin measurements**

A venous blood sample was obtained before red cell exchange and at regular intervals throughout the procedure. The Hb level was determined on the Coulter Counter Model S. Red cell lysates were electrophoresed on cellulose acetate and quantitated by integrating densitometry.

**Case report and results**

**Case 1**

In May 1976 a 56-year-old woman presented with drooping eyelids, weakness of the neck and difficulty in swallowing. A response to an intravenous injection of short-acting anticholinesterase (Tensionil) established the diagnosis of myasthenia gravis. An acceptable level of skeletal muscular activity was maintained with proximine 15 mg 3 times a day, and prednisone 10-40 mg on alternate days. Chest radiography and mediastinal tomography suggested a thymoma, and thymectomy was performed 1 month after diagnosis. The histological examination of the tumour showed a mixed cell thymoma with a predominantly epithelial component.

Two days postoperatively the patient had a sudden respiratory arrest requiring tracheostomy and intermittent positive pressure ventilation for 1 week. Subsequent recovery was uneventful, and she was discharged from hospital 1 month later on 20 mg prednisone on alternate days, and 15 mg neostigmine and 60 mg pyridostigmine (Mestinon) 3 times a day. After a further month of this treatment the patient's condition started to deteriorate with gradually increasing weakness in the extremities progressing to respiratory failure, again necessitating tracheostomy and intermittent positive-pressure ventilation. Tensionil tests at intervals showed a slight improvement in some muscle groups but respiratory insufficiency remained a problem. Anticholinergic drugs and steroids were adjusted according to muscle weakness.

A decision to commence plasmapheresis was made 8 months after the initial diagnosis of myasthenia gravis. Intensive daily 2-litre plasma exchanges via an arteriovenous shunt were carried out for 2 weeks, during which time immunosuppressive therapy with 50 mg azathioprine and 50 mg cyclophosphamide a day was commenced. The patient (50 kg body weight) showed clinical improvement only after the 6th week of this regimen, reflected in steady increase in the strength of respiratory and neck muscles, with concomitant increase in vital capacity.

Acetylcholine receptor antibody titres were monitored (Fig. 1). It can be seen that the pretreatment level between 39 and 54 x 10^9M reverted to a stable post-plasmapheresis level of approximately 4 x 10^9M.

![Fig. 1. Response in acetylcholine receptor antibody titre to plasmapheresis.](image-url)

An attempt to reduce maintenance immunosuppressive therapy was unsuccessful, leading to recurrence of clinical signs and symptoms. Increase in anticholinergic drugs, immunosuppressive therapy and repetition of plasmapheresis were again successful. The patient was eventually discharged home 11 months after her second relapse on maintenance doses of 50 mg azathioprine daily,
60 mg pyridostigmine 4 times a day, and 30 mg prednisone on alternate days with weekly plasmapheresis. The plasmapheresis was gradually reduced and was discontinued 7 months later.

At the present time the patient leads a normal life with only minor weaknesses in the bulbar muscles, reflected in nasal speech.

Case 2

A 60-year-old woman developed bulbar symptoms with dysphonia and dysphagia 2 years before referral. The diagnosis of myasthenia gravis was confirmed on testing, and mediastinal tomography showed a tumour mass which was uneventfully resected. Histological examination showed a benign thymoma. Transient clinical response followed the operation and relapse was controlled with anticholinesterase drugs.

Eight months before the present admission further deterioration necessitated corticosteroids (prednisone 1 mg/kg) with short-lived improvement in bulbar symptoms. In the previous 6 months there had been steady deterioration, with marked change in speech and inability to eat. All nutrition was provided by means of nasogastric intubation. On examination there was prominent nasal speech and classic muscle fatigue on repetitive movements.

In the face of a refractory and progressive bulbar myasthenia, prednisone (0.5 mg/kg/24 h) and azathioprine (2 mg/kg/24 h) were added to the established cholinesterase regimen, and plasmapheresis against fresh frozen plasma was commenced 3 times a week. The response was dramatic. The speech started to revert to normal after the second 2-litre exchange and within 1 week the patient was able to swallow normally and eat solid foods.

Comment

In patients with myasthenia gravis the elaboration of an antibody directed against acetylcholine receptors on the motor end-plate interferes with normal muscular function and is thus considered to arise on an auto-immune basis. The first essential step is to remove any mediastinal tumour that may exist since therapy is less satisfactory in patients with a thymoma. Attempts to prolong the survival of biologically produced acetylcholine by giving cholinesterase inhibitors remains the standard form of medical management. In patients where this is unsuccessful, and, particularly where antibody can be demonstrated in plasma, immunosuppressive regimens combining corticosteroids and either azathioprine or cyclophosphamide are rational third lines of treatment. When these measures are unsuccessful, intensive plasmapheresis to remove a percentage of the antibody has recently been introduced. Most of the experiences suggest that the greatest benefit is found in the early stages of treatment while immunosuppressive drugs are producing their effect. This was clearly the case in the one patient, but the good response may have been due to immunosuppressive drugs, plasma exchange or both. From experience with the other patient it appears that not only is plasmapheresis now an important form of treatment in the patient with refractory myasthenia gravis, but, notably, considerable periods of time may elapse before clinical improvement becomes manifest.

It is therefore clear that while many patients will respond to early intensive plasmapheresis, failure to achieve objective improvement within the first 4-6 weeks should not be considered a contraindication to maintaining an intensive programme of plasma exchange for more prolonged periods.

Case 3

A rhesus (D)-negative woman with a history of 2 previous pregnancies presented in June 1979 at 26 weeks’ gestation. The first pregnancy in 1968 had been uncomplicated and a normal infant was delivered at 40 weeks showing no signs of jaundice. Following this pregnancy, anti-Rho (D) gammaglobulin was not administered. The latter procedure is now standard practice to prevent Rh iso-immunization. During the second pregnancy increased levels of anti-Rho (D) antibody were detected. This infant was delivered by caesarean section at 38 weeks and required two exchange transfusions.

On presentation with the third pregnancy the anti-Rho (D) titre was 1:256 and amniocentesis showed a raised optical density density (ODD) level of 0.544, which is in the upper zone of Liley’s graph. The serum bilirubin level was 9.4 µmol/l, and serum protein was 5.5 g/l. These findings suggested a severely affected fetus.

Plasmapheresis began at 27 weeks, when the anti-Rho (D) titre was recorded at 1:256 by the antiglobulin technique. On alternate days plasmapheresis (50 ml/kg) was performed, with an effective reduction in antibody titre (Fig. 2). A caesarean section was performed at 32 weeks’ gestation with no complications in the mother. The infant required four exchange transfusions and the total serum bilirubin level rose to 350 µmol/l. During each exchange transfusion this level was lowered. Thirty-six hours after birth the infant developed respiratory distress and required intubation and ventilation with positive pressure for 104 hours. No further complications occurred, the infant commenced oral feeding on the 42nd day and continued to improve until it was discharged on the 58th day.

![Fig. 2. Anti-Rho (D) titre before and after plasma exchange.](image)
Comment

Rhesus iso-immunization, particularly when high antibody levels are present in the mother, is a major risk factor for neonatal jaundice. To prevent the development of hydrops fetalis delivery would be required at a time during gestation when the fetus is at risk from the respiratory distress syndrome. In the normal course of events iso-immunization is prevented by the administration of anti-Rho (D) immunoglobulin in any situation where the mother is at risk of fetomaternal haemorrhage. Failure to deliver such prophylactic therapy with the subsequent development of rising titres in the mother has until recently presented a major challenge for the obstetrician. The availability of continuous-flow plasma exchange, as illustrated by this case, is an effective means for the management of this clinical syndrome.

Case 4

A 15-month-old girl presented with frequency, dysuria and fever. A diagnosis of acute pyelitis was made and treatment commenced with sulphonamides and streptomycin. Some improvement was evident after 3 days, but a week later the child was still listless and anorectic. Examination showed pallor of the mucous membranes, a firm, non-tender 4 cm splenomegaly, and a soft, non-tender hepatomegaly. The haemoglobin concentration was 9 g/dl and a diagnosis of haemolytic anaemia was made. Further investigation showed a reticulocyte count of 11%, and a serum bilirubin value of 42.5 μmol/l. Sickling of red cells was noted on a peripheral blood smear. Haemoglobin electrophoresis confirmed the presence of large concentrations of Hbs. During childhood two further crises arose after upper respiratory tract infections, each associated with a fall in haemoglobin levels. Further growth and development was normal.

At the age of 19 years the patient presented with upper abdominal pain. An oral cholecystogram confirmed the clinical diagnosis of cholelithiasis. An elective cholecystectomy was planned, and to prevent sickling of red cells during general anaesthesia and the operation, it was decided to use continuous-flow red cell exchange to reduce the Hbs level. Before this procedure, the haemoglobin level was 8 g/dl of which 2.3% was HbA, 85.3% HbS and 11.4% HbF. After an exchange procedure (2.825 ml) and the addition of 750 ml of blood the haemoglobin level was 11.8% g/dl, HbA had risen to 90.8%, HbS was reduced to 5.2% and HbF to 2.4% (Fig. 3). The exchange transfusion was performed without any side-effects and the operation and postoperative course were uncomplicated. Thirty days later, at follow-up, the HbA had returned to 85.9%, HbF was 4.0% and HbAs was 8.1%.

Comment

Although a similar reduction could have been obtained by single-unit exchanges, the ease and convenience for patient and attending physician using continuous-flow procedures represents a substantial advance in managing patients with these problems.

Although not common, homozygous Hbs production results in clinical syndromes which may become symptomatic with precipitating causes such as hyperoxia, infection, dehydration and acidosis. The availability of a technique which can rapidly and efficiently exchange HbA for Hbs with each crisis may be a life-saving measure.

Case 5

In May 1975 a 17-year-old girl presented with a 1 month history of backache and headaches. The headaches involved the whole cranium, but did not interfere with sleep, and the backache was associated with strenuous exercise involving the left lower lumbar region. Examination showed pallor of the mucous membranes and tenderness over the left lumbar area. Lymphadenopathy and splenomegaly were present. The peripheral blood smear showed a haemoglobin level of 6.3 g/dl, a white blood cell count of 26.3 x 10⁷/l with 97% lymphoblasts, and a platelet count of 68 x 10⁹/l. Examination of the bone marrow was diagnostic of acute lymphoblastic leukaemia (FAB-L1).

Induction was commenced with vincristine (2 mg) and prednisone (60 mg/d) given once a week. After 6 weeks of this therapy, bone marrow examination confirmed complete remission. Craniospinal prophylaxis was commenced with biweekly lumbar punctures for 3 weeks and thereafter monthly, with the administration of intrathecal methotrexate (12 mg/m²) alternating with cytosine arabinoside (30 mg/m²).

Maintenance therapy was commenced with thioguanine (40 mg/d), the dose being monitored by the peripheral blood count. During this period the patient developed pancytopenia with nausea and vomiting, requiring discontinuation of therapy. Four months after the induction period the peripheral blood count showed 21% lymphoblasts. Various combinations of drugs were then administered without success and 3 months later the blast count was 72% and the bone marrow had been totally replaced by leukaemic infiltrate. Periods of pancytopenia associated with infection required antibiotic therapy and granulocytic support. A decision was made to undertake bone marrow transplantation for drug-resistant disease. Although the donor and recipient were HLA-identical and MLC-non-reactive, the recipient's blood group was B Rh-positive, and that of the donor AB Rh-positive. Prior to the transplantation a preliminary plasmapheresis was performed against AB plasma. Six litres were exchanged over a period of 6 hours. The baseline anti-A titre before the procedure was 1:512 at 4°C and 22°C, on completion the anti-A titre was 1:16 at 4°C and 22°C. (Fig. 4).
Continuous-flow plasma exchange is a practical method for reducing naturally occurring iso-agglutinin so that bone marrow transplantation may be carried out across the barrier of blood group incompatibility. This is likely to be an unusual indication but again illustrates the central role that these instruments have come to occupy in leukaemia and bone marrow transplantation services.

**Discussion**

There are a number of clinical situations where symptoms of ill-health arise from an abnormality in either plasma or red cells. Examples of the former are hyperviscosity in the patient with myeloma, antibody-mediated disease such as Goodpasture's syndrome and rheus iso-immunization, immune complex disorders including rheumatoid arthritis, systemic lupus erythematosus, and neureitis or the autoimmune disease exemplified by myasthenia gravis.

Special interest centres on thrombotic thrombocytopenic purpura. Initially, plasmapheresis was shown to be effective in controlling the disease but subsequently infusion of fresh frozen plasma appeared to be equally effective. More recently the controversy has been reopened, and at present continuous-flow exchange against fresh-frozen plasma would appear to be the safest course to follow. It has been shown that after bites from certain venomous snakes the poison is limited to the plasma compartment and that the patients would benefit from removal of this pool of venom. Poisoning, for example by paracetamol overdose, is also amenable to treatment in this way.

In a pilot study we have reported the use of this technology as one approach to the mobilization of xanthomatous hyperlipidaemia. The resolution of the skin changes was associated with decrease in angina pectoris and may therefore reflect parallel reduction in coronary arterial atheromatous plaques. A prospective controlled study is now to be started to establish the possible role of long-term plasma exchange in the treatment of selected heterozygous hyperlipidaemic patients. Similarly, for the red cells, the ability to remove pathological haemoglobins from the circulation, particularly in situations where they pose short-term problems, is of great benefit to the patient.

In each of these situations exchange procedures using the older approach in which single units are collected and replaced are perfectly feasible but cumbersome and time-consuming. The introduction of this newer method centred around continuous-flow blood fraction separators has greatly increased the number of conditions amenable to control by a variety of exchange techniques. To avoid abuse of a costly procedure and to accumulate scientific data as opposed to further proliferation of anecdotal experience, it is stressed that patients being treated in this way be restricted to a limited number of centres and be entered on a carefully designed protocol study. Attempts to bypass such a structured approach will delay accumulation of the data necessary to place in perspective the role that continuous-flow plasma or red cell exchange has to play in clinical practice.

Although these machines provide excellent safeguards for the patient, each procedure is potentially dangerous. It is therefore mandatory to have constantly present a highly trained and expert staff thoroughly familiar with all aspects of machine operation. In practice we have
Premature gonadal failure

J. V. VAN DER MERWE

Premature gonadal failure is a relatively rare cause of amenorrhoea, with an approximate incidence of 4.8%. Apart from intense psychological, sociological, and practical implications of this condition, health-threatening associations are also well known. The association with other endocrinopathies is well documented. A higher incidence of ischaemic heart disease and severe osteoporosis is also associated with premature ovarian failure. Patients with premature gonadal failure are often subjected to unnecessary and extensive examinations for infertility. Furthermore, not much is known as regards the aetiology of this condition. This study was undertaken to illuminate the diagnostic procedures important in the management of these patients, as well as the aetiology of the condition.

Date received: 11 June 1980.

Patients and methods

Fifty patients with hypergonadotrophic amenorrhoea under the age of 40 years were studied. Obvious cases of intersex or gonadal dysgenesis were excluded.

Depending on whether normal sexual characteristics were present, these patients were divided arbitrarily into a primary and secondary gonadal failure group, a classification of which is seen in Table I.

Comparison of Filtration to Continuous-Flow Centrifugation for Plasma Exchange

Lucille Wood, Rodney Bond, and Peter Jacobs

The University of Cape Town Leukaemia Centre and The Department of Haematology, Groote Schuur Hospital, Observatory, Cape Town, Republic of South Africa

The Asahi Plasmaflo Hollow Nylon Fibre Filtration System (n = 13) was directly compared to the NCI-IBM 2990 Continuous-Flow Blood Fraction Separator (n = 10) for plasma exchange. The systems were equally efficient in achieving plasma separation. There were significant differences favouring filtration for clearance of fibrinogen (P < 0.05), and the fourth component of complement (P < 0.01). Greater loss of urea (P < 0.05) was found after plasma exchange, using the cell separator. The flow characteristics were markedly different. In a standardized 4-L plasma exchange, filtration took place at 35 ml/minute, with a procedure time of 109 ± 45 minutes in contrast to centrifugation at a plasma flow collection rate of 19 ml/minute, requiring 208 ± 17 minutes. This time advantage for the former procedure was offset by 195 minutes required to regenerate the hollow nylon fibre unit and a further 90 minutes required for cleaning under strictly controlled aseptic techniques prior to reuse. Each filter was regenerated at least twice and reused without infection, but there was incremental loss of filtration efficiency demonstrated by decreasing clearance of an intravascular marker dye. In two of the 13 procedures using the Plasmaflo system, serious reactions necessitated termination of the procedure; this did not occur using the cell separator. Restriction of the number of times that the filter unit could be regenerated without loss of efficiency, the prolonged time required for regeneration and cleaning, coupled with the need for artificial vascular access to meet high blood flow rates required, limit the usefulness of this technique for plasma exchange.

Key words: filtration, hollow nylon fibres, continuous-flow centrifugation

INTRODUCTION

The ease and relative safety with which large volumes of plasma can be exchanged is the result of technical advances, culminating in the development of blood fraction separators and filtration techniques. Increasing experience has shown that such procedures can favorably influence the clinical course in a number of diseases, some of which are immunologically mediated [1–11]. However, much of the experience is anecdotal, and controlled studies will be necessary to define those entities where plasma exchange is likely to have major benefit. Among the other applications currently being evaluated are conditions characterised by quantitative and qualitative changes in normal plasma constituents, such as antibodies [5] and cholesterol [12]. More recently, improvement in patients with thrombotic thrombocytopenic purpura has been attributed to restoration of normal plasma constituents using this technique [13–15].

The increasing therapeutic application of this procedure has inevitably resulted in its use by less-experienced operators, so that maintenance and improvement in safety is an important technical objective. At the same time, rising costs have focused attention on new developments to enhance filtration efficiency, shorten exchange times, and explore methods for improving cost-effectiveness by reusing expensive items such as the filters.

In a prospective study, filtration using the Asahi Plasmaflo Hollow Nylon Fibre Unit was compared to continuous-flow centrifugation on the NCI-IBM 2990 Blood Fraction Separator. The physical requirements of each procedure, including filtration efficiency and donor response, were determined and the effects of regenerating the filter units on subsequent performance established.

PATIENTS

Patients with myasthenia gravis or immunoproliferative disorders were serially studied. The protocol was approved by the university and hospital ethics committee, the patients were fully informed of all aspects of either procedure, and signed consent was obtained.

MATERIALS AND METHODS

Haematological and biochemical measurements were determined before and after each procedure using the

Received for publication February 2, 1983; accepted October 12, 1983.

Coulter Counter Model S-Plus (Hialeah, FL) [16] and the Multi-Channel Analyser (Technicon, NY) [17], respectively. Standard techniques were used for determination of plasma protein by electrophoresis [18], immunoglobulins [19], haptoglobin [20], prothrombin time, partial thromboplastin time and fibrinogen [21], plasma haemoglobin [20], and total haemolytic complement as well as C3 and C4 components [22]. The presence of residual formaldehyde in the filters was determined by the Sjörenson's formal titration using the interaction with amino acids described by Schiff [23].

Blood cultures were performed on all patients undergoing plasma exchange, using the regenerated filtration units.

Filtration efficiency of the hollow nylon fibre filter was assessed by serially measuring clearance of the intravenous marker, Evans' blue dye [24]. Determinations were based on optical density and carried out at fixed intervals during the course of eluate formation. Serial studies were carried out using filters and comparing the initial slope for dye clearance to similar curves following one, and then two, regeneration procedures.

**Asahi Plasmaflow Hollow Nylon Fibre Filter**

Thirteen procedures were carried out using this system. The filters are made from cellulose di-acetate fibres with an effective surface area for exchange of 0.65 m² and a maximum pore size of 0.2 μm. These are housed in a synthetic polymer sleeve and the entire unit gas sterilized.

Whole blood filtration rates in excess of 100 ml/minute are required for optimal filtration, defined as filtrate formation at approximately 30% of flow rate. Although it is certainly possible to achieve flows of 200 ml/minute, this was found to be associated with hypotension, whereas rates between 100 and 120 ml of whole blood/minute were tolerated without fluctuations in blood pressure. To sustain these flow rates creation of an arterio-venous fistula or placement of a Scribner shunt [25] was necessary.

The output line from the patient (Fig. 1) passes sequentially through a roller pump, a blood microaggregate filter with airlock warning device (Pressure Isolator, model RSA 4410, Surgiprod, South Africa), a pressure monitor (Tycos Gauge, 5090/03), and into the fibre unit. Plasma leaving the pores is collected at the opposite end of the filter. Whole blood passing through the hollow nylon fibres is collected at a second microaggregate filter, filled with the same airlock device and pressure monitor, and flow adjusted to maintain transmembrane pressures below 100 mm of mercury by adjustment of flow rate. The filtered plasma is replaced with exactly equal volumes of 2.5% albumin in Ringer's lactate solution which is pumped into the whole blood line proximal to the second filter by means of a roller pump. The reconstituted whole blood is returned to the patient and since the volume removed accurately matches that replaced, the entire procedure is isovolaemic.

Prior to initiating the exchange, the filter is primed using 1,000 ml of physiological saline containing 50 mg (1 mg = 100 international units) of heparin as anticoagulant; further heparin is given at a rate of 20 mg for each litre exchanged.

Filters are regenerated after completion of the procedure by removing residual plasma with an air-rinse technique. Tap water is passed through the filter at a rate of 500 ml/minute for 2 hours to clean the core of the hollow nylon fibres. The tap water was not sterile, although it is the subject of regular water testing as defined by the local authority [26]. The rinsed filter is stored in 3% formaldehyde solution for a minimum of 48 hours, or until required. Prior to second or subsequent use, the formalin is removed by allowing 10% of sterile physiological saline to flow into the fibres and out through the plasma collection port. No formalin could be detected in the eluate [23]. Fluid from the final rinse was cultured for bacteria and fungi, using standard methods [27,28].

**NCI-IBM 2990 Continuous-Flow Blood Fraction Separator**

Ten procedures were carried out using this separator with ACD-A as anticoagulant and percutaneous venous access as previously described [29]. This instrument has
a reusable polycarbonate bowl which is cleaned and gas-
sterilised between procedures. Centrifugal speeds were
1600 rpm and total whole blood flow rates were 40 ml/
minute with isovolaemic plasma exchange taking place at
20 ml/minute.

Preparation of Equipment

Both systems required approximately 30 minutes for
priming, but the shorter procedure time for the filtration
method was offset by the laborious nature of filter regen-
eration, which required 195 minutes and a further 90
minutes for cleaning under strictly controlled aseptic
technique prior to reuse.

Patient Monitoring

The physical characteristics of each procedure were
constantly monitored, and they included whole blood
flow, filtration rates, and transmembrane pressures. Pa-
tients were under continuous observation for changes in
vital signs or development of symptoms, with special
attention given to hypotensive, haemolytic, or febrile
reactions. Before and after the procedure full blood count,
biochemical profile, and haemostasis screening tests were
carried out.

Statistics

Statistical analyses were carried out using standard
methods [30,31].

RESULTS

Filtration Rates

Twenty-three plasma exchanges were performed, each
of 4 L. Both filtration (n = 13) and centrifugal separation
(n = 10) were carried out in a cell support unit and
patients were constantly supervised by one of the invest-
gigators. The filters were regenerated using a strict aseptic
technique.

The plasma collection rates were significantly faster
with the membrane filtration technique at 35 ml/minute,
resulting in a mean procedure time of 109 minutes (SD
± 45 minutes) in comparison to 19 ml/minute using the
separator, with a mean procedure time of 208 minutes
(SD ± 17 minutes).

Haematologic Data

During the course of filtration minor differences were
demonstrable in packed cell volume, total white cell
count, and platelet count between the beginning and the
end of the procedure (Table I). Similar changes were
demonstrable during the course of continuous-flow filtra-
tion (Table II). However, when the percentage change
for these measurements was compared between the two
procedures, statistical significance (P < 0.001) was
achieved only for the total white cell count, where greater
rise was demonstrable in patients being treated by contin-
uous-flow centrifugation; at no time did white cell count
rise outside normal limits. It is not known whether this
rise reflects mobilization of the marginated granulocyte
pool or release of cells from the bone marrow, possibly
in response to circulation in the reusable polycarbonate
bowl. Appreciating that cell counts are concentration
measurements, we paid meticulous attention to maintain-
ing balance between plasma removed and replaced in
both systems to ensure that changes measured were ab-
solute and did not merely reflect differences in fluid
balance during the course of the procedure.

Biochemical Changes

During the course of filtration and continuous-flow
separation, changes were demonstrable between the be-
ginning and the completion of the procedure (Tables I,II)
and statistical changes were also evident when the two
systems were compared (Table III).

Plasma collection was achieved with equal facility in
both systems. The filtration technique more efficiently
removed fibrinogen (P < 0.05) and the fourth compo-
nent of complement (P < 0.05). In contrast, centrifuga-
 tion resulted in greater reduction of urea (P < 0.05).

Filtration Efficiency

In 500 consecutive procedures, the separation charac-
teristics of the reusable polycarbonate bowl in the NCI-
IBM 2990 instrument were found to be completely stable
and predictable [Wood and Jacobs, unpublished].

The Asahi Plasmaplo Hollow Nylon Fibre Filters
showed an incremental loss of efficiency when the slope
of the dye elution curve was compared between first,
second, and third procedures (P < 0.01) (Fig. 2). In
addition, there was reduction in clearance of the gam-
maglobulin fraction with each regeneration and reuse of
a particular filter (P < 0.02).

Procedure Safety

There were no untoward reactions in the group of
patients (n = 10) who underwent plasma exchange using
the NCI-IBM continuous-flow blood fraction separator.

Two of the patients (n = 13) undergoing exchange
using the Asahi Plasmaplo Hollow Nylon Fibre Filtration
System required termination of the procedure because of
serious reaction. The first patient became hypotensive
early during the procedure and failed to respond to infu-
sion of intravenous fluids. This patient subsequently
underwent plasma exchange using the filtration system
on a further four occasions without incident. In a second
patient, haemolysis occurred associated with an elevation
of the free plasma haemoglobin after 3,500 ml of eluate
had been collected. The procedure was discontinued but

the same filter regenerated successfully and the patient underwent further plasma exchanges without incident.

Culture for bacteria and fungi in the patients and the regenerated filters failed to reveal any abnormality.

Intravenous supplementation of calcium and potassium were administered prophylactically to both groups of patients, so that comments about changes in these cations is not possible. Donor symptomatology and vital signs of all patients in both groups were no different, apart from the two incidents described above.

**Cost**

A single filtration procedure cost $672.00 and that on the cell separator $385.00 (Table IV).

**DISCUSSION**

Plasma exchange using continuous-flow blood fraction separators is now an established technique for the management of patients with plasma hyperviscosity, although it may be useful in the treatment of a number of diseases mediated by circulating immune complexes or antibodies.

![Fig. 2. Changes in efficiency following hollow nylon fibre filter regeneration. The intravascular marker dye, T-1824 or Evans blue, is measured at 620 nm against the eluate in ml. There is decreasing efficiency between first use of the filter (●, n = 3), second use (△, n = 2), and third use (■, n = 4).](image-url)

[2, 28, 32]. Nevertheless, there is not yet consensus about all the indications for plasmapheresis and therefore, not surprisingly, a very wide range of clinical syndromes are currently being intensively studied. These investigations have been encouraged by the extensive testing and relative safety of these separators [2], although it is not yet adequately appreciated that morbidity and even mortality is associated with their use [33]. Furthermore, apart from the capital outlay for the purchase of the instruments and the salaries for the staff, the cost of plastic and exchange fluid is currently around $350.00 for each procedure.

It is against this background that new techniques must be assessed. Membrane filtration, using the hollow nylon fibre filter, has been demonstrated as an effective means for plasma exchange [34–36], achieving 60% reduction of total protein from initial levels and a decrease of fibrinogen by 50% in the course of a single procedure; our results compare favourably with these figures. Packed cell volume changes, although small, were significant for the individual procedures (P < 0.01) during the course of the plasma exchange but were not different for the two methods (P < 0.05). The significantly elevated total white cell count is different between the two procedures and contrary to published reports [34–36]. The increase was never outside the upper limit of normal, and redistribution of the margined granulocyte pool would appear the most obvious explanation for elevation of count in the absence of infection or the administration of drugs known to produce similar change. It is not known whether this may reflect elution of some stimulator substance from the reusable bowl or the membrane, since a similar change occurred with the filters.

Although the mean packed cell volume and platelet counts were lower in a group of patients treated on the filters than those on the separators there were, within each series, subjects who could be studied at roughly comparable levels. In each of these individual comparisons the data were consistent with that recorded for the total group. Similarly, it is apparent that mean blood urea levels, although not those for creatinine, were also different between the two groups. The explanation for this is found in one patient with severe renal failure altering the mean level. Here again there were sufficient observations lying in the normal range amongst procedures carried out with the filtration technique to ensure that the group characteristics were reliable and reflected the same pattern of change seen before and after individual plasma exchanges. The results of statistical analysis when com-

The figures are those currently prevailing in the Cell Support Unit at the University of Cape Town and Groote Schuur Hospital during the study period in 1982.

Comparing filtration to centrifugation are not influenced by the different mean urea levels. Unlike the plasma fibrinogen level which fell with both procedures, significantly more so with the filtration technique, only minor changes were recorded in the prothrombin and partial thromboplastin times: None of these reached statistically significant levels.

The advantages of the Plasmaflo Hollow Nylon Fibre Filter System include faster filtration rates, shorter procedure times, and a cell-free eluate obtained with ease of operation and patient accessibility. The first two of these considerations are at the expense of high whole-blood flow rates required by this technique, so that artificial venous access in the form of an arterio-venous shunt is a necessity. It needs to be emphasized that, although no difficulties were experienced in this study, the creation of such vascular access is not without risk, including disconnection of the exteriorised shunt with exsanguinating haemorrhage or shunt occlusion. However, had percutaneous venous cannulation been used, the filtration rate with the Plasmaflo system would be less than the corresponding rate for the centrifugal continuous-flow method, with both a time penalty and an inability to sustain flow rates essential for efficient plasma separation. The hardware necessary for both methods is equally mobile so that there is no advantage for the Plasmaflo system in treating patients nursed away from the main separator unit, as would occur in the intensive care wards.

Excluding the initial cost of the two systems and staff salaries, the disposable plastics for each procedure were found to be $310.00 for the cellulose acetate hollow nylon fibre filter compared to $77.00 for the cell separator. To be equally cost-effective, each filter would need regeneration. This requirement, although time consuming and cumbersome, can be achieved, and the use of regenerated filters was associated with a surprising lack of side-effects. The fall-off of efficiency, however, precludes a sufficient number of regeneration cycles necessary to compete with the cost of disposables employed in operating the separator. In addition, the potential risk to the patient, although not realised in our studies, together with the time required by a skilled member of staff, are compelling arguments against filter regeneration. Continued experience with this system and the development of expertise by staff members may, theoretically at least, partially offset these disadvantages.
Two serious reactions were encountered with the use of the Plasmaflo Hollow Nylon Fibre Filter System. The first was considered an allergic reaction to antigen contamination in the plasma protein replacement solution. The second was caused by haemolysis during the procedure. The transmembrane pressure did not exceed 100 mm of mercury and was insufficient to cause red cell breakdown. This patient suffered from Bence-Jones myeloma and it is theoretically possible that protein coating the membrane may have been responsible for this reaction. It is noteworthy that subsequent regeneration and reuse of the filter was uneventful.

It is recognised that plasma exchange separation is a function of centrifugal speed, packed cell volume, and operator selection of plasma and red cell interface. Furthermore, there is a need to adjust blood flow and the addition of anticoagulant to avoid the development of symptoms due to hypocalcaemia when ACD-A is employed. In contrast the membrane filtration system has, as its major limitation, the need to maintain whole blood flow rates at or above 100 ml/minute in order to obtain optimum efficiency. These factors which influence plasma collection are fundamentally different between the two techniques, but this prospective study showed that the Asahi Plasmaflo Hollow Nylon Fibre Filtration System has equal clinical utility to the NCI/IBM 2990 Continuous-Flow Blood Fraction Separator when comparable volumes of plasma are exchanged. However the inferior cost-effectiveness of the filtration system together with the need for the creation of artificial vascular access are considered to limit its clinical usefulness at the present time.

Studies on Platelets Contained in Eluates Following Filtration Leukapheresis

L. Kernoff, D. Shackleton, D. Dubovsky, K. Blake and P. Jacobs

From the Leukaemia Centre, University of Cape Town and the Departments of Haematology and Medical Physics, Groote Schuur Hospital, Cape Town, South Africa

Platelets eluted from nylon fiber filters after filtration leukapheresis have been studied. The platelet yield from 61 routine donations was $1.25 \pm 0.18 \times 10^{11}$ (mean ± SEM) corresponding to $1.78 \times 10^{9}$ per 500 ml blood processed. Filtered platelets labeled with radiochromate demonstrated reduced recovery in vivo 15 minutes after infusion (38.5 ± 1.7%) when compared to the control value (68.5 ± 6.8%, p < 0.001). The survival of those platelets remaining in the circulation after 15 minutes did not however differ from the control value. ADP (10 μM, 100 μM, 1 mM), adrenaline (100 μM) and collagen (7.25 mg/ml) added in vitro induced less aggregation of filtered platelets than normal control platelets and electron microscopy revealed structural abnormalities. It is concluded that recipients of granulocyte transfusions obtained by filtration leukapheresis are unlikely to be benefited by the platelets contained in these transfusions.

The high mortality from infection and hemorrhage that is associated with bone marrow suppression, has led to the development of improved methods of collecting granulocytes and platelets for the supportive care of patients in this clinical situation. These methods employ machines which selectively remove granulocytes and platelets from donor blood circulated through them, either by continuous or discontinuous centrifugation or by filtration through a nylon fiber filter. 13 Whereas both methods are used for harvesting granulocytes, only centrifugation is used as a method of collecting platelets. It has been observed that platelets are eluted together with granulocytes obtained by filtration leukapheresis. 9,12 The platelets might be of benefit to patients receiving granulocytes obtained by this method, as has been reported in patients receiving platelets obtained by other techniques. 4,6 Such benefit would be contingent upon the provision of platelets in sufficient number and of proper function. Since no such data was previously available, we have undertaken a study of these platelets and the results obtained form the basis of this communication.

Materials and Methods

Our procedure for routine filtration leukapheresis is to use two Leuco-Pak 14 nylon fiber filters set in parallel through which heparinized donor blood is perfused for 90 minutes at a flow rate of 40 ml per minute. Thereafter the adherent cells are eluted with 1,000 ml per filter of an ACD (125 ml), plasma (125 ml) and saline (750 ml) mixture of pH 6.5, accompanied by gentle mechanical tapping of the filters. The total number of platelets contained in each eluate was calculated as the product of the volume of the eluate and the platelet concentration. Platelet counts were performed on a Coulter Counter Model FN and data were obtained on 61 leukaphereses.

Platelet survival was studied in seven members of the hospital medical staff. Four-hundred ml of blood was collected into 60 ml ACD (NIH solution-A) and centrifuged at $300 \times g$ for 15 minutes in order to obtain platelet-rich plasma (PRP). The PRP was transferred to a satellite bag and the red blood cells returned to the donor. The pH of the PRP was adjusted to 6.3 ± 0.2 by the addition of approximately 15 ml of ACD and spun at 1,500 $\times g$ for 15 minutes in order to prepare a platelet pellet. All but 20 ml of the supernatant platelet-poor plasma (PPP) was transferred to a satellite bag. The platelet pellet was gently resuspended in the remaining 20 ml PPP and incubated with 400 μCl of isotonic sodium radio-
FILTERED PLATELETS

chromate ($\text{Na}_2\text{HCrO}_4$) at room temperature for 30 minutes. After incubation the platelets were washed twice with approximately 100 ml of PPP, particular care being taken to exclude contaminating red blood cells from the final labelled platelet suspension. Nonplatelet bound radioactivity constituted less than two per cent of the radioactivity in the preparation for injection. After injecting the labeled platelets, 5 ml samples of whole blood were obtained from the opposite arm at 15 minutes, one hour, three hours and daily thereafter whenever possible for eight days by which time the radioactivity had fallen to approximately 15 per cent of the 15 minute value. The whole blood samples were counted in a gamma spectrometer to a standard deviation of less than two per cent.

Platelet recovery is defined as the percentage of platelet-bound radioactivity (PBR) remaining in the blood 15 minutes after infusion. This value was calculated from the formula:

$$\frac{\text{PBR/ml Blood} \times \text{Blood Volume}}{\text{Total PBR injected}} \times 100$$

The blood volume was estimated from height and weight measurements.\textsuperscript{16}

In view of the uncertainty concerning the most appropriate model for analysing platelet survival curves,\textsuperscript{16} the observed data were fitted to linear and exponential functions, using a UNIVAC model 1106 computer, and platelet mean lifespan (MLS) was calculated for each decay model. For linear functions, the values of radioactivity $y_t$ at time $t$, were fitted by the method of linear least squares to the function $y(t) = a \cdot e^{bt}$ from which platelet MLS was obtained as MLS = $a/b$.

For exponential function $y(t) = a \cdot e^{bt}$ the data were fitted to the equivalent linear relationship, $\ln y(t) = \ln a - bt$ by the linear least squares method. Goodness-of-fit for linear and exponential

models was assessed by the chi-square test. The seven individual results for platelet recovery and platelet MLS were means to give a single value for the group.

Three to five months after the completion of the control measurement, the survival of filtered platelets was studied in the same seven volunteers, thereby enabling each individual to act as his own control. The most appropriate experimental design would have been to label platelets after their elution from the filter following a routine donation. However, because these eluted platelets could not be separated adequately from contaminating red blood cells prior to labeling, (essential since erythrocytes have a much higher affinity for radiocromate than do platelets), and because of uncertainties about the labeling characteristics in the eluting fluid medium, an alternative method of obtaining filtered platelets was devised, comparable, as far as was possible with the routine donation procedure. Blood was collected into ACD and platelets were labeled with radiocromate as for the control study. The red blood cells were returned to the donors and then 350 to 400 ml of blood were collected into 2,500 units of heparin, (two blood collections were necessary, since ACD blood was needed for labeling and heparinized blood is needed for filtration-elution). The labelled platelet preparation (20 ml) was added to this heparinized blood. The blood and added platelets were mixed by inversion and then by means of a rotary pump continuously circulated at a rate of 20 ml/minute through a single Leuco-Pak filter for 90 minutes. During this time one ml aliquots were sampled distal to the filter to observe the efficiency with which the filter extracted the platelets, and to ascertain whether the prior radioactive labeling of the platelets had in any way modified their behavior in relation to the filtration process. On completion of the procedure, the filter was removed and the adherent platelets eluted as described above. The eluate was concentrated by centrifugation and an aliquot was removed for platelet aggregometry. The remainder of the eluate measuring approximately 35 ml and containing a mean of 6.6 x 10^10 platelets, was injected

into the volunteers. Subsequent sampling and calculation of platelet recovery and platelet MLS being the same as for the control study.

Platelet aggregometry was performed on aliquots of the seven eluates as prepared above, and the eluates obtained from ten donors following routine leukapheresis for patients requiring supportive care. Citrated blood was also obtained from these persons in order to prepare control platelets and also to prepare PPP. The eluate was centrifuged for 5 minutes at 100 × g. The upper platelet-containing layer was removed and then the platelets were concentrated by centrifuging at 1100 × g for 10 minutes. The platelets were then resuspended in control PPP in order to restore the pH, fibrinogen and calcium ions necessary for aggregation. Both control and filtered platelets were adjusted to a concentration of 300 × 10^9/l. Aggregometry was performed within two hours using a Payton twin-channel aggregometer. The aggregating agents were used in the following final concentrations: ADP 10 μM, 100 μM, 1 mM, adrenaline 100 μM and collagen 7.25 mg/ml. The effect of these agents was recorded as the maximal increase in light transmission after 8 minutes on a scale where PRP corresponded to 0% transmission and PPP to 100%. The individual results obtained for control and filtered platelets with each agent were meaned and the significance of the difference between means assessed by Students t test.

Electron microscopy was performed on platelets from three eluates obtained for therapeutic purposes. Citrated blood for control platelets was obtained from the same three donors. The control PRP and the eluates were first fixed in phosphate buffered gluteraldehyde and post fixed in osmium tetroxide. The samples were dehydrated in 2% uranyl acetate in increasing concentrations of acetone, embedded, sectioned and stained with saturated uranyl acetate and 0.2% lead citrate.

Results

The average platelet yield per run was 1.25 × 10^10, (n = 61, SEM = 0.18 × 10^10), corresponding to 1.78 × 10^10 per 500 ml blood processed. The total platelet count and PBR in samples of blood having passed through the filter is demonstrated in Figure 1. Compared with the prefiltration values, a fall in both PBR and total platelet count was observed. The labeled platelets were initially extracted less well than the unlabeled platelets, the former falling to 18 per cent and the latter to 9 per cent of their prefiltration level at 1 minute. This difference was not however significant at the 0.01 level and the labeling procedure per se appears not to have adversely affected the platelets in respect to the filtration process.

The values for the total platelet count and PBR after 90 minutes of filtration were 26 and 30 per cent respectively. These values were greater than the corresponding 1 minute values, suggesting a net loss of platelets from the filter during filtration. The differences were not significant (0.01 < p < 0.05), and the majority of platelets can be considered to have been retained within the filter throughout the period of filtration.

Recovery 15 minutes after injection of control platelets was 68.5 per cent which is in good agreement with other series.13-15 The recovery of 38.5 per cent ± 1.7 of the filtered labeled platelets was significantly less than the control value (p < 0.001). This low recovery is most likely to be the consequence of damage caused to the platelets during filtration and/or elution, resulting in their rapid removal from the circulation. Lesser degrees of damage permitting the

Concentrations are final concentrations, and per cent aggregation that observed at eight minutes. C = Control platelets; F = Filtered platelets.
return of some platelets to the circulation presumably accounts for the slight increase in recovery observed during the first three hours of the survival study (Fig. 2).

The control platelet MLS was 213 ± 15 hours (mean ± SEM) and 116 ± 8 hours by the linear and exponential models respectively. These results are in agreement with other series.\textsuperscript{5,6,14} Filtered platelet MLS by linear and exponential functions was 203 ± 8 hours and 118 ± 5 hours respectively (Table 1). These values were not significantly different from the control. Although approximately half the infused filtered platelets are irreversibly damaged, as demonstrated by the low mean recovery value, those platelets not initially removed from the circulation survive normally. Whereas the control survival data are satisfactorily described by both linear and exponential functions, only the linear function fits the filtered data, the exponential fit being rejected. Accordingly only the linear least squares fit is presented (Fig. 2).

Maximum aggregation after eight minutes in response to the aggregating agents used, was in all instances less for the filtered platelets than for the control platelets. Using concentrations of adrenaline (100 µM) and ADP (100 µM, 1 mM) greater than is generally used for routine testing, did not significantly increase the degree of aggregation. Thus for all aggregating agents the difference between filtered and control platelets was significant (p < 0.01 or p < 0.001).

The data obtained on the seven specially prepared eluates are presented in Table 2, and the results obtained on the ten routine eluates are presented in Table 3.

Abnormalities of ultrastructure were noted in all three eluates studied and comprised degranulation or complete disruption of cells, (Fig. 3). Control platelets were not altered structurally.

Discussion

Continuous and discontinuous centrifugation permits the selective harvesting of granulocytes or platelets according to patient requirement, whereas nylon fiber filtration is employed for granulocyte harvesting alone.\textsuperscript{3} MacPherson et al.\textsuperscript{9} documented an average yield of 0.64 × 10\textsuperscript{11} platelets from five filtration leukaphereses, and Russel and Powles\textsuperscript{10} also noted the presence of platelets in eluates, but no data were presented. We have documented an average of 1.25 × 10\textsuperscript{11} platelets per leukapheresis. This amount bears favorable numerical comparison with 1.03 × 10\textsuperscript{11} for double manual plateletapheresis but not with mechanical methods for example 2.5 – 3 × 10\textsuperscript{11} for six cycle discontinuous centrifugation in ACD.\textsuperscript{4}
The function of the filtered platelets was greatly impaired. Deficient aggregation in response to three physiologic agents was observed. Although no ultrastructural abnormalities to account for abnormal aggregation were observed following discontinuous centrifugation, it is the present study defective aggregation can, at least in part, be explained by platelets having already undergone partial degranulation. Additional evidence of platelet damage was provided by the 51Cr study in which approximately one half of the platelets were removed from the circulation within 15 minutes of infusion. Those platelets remaining in the circulation, even though they have a normal lifespan, are unlikely to be of value since their number (approximately $0.6 \times 10^{11}$) is less than that which could be expected to obtain satisfactory increments in recipients. Any effect is likely to be further diminished, by the presence of the associated fever and infection for which purpose the granulocyte transfusions are being administered.

Platelets were collected using the dual-channel module on the IBM 2997 Blood Fraction Separator. We carried out 320 procedures to harvest platelets for therapeutic purposes and yielded 5.1 ± 1.5 × 10¹¹ platelets (mean ± SD). Infusion into previously unsensitized recipients with hypoplastic or aplastic thrombocytopenia achieved increments at 1 hr of 19 ± 7.3 × 10⁹/liter/m² (mean ± SD) and at 24 hr of 15 ± 6.3 × 10⁹/liter/m². The only consistent donor reaction was mild hypocalcaemia, easily corrected by calcium gluconate infusion. Changes in donor packed-cell volume and white cell count were not statistically altered (p > 0.05) but donor platelet counts fell from 216 ± 43.1 × 10⁹/liter to 162.5 ± 41.7 × 10⁹/liter (mean ± SD; p < 0.01). Additional plateleterapheresis were carried out in seven normal volunteers, using the same technique, in order that the function of the harvested platelets could be studied. Following radiochromium labelling and reinfusion into the same donors, normal in vivo recoveries were obtained at 10 min (59.4 ± 3.4%; mean ± SD) and platelet mean life span was also normal (218 ± 12 hr; mean ± SD). Furthermore, in vitro platelet factor III availability and aggregation patterns of the harvested platelets did not differ from control values and their ultrastructural appearance was normal.

Key words: survival, aggregometry, ultrastructure, therapeutic transfusions

INTRODUCTION

Thrombocytopenic bleeding, due to bone marrow suppression, exposes patients to significant morbidity and mortality. Clinical studies have demonstrated the value of platelet transfusions in the management of such individuals [1]. The effectiveness of this therapy, however, depends on obtaining a sufficient number of normally functioning platelets from donors for infusion, a problem that has largely been resolved by the use of blood cell separators [2–4]. Cell collection, including platelets, has been based on adaptations of plasmapheresis techniques [5]. In the earlier instruments, centrifugation took place in reusable polycarbonate bowls, but disposable plastic channels have now replaced these cumbersome and potentially dangerous components of the older instruments [6–8].

More recently, the collection channel has been redesigned to enhance the efficiency of platelet collection further [9], and we report our experience of plateleterapheresis with this dual-channel module, used in conjunction with the IBM 2997 continuous-flow blood cell separator.

MATERIALS AND METHODS

Platelet Donations for Therapeutic Purposes (N = 320)

Donors fulfilling standard criteria [10] were given a full description of the nature of the procedure and gave written informed consent. Full blood counts [11], differential [12], and platelet counts [11,13], were performed on each donor before and after plateleterapheresis. This procedure was carried out using the dual-channel module on the IBM 2997 Cell Separator following priming with physiological saline containing acid-citrate-dextrose (ACD-A; Fenwal Laboratories, Morton Grove, IL) at a ratio between 1.65 and 1.75 to whole blood as determined by donor packed cell volume. Blood was removed and returned to the antecubital veins, using a 16 gauge cannula (Intracath, Johnson & Johnson, South Africa).

The flow rate was 42 ± 8 ml/min at a centrifuge speed of 2400 rpm. Anticoagulation was maintained during the procedure with one part of acid-citrate-dextrose to seven parts of whole blood. Blood samples were collected during the procedure in order to monitor platelet count, haemoglobin concentration, and packed cell volume.

Studies on Normal Volunteers (N = 7)

Brief Report: Platelet Collection on the Cell Separator 259

University and Hospital Ethics and Research Committee. The pH of approximately 100 ml of platelet-rich plasma was adjusted to 6.5 ± 0.2 by the addition of further ACD-A and incubated with 400 μCi of sodium radiochromate, according to the recommendations of the International Committee for Standardization in Hematology [14]; the efficiency of labelling under these circumstances is approximately 10%. Following injection of the radiolabelled platelets, 5-ml samples of whole blood were obtained from the opposite arm at intervals of 10 min, 1 hr, 3 hr, and daily thereafter for 8 days. The level of radioactivity in these samples was counted in a gamma spectrometer (Packard, Model 3820, IL) to a standard deviation of 1%. Platelet recovery was defined as the percentage of the injected platelet-bound radioactivity remaining in the circulation 10 min after injection and was derived from the formula:

\[
\text{Recovery} = \frac{\text{cpm/ml} \times \text{blood volume}}{\text{total radioactivity injected}}
\]

Blood volume values were derived from standard tables [15]. Platelet survival curves from the observed radioactivity data were used to calculate platelet mean life span using a linear function [16].

Platelet aggregometry. A control blood sample was obtained from donors at the start of the procedure and anticoagulated with ACD-A using the same ratio of blood to anticoagulant as that required for the apheresis procedure. This sample was immediately centrifuged to obtain platelet-rich and platelet-poor plasma. Platelet counts were determined by phase contrast microscopy [17] or the Coulter Counter (model ZF) or Thrombocounter-C (Coulter Electronics Incorporated, Hialeah, FL) [11]. The postapheresis sample was taken directly from the collection bag at the conclusion of the donation. No additional anticoagulant was added to the sample and the virtual absence of contaminating red cells made additional centrifugation unnecessary. These harvested platelets were counted and the level adjusted to correspond to the control sample by the addition of appropriate volumes of autologous platelet-poor plasma. The level of calcium was adjusted to 2.2 mmol/liter, where necessary, with calcium chloride.

Platelet aggregation was carried out by the method of Born and Cross [18], using the Payton Twin-Channel Aggregometer (Payton Associates Incorporated, Roswell Park, NY). The final concentration of the aggregating agents was ADP 10 μM, 100 μM, and 1 mM (Sigma Chemical Company, St Louis, MO), adrenaline 100 μM (Wyeth Laboratories, Philadelphia, PA), and collagen 7.5 mg/ml (Type V, Sigma Chemical Company, St Louis, MO). The effect of these agents was recorded as the maximum increase in light transmission after 8 min on a scale where platelet-rich plasma corresponds to 0% transmission and that for platelet-poor plasma to 100%. The individual results obtained from control and apheresis platelets, with each agent, were expressed as a mean, and the significance of the difference between the means assessed by the Students t test [19].

Platelet factor III availability. This was assayed using standard methods [20,21].

Ultrastructure. Samples of control and harvested platelets were concentrated by centrifugation at 200 g, fixed in phosphate-buffered gluteraldehyde, and postfixed in osmium tetroxide. The samples were block stained in 2% uranyl acetate in 10% acetone and then dehydrated with increasing concentrations of acetone and embedded in spars resin. Sections were prepared on a Reichert Ultratome (UM3) and stained with uranyl acetate and 0.2% lead citrate. The sections were viewed with a Siemens Electron Microscope (Model 101A).

RESULTS

Platelet Donations for Therapeutic Purposes

The mean procedure time was 87 ± 13 min and in no instance was this discontinued because of mechanical failure. In 35 patients, 11% mild hypocalcaemic symptoms developed, which were rapidly reversed after the infusion of 10 ml of 10% (w/v) calcium gluconate (Glaxo, England). A single patient developed transient vasovagal attack during the venipuncture.

The volume of blood processed was 4190 ± 533 ml (mean ± SD). The product volume in the collection bag was 238 ± 27 ml (mean ± SD). Packed red cell volume was 0, and contaminating leucocytes were 0.2 ± 0.30 × 10⁹/liter (mean ± SD).

The absolute platelet yield was 5.1 ± 1.45 × 10¹¹ (mean ± SD). The extraction efficiency, defined as the yield of platelets divided by the number presented to the machine, multiplied by the volume processed, was 62.11% and is therefore superior to the 51% reported for platelets harvested using the single channel module [7]. The platelet yield was significantly correlated with the volume processed (r = 0.89; p < 0.001) and the platelet precursor (r = 0.51; p < 0.01). There was no statistically significant difference in platelet yields between males and females (p > 0.05).

Donor platelet count fell from 265 ± 68.5 to 189 ± 46.3 (mean ± SD) (p < 0.01) and lymphocyte count from 2.1 ± 0.73 to 1.8 ± 0.67 × 10⁹/liter (mean ± SD) (p > 0.05). There were no changes demonstrable in red cell or absolute granulocyte count.

Infusion of platelets into previously unsensitized recipients with hypomegakaryocyte thrombocytopenia achieved a 1-hr increment of 19 ± 7.3 × 10⁹/liter/m²
(mean ± SD) and a 24-hr level of $15 \pm 6.3 \times 10^9$/liter/m² (mean ± SD).

Studies on Normal Volunteers

Platelet survival. The platelet recovery at 10 min was 59.4 ± 3.4% (mean ± SD) (normal 63.5 ± 4.2). The linear estimate of platelet mean life span was 218 ± 12 hr (mean ± SD) (normal 213 ± 15 hr) [16].

Platelet factor III availability. In the individual studies, maximum time differences between any of the tubes was 4 sec; no abnormal results were obtained (Table I).

Platelet aggregometry. Initially, suboptimal responses were obtained from platelets in the collection bag. In all instances this was immediately corrected by resuspending the platelets in control platelet-poor plasma. Further examination showed the abnormality to be related to a low calcium concentration of 1.83 mmol/liter and when this was corrected to 2.2 mmol/liter, response to standard aggregating agents was normal.

Ultrastructural studies. There was no difference demonstrable between platelets recovered from the apheresis collection bag at the end of the procedure and those obtained by venipuncture before its commencement.

DISCUSSION

Thrombocytopenic bleeding due to diminished platelet production can be controlled by the infusion of adequate numbers of functionally normal allogeneic platelets with the proviso that prior sensitization has not taken place [5,22,23]. The platelets may be obtained from single units of whole blood or collected on cell separators [23]. The latter machines are efficient. The yield from a single donor is comparable to that from six units of whole blood; it can be obtained in a reasonable period of time, and there is minimal risk or discomfort to the donor. A number of different separators are currently in use, including the Hemonetics [24,25], the IBM 2997 using the single channel module [7], and the Fenwal CS3000 [26].

A recent modification to the original single channel used with the IBM 2997 separator is known as the dual-channel module and has been specifically engineered to enhance platelet collection [9]. In this system flow is directed to result first in separation of red cells and thereafter platelets are recovered from the platelet-rich plasma by differential centrifugation. This unique design provides an efficient system for platelet harvesting so that a single procedure can be carried out in approximately 90 min and will result in an absolute mean platelet count of $5.1 \times 10^11$. Contaminating red cells and white cells are, for practical purposes, absent. The overall extraction efficiency has been raised to 62% from the 51% previously reported for the single channel used on the same separator [7]. A further point of distinction between the two channels is that the higher yields obtained from men using the single channel is not evident when the dual-channel module is employed. However, both platelet and lymphocyte depletion are of approximately the same magnitude as occurs with the single channel instrument [8], whereas red cell contamination was 2% with the single channel and absent using the dual channel.

The function of the harvested platelets as assessed by in vivo survival and in vitro platelet factor III availability and aggregometry did not differ significantly from normal control value. It was, however, of note that the platelets in the bag showed defective aggregation patterns that were related to suboptimal calcium concentrations, and this is consistent with minor degrees of hypocalcaemia occurring in 11% of our patients and also with the well recognized effects of citrate anticoagulation on the donor [27]. It is noteworthy that correction of the low calcium levels in the bag, either by titration into the normal range with chloride or resuspension of the platelet pellet in pretreatment autologous donor plasma, resulted in immediate return of function to normal. Furthermore, ultrastructural studies showed morphology to be indistinguishable from normal controls.

The postinfusion platelet increments in these patients who had not been previously sensitized, who were not bleeding, and who did not have clinically palpable spleens are less than previously reported figures of corrected posttransfusion increments of $75 \times 10^9$/liter/m² at 1 hr and $45 \times 10^9$/liter/m² at 24 hr [28,29] but are consistent with more recently described figures at 1 hr of $18.3 \pm 2.6 \times 10^9$/liter/m² and corrected 20-hr posttransfusion increment of $13 \pm 1.4 \times 10^9$/liter/m² [8]. This response was obtained in all but six of the patients receiving therapeutic donations. It should be pointed out that this study did not specifically address the question of whether there was any clinical benefit from these increments obtained by allogeneic platelet transfusion.

Plateletpheresis can be carried out with minimal discomfort to the donor and symptoms are restricted to transient and easily reversible hypocalcaemia. It is concluded that the dual-channel module provides a safe, simple, and efficient system for high yield collection of functionally normal platelets with negligible cellular contamination.

Exchange Transfusion in Sickle Cell Disease using a Continuous-Flow Blood Cell Separator

L. M. Kernoff, M. C. Botha, and P. Jacobs

From the Department of Haematology, University of Cape Town, the Groote Schuur Hospital, and the Cape Provincial Blood Grouping Laboratory, Observatory, Cape Town

An exchange transfusion was performed preoperatively on a patient with sickle cell disease using a continuous-flow blood cell separator. An exchange of 2,825 ml red blood cells achieved a hemoglobin A level of 90.8 per cent. The continuous-flow blood cell separator appears to offer a safe and effective method of exchange transfusion in sickling disorders.

Exchange transfusion is frequently of benefit to patients with sickling hemoglobins, but performed in the conventional way may be time consuming and relatively inefficient. The continuous-flow blood cell separator offers an alternative means of exchange transfusion, and the efficiency of this method was assessed in a patient with sickle cell disease who required exchange transfusion prior to surgery.

Case History

The patient, a 19-year-old female, was diagnosed as having sickle cell disease at the age of 15 months. The events leading to the diagnosis and her early medical history have been reported previously. Her subsequent growth and development was normal, and she remained in good health until she developed episodes of upper abdominal pain. The clinical diagnosis of cholelithiasis was confirmed by oral cholecystogram, and at operation numerous mixed gallstones and a small splenic remnant were found. The operation and postoperative course was uncomplicated, and she was discharged on the seventh postoperative day.

Method

Exchange transfusion was performed with an IBM Blood Cell Separator (Model 2990), four days before surgery. The system was primed with 280 ml of normal saline containing 5,000 units of heparin. Further heparin was infused during the exchange at a rate of 250 units per hour. The exchange procedure comprised two phases. Initially 300 ml of the patient's red blood cells were exchanged with normal saline, this being, in effect, a venesection. This served the purpose of reducing the amount of blood in the circulation which would dilute the incoming normal blood. Thereafter 2,825 ml of the patient's red blood cells were exchanged with an equivalent volume of normal red blood cells with a hematocrit of 80 per cent. The exchange procedure lasted 3.5 hours, being performed at a flow rate of 10 to 15 ml/minute, with the centrifuge bowl at a speed of 1,000 rpm. After completing the exchange, the patient received a transfusion of 750 ml of red blood cells.

Venous blood was obtained prior to commencing the exchange, and thereafter at regular intervals for the measurement of the hemoglobin concentration (Coulter Counter Model S) and hemoglobin components. Red blood cell lysates were prepared and hemoglobin electrophoresis on cellulose acetate performed according to Lehman and Huntsman. The electrophoretic fractions were eluted with distilled water and quantitated spectrophotometrically. Since HbF is not separated from HbS with this form of electrophoresis, HbF was quantitated by an alkali denaturation method.

Results

The change in hemoglobin concentration observed throughout the procedure is presented in Figure 1. The hemoglobin concentration fell from 8.0 g/dl to 6.3 g/dl after the 300 ml venesection, but rose to 11.8 g/dl by the end of the exchange. This rise in concentration during an exchange of
equal volume was accounted for by the higher hematocrit of the blood entering the system (80 per cent) than that being removed. Before the exchange the values for the hemoglobin components were: HbA 2.3 per cent; HbS + F 97.7 per cent; HbF (alkali denaturation) 11.4 per cent. After the 2825 ml exchange, HbS + F had fallen to 7.4 per cent; HbF to 2.4 per cent, and the HbA had risen to 90.8 per cent. After the 750 ml transfusion HbS + F fell to 4 per cent; HbF fell to 1.7 per cent, and HbA rose to 94.7 per cent. These changes are illustrated in Figure 2. At follow-up, 30 days later, the HbS + F was 89.9 per cent, HbF 4.0 per cent and HbA 8.1 per cent.

Discussion

The exchange transfusion described above was performed without any side effects or discomfort to the patient, and provided her with greater than 90 per cent of normal hemo-
moglobin. Because her veins were of poor caliber it was not possible to exchange at the usual speed of 40 ml/minute. Had this been possible, the time taken for the procedure could have been reduced by half. The level to which the hemoglobin rose was greater than anticipated and, in retrospect, the transfusion following the exchange was probably not necessary.

The indications for exchange transfusion in sickling disorders have been discussed elsewhere, and it is not suggested that these should be altered in the light of the present report. However, the increasing availability of the continuous-flow blood cell separator and the present demonstration that it can be used to perform a rapid, safe and effective exchange, commend this method to further trial under these differing clinical situations.

The Function and Structure of Granulocytes Collected Using the IBM 2997 Separator

Lucille Wood, Jeane P. Hester, and Peter Jacobs

The University of Cape Town Leukaemia Centre and The Department of Haematology, University of Cape Town and Groote Schuur Hospital, Observatory, Cape Town, South Africa (L.W., P.J.), and The M.D. Anderson Hospital and Tumor Institute, Houston, Texas (J.P.H.)

The effect of oral methylprednisolone and the sedimenting agent, hydroxyethyl starch, on granulocyte recovery, morphology, and function was studied in a volunteer donor programme. Using the IBM 2997, 10 litres of whole blood were processed, with an average procedure time of 2.4 hours and a collection volume of 300 ml. Donors not receiving methylprednisolone (n = 80) had a mean total granulocyte count of \(3.5 \times 10^9/\text{litre}\) (range 1.6-5.3 \(\times 10^9/\text{litre}\)) and mean granulocyte yields were \(1 \times 10^8\) (range 0.2-3.0 \(\times 10^8\)). Those receiving 48 mg oral methylprednisolone 6-8 hours before the procedure (n = 320) had a mean granulocyte count of \(6.3 \times 10^9/\text{litre}\) (range 3.2-11.4 \(\times 10^9/\text{litre}\)) and significantly superior mean granulocyte yields of \(2.0 \times 10^9\) (0.3-6.5 \(\times 10^9\)) (P < 0.05). For both groups the mean packed cell volume of 0.08 litre/litre (range 0.02-0.17) and platelet contamination 1.9 \(\times 10^{11}\) (range 0.3-5.0 \(\times 10^{11}\)). In all these procedures, hydroxyethyl starch was added to the blood entering the centrifuge channel. In none of the procedures were any untoward symptoms experienced by the donors. Light microscopy and ultrastructural studies showed no difference between control granulocytes and those collected following the addition of hydroxyethyl starch or after oral methylprednisolone. Similarly, granulocyte function measured with a random migration, chemotaxis, phagocytosis, and intracellular killing was not significantly different between control cells and those exposed to the sedimenting agent or the adrenocorticosteroids (P > 0.10). It is concluded that donor presedation with methylprednisolone significantly enhances granulocyte yields in the presence of hydroxyethyl starch and neither agent has any demonstrable effect on granulocyte morphology or function.

Key words: adrenocorticosteroids, hydroxyethyl starch, granulocyte structure and function

INTRODUCTION

Optimum granulocyte transfusions depend upon obtaining the largest number of functionally intact cells, and modern apheresis techniques are ideally suited to this purpose. Of the methods available, continuous-flow filtration has fallen into disrepute because of donor reactions [1-3] and evidence that the harvested cells may be morphologically [4] and functionally [5,6] abnormal. By contrast, centrifugal techniques are widely used, with optimal granulocyte yields being influenced by the type of instrument used, the duration of the procedure, and the initial white cell count of the donor. In an attempt to expand the circulating granulocyte compartment, donors have been treated with drugs which include eticholalone [7,8], dexamethasone [9,10], hydrocortisone, and prednisolone [11]. Efficiency is further enhanced by the use of sedimenting agents such as dextran or hydroxyethyl starch [12] to improve cell separation during centrifugation. Results reported with adrenocorticosteroids and hydroxyethyl starch are essentially similar to our earlier experience using the IBM 2990 cell separator [Wood L, Jacobs P: unpublished observations].

More recently there have been considerable technical improvements in the IBM series of separators, resulting in the production of a second generation instrument, designated the IBM 2997. In the new machine, the reusable polycarbonate bowl has been replaced by a single disposable plastic unit with separation taking place in a narrow channel. This technique was studied to define the effects of methylprednisolone, an adrenocorticosteroid which has not been extensively used in granulocyte collection, on donor counts and cell yields and to assess the effect of both this and hydroxyethyl starch on morphology and function of the harvested cells.

MATERIALS AND METHODS

Granulocyte Donors

Two groups of individuals were studied. The first were siblings of patients on a leukaemia or bone marrow transplantation programme where intensive granulocyte collection was carried out on 5 consecutive days. The second were random volunteers who donated with a max-

Received for publication November 15, 1983; accepted January 10, 1984.

imum frequency of once every 4 months in view of the rare but recognized complications of hydroxystarch [13]. All donors fulfilled the standard requirements of the American Association of Blood Banks [14], being ABO-compatible and negative for hepatitis-B surface antigen and serologic evidence of syphilis. Participants were fully informed about the procedure and signed informed consent. In a control group (n = 80), white cells were collected without prior adrenocorticosteroid administration. In the test group (n = 320), donors took 48 mg oral methylprednisolone 6–8 hours before the procedure. This schedule was selected on the basis of donor convenience, effect on granulocyte mobilization [15], and confirmed by our own observation that this timing and dosage will consistently roughly double peripheral blood granulocyte counts.

Granulocyte Collection

All procedures were performed on the IBM 2997 continuous-flow cell separator. The collection line and channel were primed with 500 ml physiologic saline containing acid citrate dextrose (ACD-A) in the ratio of 13:1. Venous access was with a 16-gauge intravenous plastic cannula (Ethclor, South Africa) and flow rates varied between 40 and 80 ml/minute according to the donor’s lean body mass and surface area. The collection rate was between 1.8 and 3.3 ml/min and centrifuge speeds were 520–820 rpm. During the procedure blood was anticoagulated by infusing a solution containing 500 ml of 6% hydroxystarch (Fresenius, West Germany) and 62 ml of a concentrated citrate solution (18 g trisodium citrate and 1.8 g citric acid in 50 ml water) into the access line in a ratio of 1:18 with venous blood. Under these circumstances, uniform anticoagulation was obtained and 10 litres of blood processed without clinical or biochemical hypocalcaemia developing.

Haematological and Biochemical Measurements

Before and after each procedure, venous blood was collected for the measurement of haemoglobin, red cell count and indices, white cell count, and platelet count using the Coulter counter, model S-Plus [16], and differential count on a Romanowsky-stained film [17]. Biochemical profile, including urea and electrolytes, was similarly recorded [18]. Haemostasis [19] and changes in complement levels (C3 and CH50) were monitored, using standard techniques [20].

Special Haematology

Throughout the study additional samples were collected from 15 donors for morphologic and functional studies on the granulocytes. In these procedures a sample of blood was collected prior to oral methylprednisolone, a second 8 hours later immediately before commencement of the procedure, a third from the donor at the end of the collection after addition of hydroxystarch, and a final sample from the bag of harvested granulocytes.

Films were prepared using a blood spinning centrifuge [21] and stained with May-Grunewald Giemsa. Ultrastructural studies were carried out on gluteraldehyde-fixed material [22]. Granulocyte function was assessed by random migration and chemotaxis using a modified raft technique with 0.5% sodium caseinate as the chemoattractant [23–26]. Phagocytosis and intracellular killing were determined by liquid scintillation counting using a combined method which employed Candida albicans labelled with uridine ([5,6-3H] uridine: specific activity 40–60 Ci/m mol: Amersham, Buckinghamshire, England) as the target [27,28]. In this method, phagocytosis is determined by the loss of labelled uridine after cell harvesting and intracellular killing on the basis of isotope exclusion.

RESULTS

Donor Safety and Side Effects

None of the donors experienced side effects from the administration of adrenocorticosteroids or the hydroxystarch. Using this particular instrument and a strictly isovolaemic technique, three patients had transient discomfort and dizziness during venepuncture but in none of them did this require discontinuation of the cell collection. The mean total serum concentration at the commencement of the procedure was 2.6 mmol/litre and at its completion was 3.6 mmol/litre (range 2.1–2.6 mmol/litre) with a percentage change which was not statistically significant (P > 0.10). No changes in haematology or biochemical profile have been found. In no instance has regular follow-up revealed late effect from hydroxystarch accumulation.

Control Group

In the 80 donors who received no oral methylprednisolone premedication the starting total white cell count was 4.5 × 10⁹/litre (range 2.5–5.0), granulocyte count before the procedure was 3.5 × 10⁹/litre (range 1.6–5.3), and after cell collection was 2.5 × 10⁹/litre (range 1.3–4.5). Mean granulocyte yields were 1.0 × 10¹⁰ (range 0.2–3.0).

Adrenocorticosteroid Pretreated Donors

In the 320 donors who received 48 mg of oral prednisolone 6–8 hours before commencing cell collection, the starting total white cell count was 7.0 × 10⁹/litre (range 2.9–16.3), granulocyte count before the procedure was 6.3 × 10⁹/litre (range 3.2–11.4), and after cell collection was 4.6 × 10⁹/litre (range 1.6–9.4). Mean granulocyte yields were 2.0 × 10¹⁰ (range 0.3–6.5).
Red Cell and Platelet Contamination

For both groups the mean packed cell volume was 0.08 litre/litre (range 0.015–0.17) and platelet contamination $1.9 \times 10^{11}$ (range 0.3–5.0).

Morphology

In neither the control ($n = 8$) or the methylprednisolone-pretreated ($n = 15$) donors were any of the cells abnormal when examined by light or transmission electron microscopy. Specifically, nuclear chromatin, presence of vacuoles, appearance of cytoplasmic projections, or abnormal granule distribution were not affected by the cell collection procedure.

Granulocyte Function Studies

The serial investigation of random migration, chemotaxis, phagocytosis, and intracellular killing showed no effect as a result of either methylprednisolone administration or the subsequent exposure to hydroxyethyl starch during the collection technique in randomly studied patients ($n = 15$) (Table I).

Recipient Reactions

Infusion of allogeneic granulocytes to neutropenic patients was associated with a pyrexial reaction of varying severity in 26%. Premedication with 4 mg Chlorotrimeton (Essex) given orally half an hour before the cells reduced the incidence of this reaction to under 10%. It is, however, not clear whether this difference is significant since there is no sound reason why an antihistamine should prevent or modify fever. In those individuals where further granulocyte infusions were necessary and reactions persisted they could be blocked by the intravenous infusion of 100 mg Cortisol or 120 mg Paracetamol half an hour before commencing the granulocyte transfusion.

DISCUSSION

Although debate continues on the role that granulocyte transfusion should occupy in current clinical practice [29–31], and such issues as optimal diagnostic technique [32,33] or noninfectious pyrexia [34] are unresolved, there is little debate that, once committed to this form of treatment, the largest number of functionally intact granulocytes should be infused. These can be collected by modern techniques but filtration is now less favoured because of donor reactions [1–3] and evidence of abnormal cell morphology and function [4–6]. By contrast, centrifugation is being increasingly used and attempts to enhance recovery have led to modifications of the instrument, variations in the duration of the procedure, and use of manipulations to raise white cell count in the donor coupled with sedimenting agents to enhance or improve the efficiency of cell separation. We have examined two of these variables, using a standardized collection procedure and the single channel module for the IBM 2997 continuous-flow blood fraction separator.

First, pretreatment of donors with adrenocorticosteroids significantly raised starting total white cell and granulocyte counts and consequently doubled the number of cells harvested. Of the agents known to produce neutro-

*In vitro comparison of cells from donor to those exposed to steroids alone or both steroids and hydroxyethyl starch shows no significant difference.
philic leucocytosis in man [7] the effects on mobilization and function of neutrophils have been characterized for hydrocortisone, prenisolone, and dexamethasone [11]. The choice of methylprednisolone in this study was based on the intermediate duration of biological activity over the shorter-acting hydrocortisone and the longer-acting dexamethasone together with the fact that it is essentially devoid of mineralocorticoid activity as opposed to prednisolone [36]. It is, however, unlikely that the magnitude of change produced by this agent is significantly different to that which could be achieved with equivalent doses of other analogs. Since the latter point was not specifically examined, we are unable to recommend our regimen over that used by other investigators: we have, however, found it a convenient and effective means for raising granulocyte counts in the peripheral circulation. Since this is a volunteer programme it is important to record that no complications such as changes in electrolyte status or blood sugar level were documented either following single or multiple exposures.

Second, the benefits of hydroxyethyl starch [36] have been confirmed. Furthermore, while adverse effects, including pruritus, have been reported [13], the accumulation of this agent in the reticuloendothelial cells from which it is then lost by subsequent slow metabolic degradation appears to be without deleterious side effects to the donor. Nevertheless, it is prudent to limit the number of procedures that volunteers undergo on the basis of currently available information on metabolism and clearance rates [36]. Thus, while no recommendations appear as yet to have been formulated, a donor panel sufficiently large to require a maximum of one procedure every 4 months is our established practice.

In a series of pilot studies, neither adrenocorticosteroid premedication nor hydroxyethyl starch infusion, when used separately, affected the morphology or function of the collected granulocytes but suboptimal cell yields were obtained. The present study extends these observations since it is known that the adrenocorticosteroids have wide-ranging effects on granulocytes [37-39]. In studies carried out on randomly selected donors, in which aliquots of cells were compared at different stages throughout the procedure, the combined effect of this pharmacological agent and hydroxyethyl starch were shown to be without recognisable effect on morphology or ultrastructure: a finding in keeping with other studies [4]. Similarly, no functional abnormality was demonstrated in the harvested granulocytes that had been exposed to methylprednisolone and the sedimenting agent, also in keeping with previous observations [40-43].

It is of interest that, although not part of the present study, we have previously shown in a small number of patients (n = 5) that bactericidal capacity of granulocytes is not affected by exposure to steroids using a coagulase-positive Staphylococcus aureus cell suspension [42]. Our current findings are in contrast with an earlier report [44] but are difficult to compare to that study because different assay techniques were employed.

CONCLUSION

It is concluded that donor premedication with methylprednisolone substantially enhances the circulating white cell count at the time of the collection procedure and, in the presence of hydroxyethyl starch, doubles the granulocyte yield. Neither adrenocorticosteroid nor the sedimenting agent, singly or in combination, had any demonstrable effect upon cellular morphology, ultrastructure, or function. It is therefore possible to endorse the recommendation that these two pharmacologic agents be combined in routine procedures to harvest donor granulocytes for transfusion. Although of infrequent occurrence, adverse effects attributed to the sedimenting agent may be disturbing to the individual donor and, therefore, an urgent need exists to examine alternatives to hydroxyethyl starch. It is also clearly necessary to formulate guidelines for donor safety, including a clear definition of currently acceptable ethical practice.

Collection and Cryopreservation of Human Stem and Progenitor Cells for Bone Marrow Transplantation

Peter Jacobs, Lucille Wood, and Sue Horak

The University of Cape Town Leukaemia Centre and The Department of Haematology, Groote Schuur Hospital, Observatory, Cape, South Africa

Bone marrow collection was undertaken from human organ donors (Group 1; n = 7) to develop a closed-system single-step technique for stem and progenitor cell enrichment, using the Cobe 2997 continuous-flow blood-cell separator. The effects of programmed freezing, storage in liquid nitrogen, and thawing were then defined using these grafts. Once standardized, this method was extended to autografting following cryopreservation of a comparable fraction (Group 2; n = 8) and then to allogeneic transplantation after ex vivo exposure to the lytic monoclonal antibody, Campath-1 IgM and human complement, but without cryopreservation (Group 3; n = 9). The median number of mononuclear cells harvested was 5.0 × 10^6/mL (n = 24), and this was not significantly different in the three groups. The ex vivo graft, composing marrow rich antiagglutinated whole blood, was recirculated in the separator at a flow rate of 60 mL/minute, with a centrifugation speed of 1,100 r.p.m., and the mononuclear cell fractions were collected at the rate of 1.5 mL/minute. The average procedure time from formation of the interface in the single disposable channel to achievement of the final volume was 90 minutes. The mean recovery of the mononuclear cells was 101.4% (SD 38.0) and the GM-CFUc was 91% (SD 43.86). These figures were not significantly influenced by subsequent cryopreservation (Group 1; n = 7 and Group 2; n = 8) or following exposure to the monoclonal antibody, Campath-1 IgM (Group 3; n = 9). The Cobe Model 2997 continuous-flow blood fraction separator is ideally suited for the ex vivo enrichment of human bone marrow stem and progenitor cells in a volume that makes handling practical by a technique that is rapid and readily applicable to both autografting and allogeneic transplantation programmes.

Key words: stem cell harvesting, continuous flow separator, Cobe 2997, CAMPATH-1

INTRODUCTION

Bone marrow transplantation is of increasing importance in clinical practice. The well-established technique for allogeneic grafting is constantly being refined by ex vivo procedures that include exposure to monoclonal antibodies [1] or cytotoxic agents [2], aimed at reducing the incidence and severity of graft-versus-host disease. However, because the availability of suitable donors is limited, autologous transplantation is rapidly being developed, and here interest centres on the use of physical and immunologic manipulations to selectively remove contaminating malignant cells and thereby reduce disease relapse [3]. In both of these procedures, there are three practical considerations. Firstly, it is necessary to achieve maximum recovery of stem and progenitor cells to ensure that adequate numbers remain after any ex vivo graft manipulation to reliably reconstitute haematopoietic and immunologic function. Secondly, the enriched population should be in a reasonably small volume of autologous plasma to limit the space required for graft storage following cryopreservation and prior to subsequent reinfusion. Thirdly, where exposure to monoclonal antibodies is employed, it is critical to standardize the ratio of these reagents to target cells, and this is achieved most easily where the relevant population is available in the concentrated preparation. Several methods have been described to selectively harvest the mononuclear cell population, including manual techniques of double centrifugation [4], density sedimentation [5], Amino-1 [6], and Hemogenics [7,8] separators, and the IBM 2991 red cell processor [9]. Recently, data has been presented for the Cobe 2997 [10–13], and we report additional and confirmatory experience with this instrument, including studies to characterise the behaviour of the enriched population following cryopreservation and ex vivo manipulation with monoclonal antibodies.

MATERIALS AND METHODS

In a feasibility study (Group 1; n = 7), bone marrow was collected as the first procedure from organ donors at a time when full cardiovascular and endocrine support was maintained [14]. This approach is easier than the previously reported method [15] and approximates the established clinical techniques. All procedures were carried out with informed consent on programmes approved by the Ethics and Research Committee at the University of Cape Town and Groote Schuur Hospital. Once the preliminary studies had established the detailed methodology, it was extended to currently active autograft (Group 2; n = 8) and allograft programmes (Group 3; n = 9).

A standard approach was used in which marrow-rich blood was aspirated from the sternum and both the anterior and posterior iliac crests under sterile conditions in an operating theatre [16]. Collection took place into plastic syringes containing McCoy’s tissue culture medium (TCM) with a final concentration of 30 i.u./mL preservative-free heparin (Polarin, Evans Medical Limited, Langhurst, Horsham, England). The ratio of TCM to marrow was 1:10. After measurement of total volume and removal of a representative aliquot to determine cellularity, absolute mononuclear count, and GM:CFUs, the bag of marrow-rich blood was suspended and recirculated through a Cobe 2997 blood fraction separator, with a flow rate of 60 mL/minute and a centrifuge speed of 1,100 r.p.m. The single disposable band was primed with physiologic saline, and ACD-A was added to the marrow in the ratio of 1:9 until a total volume of 400 mL had accumulated in the system. From the time that the interface became established, a mean procedure time was 90 minutes and the mononuclear cell fraction was collected at a rate of 1.5 mL/minute into a final volume between 120 and 150 mL of autologous plasma and heparin-containing TCM. In this technique, volumes as low as 500 mL could conveniently be processed.

Following completion of the procedure, triplicate counts on both the collection and discard bags were carried out to determine the mononuclear cell fraction in each. Specifically, there should be quantitative recovery of this fraction and less than 10% of the original number of monocytes and lymphocytes should be present in the discard bag. The contents of the latter was reinfused into the donor, if necessary with diuretic cover, to avoid fluid overload.

In the organ donor and autograft programme, cryopreservation was undertaken by adding dimethylsulphoxide (DMSO). The freezing medium consisted of 20% of autologous plasma and 20% DMSO in tissue culture medium, so that the final concentration of the cryoprotectant was 10%. The harvested cell fraction was transferred to freezing bags (Delmed: Type 3200-2), and the temperature was reduced in a freezing chamber coupled to a programme controller (Union Carbide Corporation, Linde Division, New York) in which the rates and settings for the machine were predetermined to give a freezing curve of −1°C/minute down to −40°C and −2°C/minute down to −80°C. The temperature characteristics of each procedure were monitored, using a chart recorder (Esterline Angus Instrument Corporation, Indiana). The bag containing the marrow was then stored in the fluid phase in a liquid nitrogen refrigerator (Union Carbide Corporation, Linde Division, New York). When required for infusion, the unit was thawed at the patient’s bedside in a 37°C water bath and administered without a filter. Since small amounts of fibrin and cell debris were present, these were retained by allowing them to settle into a corner during this procedure simply by holding the bag at an angle of 45°. The final volumes of DMSO infused into the patients varied between 24 and 34 mL, and side effects were infrequent but included hot flushes, an unpleasant taste in the mouth, and a strong smell of the agent around the patient for approximately 12 hours.

In the current allograft programme, T-lymphocyte depletion was undertaken using the lytic monoclonal antibody Campath-1 IgM combined with human complement as part of a collaborative study [17] and marrow was reinfused without cryopreservation. The efficacy of the ex vivo manipulation was quantitated and expressed in absolute cell numbers and residual T-cells defined using sheep rosette formation.

In all these studies, GM:CFUs was determined, using a standard assay [18], on mononuclear cells that had been separated on a Ficoll-Hypaque density gradient (Lymphoprep, Nycomed AS, Oslo, Norway; specific gravity 1.077 g/mL) using aliquots derived from the original marrow-rich sample. The in vitro culture studies were repeated on the enriched population after separation, following T-lymphocyte depletion, or after the rapid thawing of the cryopreserved units.

RESULTS

Marrow harvesting from organ donors, patients for autografting, and siblings for allogeneic transplantation were equally effective (Table 1). Although mean volumes as well as total nucleated cells varied, their concentration in the three groups was comparable (P > 0.05). Similarly, the concentrations of the total mononuclear cells, determined by differential counting, did not differ significantly (P > 0.05). Cell viability on all these fractions was the same and approximated 100%.

Cell viability was determined by trypan blue exclusion. Equal volumes of 0.73% trypan blue were mixed

S.D. = standard deviation.

with 1.8% sodium chloride, and equal volumes of this mixture were added to the cell suspension; non-viable cells took up the dye-staining blue.

In vitro GM:CFUc for an aliquot collected from the graft prior to manipulation and expressed in colonies and clusters was 22.36; 38.87; and 78.113, respectively. When corrected for the mean total volume harvested, there was no difference between these three sources of committed progenitors; the median was 5.0 × 10⁵ (S.D. = 2.7; range 2.3–7.7).

Continuous-flow separation (Table II) gave comparable results for final collection volumes and mononuclear cell recovery. There was no difference between the three groups for mean pre-separator red cell, granulocyte, and platelet count, and similar reduction in each of these formed elements was evident after the procedures. The reduction in mean haemoglobin from the marrow-rich blood to the stem cell concentrate was 85%, with no significant change in the total number of white cells, but the composition changed with granulocytes falling from 80 to 20%, lymphocytes being enhanced from 18 to 60%, and platelet concentration increased approximately threefold following the separation procedure.

Post-separator GM:CFUc recovery was a mean of 82%, with the three groups being 60%, 93%, and 93%, respectively; there was no loss of viability on trypan blue testing.

Cryopreservation resulted in an average loss of viability on using trypsin blue exclusion of 13.6%. In contrast, the GM:CFUc recovery was at a mean of 105%, with a standard deviation of 40.2. The respective figures for cadavers (Group 1) were 104.7% (SD = 20.4; range 84.3–125.1), for autografts (Group 2) 72.3% (SD = 22.7; range 49.6–95.0), and allografts (Group 3) 123.1% (SD = 54.3; range 68.8–177.4); these results are not significant (P > 0.05).

Following ex vivo exposure to Campath-1 IgM, viability could not be assessed because of extensive cell death due to the effect of antibody and complement. In these studies, mean residual T-cells were 0.54% (SD = 0.36; the numbers infused were 6.13 × 10⁷/kg (SD = 4.84; range 1.29–10.97).

In Groups 2 and 3, the rate of post-transplantation haematopoietic reconstitution was comparable. Thus, with regular monitoring of the peripheral blood count, the median time to reach 1 × 10⁹/L granulocytes was 21 days, and to achieve an unmaintained platelet count > 50 × 10⁹/L, 30 days.

DISCUSSION

The enrichment of stem and haematopoietic progenitor cells in human grafts by ex vivo techniques is possible, using manual methods [4,5] or by processing the marrow-rich blood on one of the different cell separators [6–10] currently available. Corresponding data for the Cobe 2997 have been reported for a dog model [11], and, recently, the earlier studies on this instrument have been expanded from three French centres [12,13]. We report further data on using this instrument that confirms its eminent suitability for procuring haematopoietic stem and progenitor cells for human transplantation programmes. This technique continues to undergo improvement in two major directions.

S.D. = standard deviation.

Firstly, since autologous transplantation is being increasingly used in human cancer therapy [19], it is necessary to be certain that the choice of cryopreservative agent, freezing techniques, and storage characteristics do not damage the graft. It has been suggested that freezing rates may be critical when monitored by recovery in bone marrow culture studies [20]. We used in vitro clonogenic assays as previously described for predicting engraftment following allogeneic transplantation [21] to monitor this procedure, and it is notable that there was quantitative recovery of these cells in the GM:CFUc assay in Groups 1 and 2. Furthermore, in Group 2, the time taken after autografting to achieve $1 \times 10^9$/L granulocytes or $> 50 \times 10^9$/L platelets is consistent with that previously reported using other instruments [14,22] without cryopreservation, thereby confirming that manipulations do not damage the subpopulation. Of interest is the recent observation that unfractionated marrow which was cryopreserved without the use of programmed freezing gave essentially comparable results [23], suggesting that these procedures could be used in centres lacking expensive instruments.

Secondly, the enriched population was found to be convenient for ex vivo treatment of the monoclonal antibody, Campath-1 IgM, as previously suggested for antibody mixtures or other forms of purging [10]. Using Campath-1 IgM, where cell lysis was effected with human complement, viability was difficult to determine with trypan blue because of the confounding influence of extensive cell death. However, efficient removal of T-cells, determined using both sheep rosette formation and appropriate monoclonal antibodies, was consistently in excess of 99%. After this procedure, overall loss of nuclear cells was small and between 0.59 and $7.45 \times 10^7$ were infused, which corresponds to between 1.29 and $10.97 \times 10^7$ cells/kg. When this figure was extrapolated to GM:CFUc recovery, the fraction should have had the same repopulating potential as the mononuclear cells that had not been exposed to the monoclonal antibody. The validity of this hypothesis, based on the in vitro culture assay, is found in the mean time taken to establish $1 \times 10^9$/L granulocytes or a platelet count $> 50 \times 10^9$/L, being no different from historical controls [24] or in the patients in Group 2 who were autografted without ex vivo manipulation.

It is concluded that the Cobe model 2997 continuous-flow blood fraction separator is well suited for ex vivo enrichment of human bone stem and progenitor cells by recirculation of the marrow-rich blood collected during the harvesting procedure. This technique makes it feasible to rapidly concentrate the desired population in small volumes of autologous plasma, which is then readily applicable to both autografting and allogeneic transplantation programmes.

Aluminium Loading During Therapeutic Plasma Exchange

Felix Monteagudo, Lucille Wood, Peter Jacobs, Peter Folb, and Michael Cassidy

The University of Cape Town Leukaemia Centre and the Departments of Pharmacology (F.M., P.F.), Haematology (L.W., P.J.), and Medicine Renal Clinic (M.C.), Groote Schuur Hospital, Observatory, Cape, South Africa

Graphite furnace atomic absorption spectroscopy was used to demonstrate a fivefold increase in the median plasma aluminium levels of four patients undergoing therapeutic plasmapheresis. This plasma aluminium loading resulted from contamination of albumin incorporated in the replacement fluids and took place during its preparation, with albumin aluminium levels of 646, 669, and 715 μg/liter present in three representative samples. Aluminium overload may result in the development of encephalopathy and osteomalacia in patients with renal impairment, indicating the need to monitor aluminium levels in the albumin-containing replacement fluids to avoid this potential hazard.

Key words: aluminium overload, albumin contamination

INTRODUCTION

The clinically relevant sources of aluminium contamination include the water used in haemodialysis, oral antacids given as dietary phosphate binders, and solutions administered in total parenteral nutrition [1–3]. The adverse effects of pathological increases in this element include a progressive severe encephalopathy and osteomalacia [3]. It is known that replacement solutions used for plasma exchange may contain large quantities of aluminium [4], and albumin has been incriminated as the source of this contamination [5] as a result of accumulation of the element by protein during the filtration process employed for its purification [6]. To further define the potential for aluminium loading four patients were serially studied whilst undergoing therapeutic plasma exchange, with measurements carried out on the plasma before and after each procedure, assay of the exchange fluid, and separate analysis of the electrolyte used in preparation of the replacement solution.

MATERIALS AND METHODS

Plasma Exchange

In a standardised procedure 1.5 times the calculated plasma volume was exchanged in a strictly isovolaemic procedure by using a vein-to-vein circuit on the IBM 2997 Cell Separator. The replacement fluid used was made up of 800 ml balanced electrolyte solution (Pamlayte B, Sabax Limited, South Africa) to which was added 200 ml of a 20% human serum albumin obtained from a single source (Western Province Blood Transfusion Service, Cape Town, South Africa).

© 1987 Alan R. Liss, Inc.
a P-E 56 Recorder. Pyrolytically coated graphite tubes were used at all times.

The spectrometer was calibrated by setting the aluminium hollow cathode lamp wavelength to 303.9 nm, slit 0.7 nm, lamp 9 mA. Standard operating conditions for drying, ashing, atomising, and cleaning were: drying 120°C for 35 seconds, ashing 1,200°C for 25 seconds, atomising 2,700°C for four seconds, and cleaning 2,700°C for four seconds, respectively. A sample volume of 10 μl was used and assays performed in duplicate; calibration was done by the method of additions.

CASE REPORTS (Table I)

Prior to the study informed consent was obtained from the patients referred for therapeutic plasma exchange. Renal function was normal apart from the fourth patient, in whom biochemical measurements deteriorated following a gastric haemorrhage a few days prior to the exchange. None of the individuals had been on aluminium-containing medications apart from the latter patient who received these for his haematemesis. No clinical evidence of aluminium toxicity was noted in short term follow-up.

RESULTS

The results are detailed in Table II.

The median serum aluminium levels before and after the exchange procedure rose from 8 μg/liter to 42 μg/liter. The major source of this loading was from contaminated albumin used in preparation of the replacement fluid.

COMMENT

The adverse effects of excess aluminium are known [3]. Concern about the potential toxicity has revealed new ways in which this ubiquitous element may gain entry into the body [1,5]. Replacement solutions used in plasma exchange have been shown to contain significant amounts of aluminium [4] in which the major source of contamination is the albumin added to maintain oncotic pressures. This procedure may be associated with significant increases in the serum aluminium [5], and a fivefold increase was found in the present study, confirming these observations. This contamination was traced to the albumin used in preparing the replacement solution, with the albumin aluminium levels being in the previously described range [5]. During the preparation of the replacement solution in the pharmacy aluminium contamination was avoided, apart from use of the metal needle for mixing the solutions and from the glass bottles in which the albumin and electrolyte solutions were supplied.

Cautions should be exercised in the preparation of replacement fluids for therapeutic plasma exchange. Particularly when this procedure is to be used repetitively or when renal impairment is present. In these situations the body burden of this element may be increased to potentially toxic levels, suggested to be serum levels between 100 and 150 μg/liter [3]. In addition, patients may also be exposed to the hazard of aluminium loading from dietary phosphate binders and the use of other intravenous fluids [1,2]. In this study only a single source of albumin was examined and as a result of these findings, the local producer is to modify the filtration technique used in isolating and concentrating this protein to avoid the aluminium contamination. However, it remains theoretically possible that this may be a much more widespread problem [6] and it merits the attention of centres using plasma exchange.

This report is based on observations from single exchange procedures and only short-term observations are reported; long-term follow-up on our patients is not available. Nevertheless, there are many situations where plasma exchange is performed repetitively and such individuals may be exposed to the hazard of aluminium loading should the exchange fluids be prepared with contaminated albumin. Paradoxically, it has also been

shown that plasmapheresis can remove aluminium from the bodies of patients with severe renal failure and dialysis encephalopathy, although such reductions did not alter the course of the disease [4]. Further controlled studies will be necessary to resolve this latter issue.

It is concluded that aluminium contamination of replacement fluids used for plasma exchange is a potential source of toxicity, particularly where serial procedures are undertaken. Attention should be directed to this possibility and the albumin added to these solutions should be screened for aluminium content.

Lack of Short-Term Effects on the Donor During Continuous-Flow Selective Mononuclear Cell Collection

Peter Jacobs and Lucille Wood

The University of Cape Town Leukaemia Centre and the Department of Haematology, Groote Schuur Hospital, Cape, South Africa

In 50 individuals, intensive harvesting of relatively pure mononuclear cell fractions from the peripheral circulation was carried out in 198 procedures. Serial collections from bone marrow donors (group 1: \( n = 35 \)) or isolated procedures from volunteers (group 2: \( n = 15 \)) were without morbidity. A median yield of \( 4.0 \times 10^7 \) mononuclear cells were recovered in a final volume of 104 ml of cell-rich plasma, for which 4,300 ml of venous blood was processed in 107 minutes. In neither group were changes documented in donor white cell count or lymphocyte numbers. In group 1, a statistically significant but clinically unimportant transient fall occurred in the platelet count at the end of the 3-day intensive schedule. It is concluded that mononuclear fractions can efficiently be collected from normal donors without the development of relevant cell depletion.

Key words: continuous-flow centrifugation, biologic reagents, allogeneic marrow boosting

INTRODUCTION

Blood fraction separators were introduced for platelet [1] and granulocyte [2] collection. More recently, they have been increasingly used to facilitate plasma exchange for diseases thought to have an immunologic basis [3-5], while commercial applications include efficient procurement of blood fractions and components. Modern apheresis techniques can also be applied to the efficient collection of buffy layer or relatively pure mononuclear cell fractions from the peripheral blood. This technique is in clinical use to facilitate engraftment following bone marrow transplantation [6], while lymphocyte depletion procedures are employed to modulate the course of patients with severe acute aplastic anaemia [7,8]. Such relatively pure populations are also useful as biological reagents to standardise lymphocyte function tests and as a source of committed progenitor cells for in vitro marrow culture studies. The effect of the collection procedure on the donor is an important consideration and has been defined by studying in vivo the response of 50 individuals during mononuclear cell collection procedures.

MATERIALS AND METHODS

All participants were screened and accepted according to standard guidelines [9]; informed consent was obtained in each case. The bone marrow donors (\( n = 35 \)) underwent collection procedures for 5 consecutive days, commencing 24 hours after marrow harvesting. The volunteers (\( n = 15 \)) were drawn from a panel established to provide allogeneic platelets and granulocytes for a leukaemia and transplant programme; each specifically agreed to the extra donation for mononuclear cell collection.

The apheresis procedure was carried out on the IBM 2997 separator employing the single channel and with centrifuge speeds at 820 rpm; anticoagulation of venous whole blood was achieved with acid-citrate-dextrose at a ratio of 11:1. The medium value for blood flow was 40 ml/min and for cell-rich plasma collection was 1.5 ml/min. The volume of blood processed was 4,300 ml, resulting in a collection volume of 104 ml of cell-rich plasma over 107 minutes. To safeguard the donors, one of the investigators (L.W.) initiated the procedure and was present throughout. The patients received 10 ml of calcium gluconate half way through the procedure.

Haematologic measurements in the donors were carried out before, immediately after the procedure, and 24 hours later. These included full blood count [10], differential count [11], platelet count [12], biochemical profile [13].

The mean for platelets is P = .05; none of the other differences before and after the procedure are statistically significant.

RESULTS

Donor Tolerance and Side Effects

There was no morbidity during any of the 195 procedures carried out on the marrow donors (n = 35) or the additional procedures undertaken on the volunteers (n = 15). Specifically, by using prophylactic calcium, no symptoms or signs of hypocalcaemia developed. The latter practice is based on our observations that ionizable calcium falls during cell collection while total calcium and magnesium levels are not altered (Jacobs and Wood; unpublished observations). All procedures were carried out by means of a vein-to-vein circuit, with cannulae introduced under local anaesthetic for each separate collection; these were excellently tolerated without exception.

Haematologic Changes In Vivo

In the bone marrow donors undergoing intensive white cell collections (n = 35) (Table I), the median values before and after the procedure were as follows: haemoglobin, 11.7 and 9.8 g/dl on day 1 and 10.9 and 9.1 on day 5; total white count, 6.9 and 5.7 × 10⁹/l on day 1 and 5.4 and 5.1 on day 5; lymphocytes, 1.9 and 1.7 × 10⁹/l on day 1 and 1.9 and 1.4 × 10⁹/l on day 5; platelets, 283 and 231 × 10⁹/l on day 1 and 222 and 188 × 10⁹/l on day 5.

In the volunteers (Table II) the median values immediately before and after the procedure and those in the bag of cell-rich plasma, respectively, were as follows: haemoglobin, 11.4, 10.6, and 1.8 g/dl; total white count, 5.9, 5.2, and 46.5 × 10⁹/l; lymphocytes, 30%, 30%, and 84%; platelets, 260 and 209 × 10⁹/l with a yield of 1.7 × 10¹¹.

COMMENTS

No invasive procedure is without risk, and donor safety becomes of paramount importance when this is undertaken without direct benefit to the individual. The repeated use of marrow donors for intensive collection of cells to enhance engraftment or of volunteers to provide mononuclear cells as a biological reagent for standardisation of laboratory techniques was therefore studied and shown to be safe, without discomfort to the donor, and to have no demonstrable effect on haemoglobin, white cell count, or lymphocyte numbers. Furthermore, the intensive cell collection in 35 bone donors carried out daily over a 5-day period was similarly unassociated with significant change in these measurements. In both groups there was a short-lived fall in platelet count, which was not associated with any bleeding disorders and which had returned to baseline level within 24 hours of collection. However, in the donors undergoing the more intensive

schedule, the difference between the initial preprocedure and the final postprocedure counts just reached a statistical significance (P = .05).

Although the procedures are strictly isovolaemic, the small and statistically nonsignificant reductions in haematologic values are thought to reflect minimal dilution, and, since they had all returned to baseline levels within 24 hours, emphasize that no cellular deficiency occurs as a result of the apheresis procedure.

These same observations suggest that if large quantities of mononuclear cells must be removed in an attempt to modulate immunologically mediated disease, then much more intensive schedules would be needed and should be seen as adjunctive to immunsuppressive therapy [14,15].

It is concluded that mononuclear cell separation and collection employing continuous-flow centrifugation is a safe and convenient way of cell harvesting in selected clinical situations and also as a source of biological reagents; large numbers of cells can be harvested safely and without significant depletion so that the haematologic status of the donor is not compromised.

In Vitro Study of Immunologic Changes in Long-Term Cytapheresis Donors

Clive R.B. Prior, Patrick J. Coghlan, Jane M. Hall, and Peter Jacobs

 Natal Blood Transfusion Service, Durban (C.R.B.P.), Western Province Blood Transfusion Service, Cape Town (P.J.C.), Institute for Biostatistics of the South African Medical Research Council, Tygerberg (J.M.H.), and University of Cape Town Leukaemia Centre and Department of Haematology, Groote Schuur Hospital, Observatory, Cape (P.J.), South Africa

Several in vitro measurements of immune function were examined retrospectively in a population of active long-term cytapheresis donors (group I; n = 50) and the results were compared to age- and sex-matched controls (group II; n = 50) who had donated only whole blood. In group I, significantly different mean absolute lymphocyte counts (P < .0025), total T-cells (P = .0026) and T-helper cells (P < .0001), and helper-to-suppressor ratios (P = .0279) were present. No differences were noted between the two groups for peripheral blood mean B-cell count, T-suppressor numbers, lymphocyte responsiveness to mitogens or alloantigens, and serum immunoglobulin level. The reduced mean absolute lymphocyte count in group I was due to the reduction in T-helper cell numbers and accounted for the imbalance in the helper-to-suppressor ratio. These disturbances are currently unexplained and, while no clinical consequences have so far become evident, there is a need to continuously monitor the immunologic status of cytapheresis donors. It is also important to determine whether reversal of the defects occurs and, if so, over what time interval.

Key words: cytapheresis, lymphocyte subsets, mitogen response

INTRODUCTION

Concern has been expressed about possible health risks to long-term cytapheresis donors [1–7], based on the observation that many otherwise healthy individuals have become lymphocytopenic, probably as a result of chronic loss of this cell population. Any risks attributable to this phenomenon remain unknown, but potential hazards of changes in immune competence include infections, malignancy, and autoimmune disorders [5]. In this regard, reliable information on alterations in circulating blood lymphocyte subpopulations and immune function in normal healthy donors undergoing repeated mechanical cytapheresis is limited [4,7,8].

Guidelines issued in August 1981 by the Food and Drug Administration (FDA), Office of Biologics [9] for the collection of platelets by cytapheresis techniques do not refer to lymphocyte loss. In an update [10], based largely on the availability of new separators, where loss is approximately 1 × 10^7 lymphocytes per procedure, 24 platelet collections per year are allowed. In addition, an expert panel published advice on how to prevent the development of moderately severe lymphocytopenia, defined as <1 × 10^9/L, in the apheresis donor [5], but conceded that insufficient quantitative data was available for circulating lymphocyte subpopulations to influence decisions regarding blood donations.

Since donors make an important contribution to the community, it is the responsibility of those running apheresis programmes to ensure that the health and safety of participants receive constant attention and that these be balanced against the need to procure products of high quality.

MATERIALS AND METHODS

Trial Design

In the years 1984 and 1985 a comparative study was undertaken between a sample of members of a long-term cytapheresis panel and a reference group, matched for age, race, and sex, who had donated only whole blood, to identify the effects of apheresis on absolute blood lymphocyte count and subpopulations, response to stimulation with mitogen or alloantigen, and serum immunoglobulin level.

globulin levels. None of the individuals was taking medication known to influence lymphocyte numbers.

**Subjects**

Healthy volunteers were randomly selected, each having fulfilled the requirements of the American Association of Blood Bank Standards [11] applicable to whole blood or cytapheresis donation. The study was approved by the University of Cape Town and Groote Schuur Hospital Ethics and Research Committee; informed consent was obtained from all participants. Exclusions were on the basis of recent infection or other illness.

Group I (n = 50) consisted of 48 males and 2 females, with a mean age of 37 years (range 25–51). All had previously donated whole blood (mean 26; range 3–81) and were now exclusively on a cytapheresis programme, having undergone a minimum of 25 procedures each (range 25–102) over a 3 to 9 year period, with a maximum of 12 procedures a year. A total of 1,949 aphereses were performed: 1,743 (89.5%) to harvest platelets and 206 (10.5%) for granulocyte collection. The latter were restricted to a maximum of two per year (mean 5; range 0–13).

Controls consisted of regular whole blood donors, individually matched for age and sex (group II; n = 50), who had given a comparable number of whole blood donations to the study group (mean 29; range 11–82). None of these individuals had undergone a cytapheresis procedure.

**Cytapheresis Protocols**

The centrifugal blood cell separators (CBCS) utilised were models 30 and V50 (Hemometrics Corporation, Braintree, MA) or the CS3000 (Fenwall, Deerfield, IL). The operating conditions for thrombocytepheresis procedures for each machine are set out in Table 1. The surge pump modification of the Hemometrics V50 was not in operation during this study period. Average cell recoveries were calculated from routine quality assurance data of 25 consecutive procedures with each machine. Leucocytepheresis donors were premedicated, when possible, with 60 mg prednisone orally 8 hours before donation [12].

**Donor Samples**

In order to minimise the effects of diurnal variation, recent cytapheresis, and the administration of starch or steroid, all donor samples were collected between 08h00 and 09h30 at least 3 weeks after the last cytapheresis procedure.

**Haematological and Biochemical Investigations**

Haemoglobin, packed cell volume, total leucocyte and platelet count were determined using the Coulter

*Mean of 25 procedures with each centrifugal blood cell separator (CBCS).

Anticoagulant ACD-B in a ratio of 1:8.

PROM 6 protocol modified for optimum platelet recovery; anticoagulant ACD-A in a ratio of 1:13.

Counter, model S-Plus II Automated Electronic Hematology Analyser (Coulter Electronics, Hialeah, FL) and the white blood cell differential using the Hematrak, model 480, (Geometric Data, Wayne, PA) counting 400 leucocytes.

Serum ferritin values were determined using a radioimmunoassay kit (Amersham International, UK). Serum IgG, IgA, and IgM were quantitated by nephelometric immuno-analysis, using the Behring Laser Nephelometer (Behringwerke AG, Marburg, West Germany) according to the manufacturer's instructions. Anti-HIV antibody assays were performed using an Abbott EIA kit (Abbott Diagnostic Products, Wiesbaden-Kelkenheim, West Germany) on all donors showing abnormal OKT4 to OKT8 ratios.

**Lymphocyte Preparation**

Donor peripheral blood lymphocytes were isolated from heparinised blood specimens by density gradient centrifugation (18–20°C at 400g) in Lymphoprep (Nyegaard & Co., Oslo, Norway) (sodium metrizoate/Ficoll solution; 1.077 g/mL) [13]. After washing three times in Hanks' balanced salt solution the lymphocytes were suspended in 5% foetal calf serum (Gibco, Grand Island, NY), in Hanks'†/HEPES buffer, and the cell count was adjusted to 4–6 × 10^9/L. Ninety-five percent of all cells were viable by trypan blue exclusion.

**Quantitation of T- and B-Lymphocytes**

Circulating B-lymphocytes were enumerated, using a direct immunofluorescent technique [14] for surface membrane immunoglobulin (SmIg). Fluorescein isothiocyanate (FITC) conjugated (F(ab')2 goat antihuman immunoglobulin (polyvalent) (Kallestad Laboratories, Austin, TX) was used to avoid the problem of conjugate binding to Fc receptors. Wet mounts of the cell suspensions were examined under a Nikon episcopic-fluorescent microscope at 400 × , the fluorescent (SmIg
positive) cells being expressed as a percentage of the total number of lymphocytes visualised.

Absolute numbers were then calculated, using the peripheral blood lymphocyte count.

T-cells were enumerated by their ability to form stable E-rosettes, using 2-aminoethylisothiouronium (AET) bromide-treated sheep erythrocytes [15].

Quantitation of T-Lymphocyte Subsets

T-lymphocyte subsets were identified and counted, using Orthomune (Ortho Diagnostic Systems, Inc., Raritan, NJ) murine monoclonal antibodies in an indirect immunofluorescence test, according to the manufacturer’s instructions. The monoclonal antibody panel employed consisted of OKT3, which identifies human T-lymphocytes (Pan-T) expressing the 19,000 dalton cell surface antigen, OKT4, expressing specificity for the 60,000 dalton cell surface antigen, primarily with inducer and helper function, and OKT8, recognising 31,000 dalton cell surface antigen, having suppressor and cytotoxic functions. Absolute numbers of T-cell subsets were calculated from the percentage of lymphocytes exhibiting fluorescence and the peripheral blood absolute lymphocyte count. The OKT4 to OKT8 ratio was calculated for each individual in the study.

Stratification by Immunophenotype

Results from the donors in each group were stratified into absolute lymphocyte counts <1.5 × 10⁹/L; OKT4 to OKT8 ratio <1.5; OKT4 to OKT8 ratio <1.0; absolute lymphocyte count <1.5 and OKT4 to OKT8 ratio <1.5; absolute lymphocyte count <1.5 and OKT4 to OKT8 ratio <1.0.

In Vitro Lymphocyte Proliferative Responses

In an assay standardised for cell numbers and concentration of mitogen, the incorporation of tritiated thymidine was compared between lymphocytes from donor and control and the results of the two groups expressed as a ratio [16]. Parallel studies using alloantigen were defined in the one-way mixed lymphocyte reaction [17], in which lymphocytes separated from a non-donor and stored in liquid nitrogen functioned as stimulators following inactivation by exposure to 25 μg of mitomycin C at 37°C for 30 minutes.

Statistical Methods of Analysis

The sample size permitted the use of the paired t-test to compare the cytapheresis donor group to the whole blood donor group. McNemar’s exact test for matched-pair data was used to examine the proportions when variables were categorised. The 5% significant level was used throughout to test the hypotheses.

RESULTS

Sample statistics for the variables were measured, and the results of the comparisons of the cytapheresis donors (Group I; n = 50) to the controls (group II; n = 50) are shown in Tables II and III. Technical errors in assay procedure account for sample sizes of less than 50.

Haematological and Biochemical Measurements

The mean haemoglobin level was statistically different (P = .0015), being higher in group I, with no anaemic individuals and only two in this group having serum ferritin levels less than 20 ng/mL. Although there was no difference in the mean serum iron and ferritin levels between group I and group II, three whole blood donors (group II) were iron deficient and a further 6 had borderline values.

The mean platelet counts of the two groups were comparable and in both instances within the normal range.

There was no difference in the mean total leucocyte counts between the two groups. However, the mean absolute lymphocyte count in group I was lower than that of group II and statistically different (P = .0025) (Table II). In addition, the proportion of lymphocytopenic donors, defined by absolute counts <1.5 × 10⁹/L, differed between the two matched groups (P = .0170) (Table IV) and was higher in the cytapheresis group (P = .0273).

The mean absolute lymphocyte loss from volunteers in group I, using the Hemotek cell separator, was calculated to be 0.5 × 10¹⁰ per procedure, with a corresponding value of 0.02 × 10¹⁰ for the Fenwall CS3000 (Table I). Surprisingly, 17/50 (34%) of the whole blood controls (group II) were found to have an absolute lymphocyte count <1.5 × 10⁹/L (Table IV). No significant difference in the mean values for any of the serum immunoglobulins was demonstrable between the two groups (Table II). All individuals in group I with abnormal OKT4 to OKT8 ratios were negative for HIV-antibody.

In the years the study was conducted anti-HIV testing was not universally established, although donors with a history for risk of this retroviral infection were, as far as possible, excluded. It nevertheless remains theoretically possible, although unlikely, that infected individuals could have been included in either group I or group II. However, in the ensuing years, when HIV testing has been routine, the very low incidence rate, for practical purposes, excludes this possibility.

Lymphocyte Studies

The results in our laboratory for total lymphocyte numbers and subsets was comparable between the control patients in group II and random normal subjects drawn from a population of similar age, where no significant differences were demonstrable between men and
women. It is recognised that blood samples were collected at a time when absolute lymphocyte counts would be at their lowest and the non-donor population was studied at the same time; under these circumstances, diurnal variation for the subsets was not carried out.

The mean percentage of B-cells, defined by SmIg positivity, differed between the two groups (P = .0002) and was higher in group I, whereas the mean absolute values for the two groups were not different. Conversely, the T-cell data showed no difference in the mean T-cell percentage between group I and group II (P = .1456). In contrast, when absolute values, defined by the Pan-T monoclonal antibody (OKT3) are considered, a lower value is evident in group I (P = .0026). Further investigation of the T-cell subsets, each expressed as a percentage of the absolute lymphocyte counts, showed that in group I the mean percentage for the helper cells, identified by the OKT4 antibody, was associated with a higher mean percentage of suppressor cells, recognised by OKT8. A comparison of group I to group II demonstrated a significant difference for OKT4% (P = .0006) and OKT8% (P = .0001).

Examination of the mean absolute counts, however, showed a statistically significant difference (P < .0001) and revealed a marked reduction in the OKT4 positive cell population in group I, but no difference in the number of OKT8 positive cells in comparison to the controls. This imbalance in absolute numbers is reflected in the

*There were 50 individuals in each of the two groups. Statistical significance using the paired t test was defined as values less than P = .05.
†Yates corrected chi-squared test used (see text).

The proportion of individuals in each of the two groups with a reduced OKT4 to OKT8 ratio (<1.5) or when this was reversed (<1.0) is set out in Table IV. Both categories showed a marked larger proportion of donors from group II. Of greater importance is the preponderance of individuals from group I who were both lymphocytopenic and had an OKT4 to OKT8 ratio of <1.5 (16/50 versus 1/50; P = .0002) (Table IV); this cut-off value, defining lymphocytopenia and clinical significance for ratio reversals, was previously defined in our laboratory. There was, however, no difference in the proportion of donors with a combination of lymphocytopenia and reversal in the OKT4 to OKT8 ratio, although the number is small.

The results of the in vitro lymphocyte function tests were not different between the two groups when lymphocyte responsiveness was tested to mitogens or by stimulation with alloantigen in the one-way mixed lymphocyte reaction (MLR) (Table III). It is notable, however, that on exposure to phytohaemagglutinin, which is predominantly a T-cell mitogen, a difference (P = .0279) (Table III) was found, whilst reactivity amongst individuals from group I was lower.

DISCUSSION

The finding of iron deficiency in the control group is consistent with the significant erythrocyte loss that accompanies regular whole blood donation and leads to depletion of body stores [18-20]. In contrast, apheresis procedures are associated with minimal red cell contamination of the harvested product and they are unlikely to result in changes in serum iron or ferritin levels [20]; an observation confirmed in results from our long-term cytopheresis donors (Jacobs & Wood; unpublished observation).

All the volunteers in group I sustained large platelet losses over a period of 3 to 9 years, yet each maintained a peripheral count within the normal range. These results are in keeping with the previously reported studies [4,21-23] and reflect accelerated megakaryocytopenia in response to increased peripheral demand.

Although substantial numbers of granulocytes are removed during cytopheresis, no donor in this study was found to be neutropenic. The maintenance of circulating levels is attributed to rapid cellular replacement [24] from the marrow granulocyte pool and also to intravascular demargination that follows prednisone premedication. The single dose of steroid, given once with each procedure, is unlikely to have, in any way, affected these results. Furthermore, it has been stated that these cells cannot be removed by any present-day technique at a rate sufficient to result in circulating levels [21].

Lymphocyte depletion, however, poses more of a problem to the long-term cytopheresis donor. The mean absolute loss during thrombocytopheresis, using the Hemonetics Model 30 CBCS, was calculated to be 0.5 x 10^10 on each occasion. It follows that 12 such procedures a year result in 15 times more lymphocytes being lost than when a person makes four donations annually. The estimated total body mass of lymphocytes is at least 1 x 10^12 cells [24]. Therefore, the individuals in group I could have lost the equivalent of 12-50% of their total lymphocyte pool over a 3 to 9 year period. This postulate is consistent with the significantly reduced circulating lymphocyte counts in long-term cytopheresis donors.
when compared to the control group, and confirms two previous reports [3,4,7,8]. Thus, we are obliged to attribute the changes exclusively to the apheresis procedures and it appears that reductions are time-related and may reflect the number of procedures undertaken, but insufficient data are available to estimate statistical value to this observation. Particularly noteworthy is the fact that counts do not return to higher or even normal levels on stopping the cytapheresis. Currently unexplained is the observation that one-third of the individuals in group II were also found to be lymphocytopenic. Attempts to determine whether these were poor controls or whether the accepted lower limits for lymphocyte counts may be inaccurate for this population of men studied in the mornings failed to show any bias and accordingly this is the subject of further study.

The reduced absolute lymphocyte counts in group I appear to be due to a highly significant decrease in the numbers of circulating T-helper cells, resulting in an imbalance of the OKT4 to OKT8 ratio in many individuals. It has, however, not been possible to confirm two other reports [4,7,8] of a significant reduction of suppressor or cytotoxic subsets, with mean absolute counts of OKT8 positive cells being comparable in groups I and II. An alternative explanation, however, is that the latter population is replenished more rapidly than the OKT4 population [8]. No difference was found between mean absolute B-cell counts in our two groups, thereby confirming two previous reports [4,8]. These findings are in contrast to reports of significant decrease in B-lymphocyte levels in cytapheresis donors [2,3]. Furthermore, our findings of comparable mean serum immunoglobulin levels between groups I and II differ from the significant decrease in immunoglobulin levels previously reported [3,8] in individuals undergoing platelet apheresis.

Knowledge is incomplete on the way in which lymphocytes are produced and peripheral blood levels are regulated [25], but information on T-cell kinetics, including their longevity [26], reduced functional activity associated with increasing age [27,28], and the presence of specific regulatory subsets raises the possibility that normal immunologic competence may be altered by their recurring loss. Thus, drainage of 5.7 x 10^10 lymphocytes from the thoracic duct, 90% of which are T-cells, impairs their functional activity, including allograft rejection, substantially diminishing primary antibody response to bacterial antigens and producing long-lasting depression of delayed hypersensitivity [29,30].

In the present study, in vitro lymphocyte function tests demonstrated significantly lower responsiveness to the T-cell mitogen, phytohaemaggulutinin, in comparison to the whole blood donor controls. In this regard, the established interaction between the mononuclear cells in these in vitro culture systems [16], giving rise to the final response to incorporation of tritiated thymidine, may be dampened by the reduced proportion of T-helper cells that we have shown to be present in the long-term cytapheresis donors.

Interpretation of our data is consistent with protracted loss of T-cells in group I, analogous to thoracic duct drainage; although in these situations the patients were not normal, and the persistence of this defect suggests that replenishment may not be as efficient as might have been anticipated. It followed that restoration of in vivo immune function, reflected in reconstitution of in vitro tests, will require correction of T-cell loss, and definition of this sequence of events will necessitate further long-term observation.

It is difficult to explain the discrepancy in reconstitution of OKT4 and OKT8 subpopulations by apheresis procedures. Differential removal of these two populations or inhibition of T-helper cell production by the procedure itself seems unlikely. Thus, if T-lymphocytes are harvested in the same proportion as peripheral blood levels, then with a normal helper-to-suppressor ratio it would be anticipated that twice as many OKT4 as OKT8 cells would be lost. Assuming that the peripheral blood T-lymphocyte subset ratios faithfully reflect their distribution throughout the total body pool, estimated at being between 30 and 40 x 10^10 cells [1], then a significant reduction in the peripheral T-helper cells in the cytapheresis donors is cause for concern.

The results of the present study suggest that recommendations based solely on the absolute peripheral blood lymphocyte count [5] are inadequate because they do not reflect the differential subset loss. Thirteen, or 26%, of the long-term cytapheresis donors with normal absolute lymphocyte counts had reduced helper-to-suppressor ratio of <1.5, and of these five had reversal, with ratios <1.0. It would seem appropriate, therefore, that on entry to a cytapheresis programme absolute as well as lymphocyte subsets be documented. Furthermore, the current observations would suggest that these measurements should be monitored on a serial basis, and it remains to be determined which interval would be most appropriate. Although it is accepted that lymphocyte sparing techniques should be used, no prospective study has, to date, been published to establish safety in terms of total number or frequency of cytapheresis procedures, and such information appears to be urgently needed.

Finally, there is no information available to exclude the possibility that subtle or occult immune dysfunction may have been created in some long-term cytapheresis donors and that the consequences would become manifest only under conditions of stress. Our data, based on in vitro tests, demonstrate that immune balance already existed in many of these individuals at the time they
were studied, but the cause for this is not clear. Careful evaluation of the various laboratory values being analyzed suggests that those having statistical significance have not been over-interpreted. To date, no in vivo changes have emerged in altered immune function and neither have the changes had any clinical consequences.

The failure to demonstrate similar defects in the control population would appear to exclude prior blood transfusion as contributory and incriminate the apheresis procedures in the generation of this immunologic defect. Accordingly, we support the recommendation [5] that a Registry be established for donors on cytopheresis programs, particularly where lymphocyte abnormalities have already been documented, and long-term surveillance be maintained. It should be noted that these data cannot be extrapolated to the Hemonetics V50 surge or the third generation centrifugal separators, exemplified by the COBE Spectra; it is entirely possible that lymphocyte depletion using the more modern instruments may approximate those found with whole blood donation, but this point has not, to our knowledge, been established.

An additional benefit of such monitoring would be an ability to document an increase in the incidence of infection, malignant disease, autoimmunity or other clinically important conditions arising in the study population. It would be appropriate that such individuals be excluded from further donation.

ACKNOWLEDGMENTS

We thank the donors of Western Province Blood Transfusion Service for their participation, Gail McElhaney and Sue Horak for help with haematological studies, Sisters C. Sims and D. Owens, Mrs. A. Taylor, and staff of the Western Province Blood Transfusion Service Separation Unit for their invaluable help, Mrs. B. Bertlin and Mrs. S. Craig for their patience and typing of drafts, Professor Martin J. Murphy, Jr., for his critical advice on the manuscript, and Jackie Davies for help with its preparation and final typing.

Abstract

Aplasia or irreversible bone marrow failure and a variety of haematologic malignancies, as well as an increasing number of solid tumours, currently include various forms of marrow or equivalent transplantation in routine management. In both allogeneic and autologous procedures stable recipient immunohaematopoietic reconstitution depends upon infusing the requisite population harvested at a precise time following commencement of a stimulatory peptide. In a first step this prospective study documented the safety of apheresis, defined side effects and enumerated mononuclear, CD34+ and CD3+ cells obtained. In the second stage delivery of the graft, characterised in this way and with the additional measurement of in vitro growth in clonogenic assay, to the suitably conditioned patient was correlated with recovery of neutrophil and platelet numbers appearing in the circulation. In a third and ongoing analysis the influence of passenger T-lymphocytes is being evaluated for impact on infection and a potential anti-tumour effect. The conclusion is that this technology is reliable, has a high degree of patient acceptability without untoward complications, and that local results correspond to international experience thereby providing an important and relevant measure of quality control.

1. Introduction

Escalation of chemotherapy, often combined with irradiation, increasingly reaches levels that require support by infusion of haematopoietic progenitors. This intervention is accepted as integral to the standard care of those with irreversible
marrow failure, many haematologic neoplasms and an expanding array of selected solid tumours. Obtaining such donations from the peripheral blood, using apheresis technology, has superseded the older practice of multiple bone marrow aspirations as the source of the graft. Successful outcome is governed by three broad variables. The first of these is patient-based and includes disease category whilst current status, coupled with prior therapy, may influence efficient mobilisation of an autograft. The second, also in the recipient, is residual integrity of the haematopoietic inductive microenvironment known to be essential in supporting recovery of blood formation and immune function. This latter tissue may have been damaged by conditioning or preparative regimens of which most are still myeloablative. Thirdly is the composition of the donation reflected in total lymphocytes and monocytes as well as CD34+ precursors measured by flow cytometry whilst repopulating potential is quantitated in colony formation using calibrated in vitro culture techniques. The interplay of these factors combine to determine the efficiency with which neutrophils and platelets reappear in the circulation. In the longer-term recovery of immunity becomes the dominant influence on a variety of infections and, ultimately, disease-free survival.

It is an ethical obligation that collection procedures are carried out with attention to donor safety and recognition that side effects may arise from the administration of molecules such as GM or G-CSF and this is particularly important in volunteer participants. Prior discussion should therefore provide reassurance and balanced information about the possibility of musculo skeletal discomfort that may be associated with self-administration of this agent. Additionally the procedure needs to be outlined so that there is familiarisation with the instrument and the various manoeuvres that take place during harvesting while the continuous presence of an experienced nurse is integral to donors peace of mind and safe management.

This ongoing trial monitors each consecutive apheresis and contrasts allogeneic and autologous experience constantly comparing results to publications [1,2] as part of safety evaluation in this department.

2. Patients

Details of the entire procedure were explained including technicalities of venous cannulation, the need and method required for mobilisation into the circulation as well as the voluntary nature of the participation. Written informed consent was obtained in each instance. Viral screens were carried out and individuals medically examined for suitability to donate. Neupogen (Roche Products SA) was administered at a dose of 300 μg subcutaneously starting on the Friday as a matter of convenience and this was designated as day 0. Where possible a vein-to-vein technique was used. All patients were interviewed on a daily basis and side effects documented through a minimum of one week [3].

3. Methods

Peripheral blood specimens were collected into EDTA as a baseline and subsequently on days 3, 4, 5 and 7. Full blood and differential counts was performed on the Cell-Dyn 1700 Haematology analyser [4] and 1000 cell differential noted on each occasion with calculation of absolute leucocyte numbers [5].

Flow cytometry was performed on each sample to quantitate CD3 and CD19 populations [6]. Two different techniques were used for CD34 quantitation but there was no overlap of methodology during any particular collection.

The ISHAGE [7] method required 100 μl of patient’s blood to be incubated with 10 μl of CD34 and CD45 antibodies. After lysing and washing, dual expression of the two surface markers was detected using direct immunofluorescence and analysed using the recommended gating strategy.

In the ProCOUNT (Becton Dickinson) [8] approach, a two-tube assay was performed by staining the sample with CD34 and Control reagent in individual TruCOUNT tubes. When using an appropriate reaction mixture fluorochrome-labelled antibodies bound specifically to surface membrane antigens while nucleic acid dye stained the DNA and RNA. The lyophilised pellet is then dissolved, releasing a known number of fluorescent beads in the Control, and so correcting for the
amount of non-specific antibody binding. FACS
lyse solution is added to destroy erythrocytes be-
fore analysis on the FACSscan flow cytometer.
During counting the absolute number of CD34+
events is determined by correcting these for signals
generated by the beads and then multiplying this
by the concentration of the latter.

Individual collections were standardised to day 4
based upon a previous study (Jacobs and Wood,
unpublished) as well as recommended guidelines
[9]. The Cobe Spectra instrument was used to pro-
cess between 3 and 5 times the estimated blood
volume with anticoagulant being acid citrate dext-
rose-A solution (ACD-Baxter SA). Calcium
replacement was as 10% gluconate (Baxter SA)
at a rate of 6ml/h with appropriate increases for
the development of symptomatic hypocalcaemia.
The volume and contents of each harvest were de-
finite in terms of mononuclears, CD34+ numbers
as well as colony formation in clonogenic assay
with CD3+ positivity also specified for allografts
where measurements were carried out prior to
adding the opsonic Campath 1 H monoclonal anti-
body [10]. Autografts were cryopreserved and

Reinfusion took place over 1 h and was pre-
ced by premedication with 100 mg of hydrocortisone,
12.5 mg of phenergan and 2 paracetamol
tablets orally. Thereafter the reappearance of
granulocytes and platelets in the peripheral blood
was noted and this pattern correlated with the cel-
lar content of the graft [12]. The T-lymphocyte
load is to be evaluated as a predictor for the in-
cidence of post-transplant infections [13] and the
potential development of acute or chronic graft-
versus-host disease [14].

4. Results

These are given in median and range as well as
mean with standard deviation.

4.1. Donor side effects

None were documented in nine procedures and
in the remainder were minor. Lower back pain
(n = 21) was associated with injections as was
headache (n = 16) and transient heaviness on the
chest (n = 6). A number of these occurred together
in the same patient. Mild citrate toxicity (n = 5)
was immediately reversed by increasing the rate
of calcium replacement.

4.2. Collection characteristics

The volume in the bag was 474 (222–645) or 388
(±73.9) mL. A single large volume apheresis was
adequate in the majority (n = 33). A second pro-
dure was needed in 4 and a third procedure in 1
but, apart from the increased amount of plasma
recovered, no adverse effects occurred.

In the allografts (n = 27) the peak in both
mononuclear cells (Fig. 1(a)) and the circulating
CD34+ population (Fig. 1(b)) occurred on day 4
in most patients. Mononuclears recovered were
6.6 (6.6–12.5) or 8.0 (±1.3) × 10^9/kg; CD3+ 4.8
(2.1–7.5) or 0.55 (±1.13) × 10^9/kg; CD34+ 3.9
(2.7–11) or 5.3 (±1.7) × 10^9/kg and GM-CFUc
1.0 (1.0–31.1) and 6.8 (±6.34) × 10^4/kg (Table 1).

In the autografts (n = 15) a different pattern
emerged for both mononuclear cells (Fig. 2(a))
and the CD34+ population (Fig. 2(b)) where a bi-
modal distribution was seen in the peripheral cir-
culation with a significant number of patients
having a second peak on day 7. Mononuclears
recovered were 7.5 (6.0–12.13) or 8.2 (±2.0) × 10^9/kg; CD34 1.4 (0.89–22.6) or 3.3 (±5.5) × 10^9/kg
and GM-CFUc 5.1 (1.5–16) or 7.4 (±5.0) × 10^4/kg (Table 2).

4.3. Recipient outcome

This is surprisingly comparable between the two
procedures.

In the allografts following infusion (n = 27), the
time to reach 0.5 × 10^9/L neutrophils was 12 (7–15)
or 11.5 (±1.6) and 1.0 × 10^9/L 12 (8–31) or 13
(±4.4). The corresponding figures for platelets to
reach 20 × 10^9/L was 17.5 (3–62) or 20 (±15.39),
50 × 10^9/L was 17.5 (6–77) or 25.7 (±18.87) and
100 × 10^9/L was 62 (10–100+) or 46 (±32.9).

In the autografts following infusion (n = 8), the
time to reach 0.5 × 10^9/L neutrophils was 13 (12–
22) or 14 (3.4) and 1.0 × 10^9/L 13 (12–22) or 14
(3.3). The corresponding figures for platelets to
reach $20 \times 10^9$/L was 57.5 (15–+100) or 58 (37.5), $50 \times 10^9$/L was 59.5 (19–+100) or 60.8 (38) and $100 \times 10^9$/L was 60.5 (21–100+) or 72 (34.7).

5. Discussion

Nowhere in medicine is the role of the professional nurse, as an integral and often central member of the multidisciplinary team, more evident than in routine management programmes that typically include administration of chemotherapy which becomes potentially hazardous as doses are escalated to myelosuppressive levels typically needing haematopoietic stem cell transplantation [15,16]. The latter procedures continue to undergo refinement and one of the most striking is a change from the older technique of harvesting bone marrow from the sternum and ilium [17] to its replacement by recovery of the same population from the peripheral blood using apheresis technology [18].

Although well-established two broad but overlapping areas of responsibility require constant attention to ensure that patient safety remains paramount in the delivery of health care. Firstly, while these observations apply to all donations,
they assume particular importance when siblings are used and even more so in matched unrelated volunteer donor programmes [19]. Thus ethical principles dictate a thorough familiarity with technical details, the availability of modern, safe and regularly tested equipment with experienced apheresis nurses carrying out each harvest in an atmosphere characterised by quiet efficiency and where patient fears are allayed by careful prior explanation of each step in the collection. To this must be added the anticipation of side effects where it is mandatory to balance appropriate information with objectivity on the one hand and administration of the least amount of the stimulatory peptide commensurate with obtaining optimum results on the other [20]. Secondly, and in context, it is crucial that the biological product obtained has an adequate margin of safety in terms of number and function of progenitors to ensure subsequent reestablishment of both blood formation and immunologic integrity [21,22].

Early experience with this methodology centred on the recovery of granulocytes for managing neu-
tropicen sepsis but the unstimulated yields were

Fig. 2. Autologous donors. Both cell populations follow a similar pattern but a bimodal distribution is noted in the CD34 cells with a second peak on day 7. This observation does not appear to have been previously documented and may reflect changes known to occur in the haematopoietic micro inductive environment and is not necessarily a consequence of prior myeloablative therapy and bone marrow transplantation [59].

relatively small and, except in children, of limited value. With the availability of highly purified molecules, known to raise white cell count, this aspect of transfusion therapy is again assuming clinical importance [23]. Thus, on the basis of the older model rests the scope of harvesting intramedullary progenitors during their passage through the circulation by means of apheresis technology [24]. Initial observations showed a marked increase in recovery following chemotherapy [25] but the use of cytotoxic drugs in otherwise healthy donors is inappropriate and has been replaced by alternative regimens using recombinant molecules [26]. Even under these circumstances it is not entirely clear whether the immunobiology of this population [27], reflected for example in varying lymphocyte subsets and heterogeneity of the CD34+ cells [28] may not, with longer follow up, predicate the use of one or other peptide or, indeed, even return to the use of bone marrow aspiration [29].

* Patients have not to date, received their stored graft.

5.1. Donor side effects

Donor side effects were evaluated at two levels. Firstly was safety and in approximately 30% no symptoms developed. In the remainder these were mild. The incidence of lower back pain, with occasional headaches, was low and both responded to simple analgesia with paracetamol. This observation is consistent with the known effect that, even at different schedules [30], mobilisation is equivalent but discomfort decreased with dose [31]. Notably, with three years of follow-up, late complications are rare [32,33]; but, in the interest of prudence, even longer observation is required. Apart from a single instance there was no discomfort either at the ante-cubital or femoral vein site used for establishing venous access.

Secondly is the effect that this intervention on the immunohaematopoietic system itself where stimulating factors transform the marrow into a highly proteolytic environment [34]. Other relevant observations are a decrease in the more primitive population [35] and an alteration in the Th 2 to Th 1 ratio thereby providing a biological explanation for the lack of severe acute graft-versus-host disease following infusion of the peripheral blood derived harvest [36]. Less information is available on children although grafts, adequate for adults, can be obtained with donor body weights as low as 15 kg [37].

Given these caveats every effort should be made to shorten period at risk. One manoeuvre is to define response to a test dose of the mobilising molecules [38] and kinetic studies, confirmed in the present work, demonstrate that rising leucocyte and platelet count predicate optimum timing [39] with the desired progenitors being higher than when conventional bone marrow grafts are used [40]. This pattern, derived from normal subjects, distinctly changes in those who have previously
been exposed to chemotherapy en route to autologous collection since recovery is suppressed in these scenarios. A word of caution is appropriate since there is considerable variation in the harvesting schedule [41], introduction of combinations as with stem cell factor [42] and the assay techniques employed [43].

5.2. Collection characteristics

Collection characteristics depend upon intrinsic reserves, how much of this capacity remains after prior chemotherapy in the case of autografting and the extent to which release of progenitors into the circulation can be enhanced by pharmacologic stimulation. Furthermore, but not specifically examined, is the ongoing debate about potential contamination of the apheresis product by tumour [44].

Three criteria were used to define adequacy.

Firstly, based on our earlier experience (Wood and Jacobs, unpublished) and recommended guidelines, a minimum number of $6.5 \times 10^9$/kg mononuclear cells was the target [45]. Since it has been shown, and confirmed, that in normal subjects optimum numbers are circulating on day 5 collections were standardised to this time [46]. During the collection cellular content of the bag was serially monitored and, in the absence of side effects, this target was reached in a single apheresis in 33 of 48 donations with the instrument preset to process approximately five times the calculated plasma volume [47].

Secondly, additional quality control required that a minimum of $2 \times 10^9$/kg CD34+ progenitors were infused with this value achieved in each instance [48]. It has previously been reported that there is a linear relationship between the different component populations and this was confirmed in the present study (Fig. 1(a) and (b)). There is evidence that increasing number of the progenitors [49] will improve engraftment characteristics defined by the appearance of a steady increase in the rate at which granulocytes and platelets appear in the circulation up to of $2 \times 10^9$/kg but, thereafter, increments are of questionable value [50]. In this context the association of T-lymphocytes may be important. A certain number are necessary for establishment of immunohaematopoietic function [51] but there seems to be an optimum balance between intensity of host conditioning and the degree of T-cell depletion in the graft where either quantitative or qualitative differences may predominate the incidence and severity of acute and therefore, subsequent chronic graft-versus-host disease (GVHD) [52].

Thirdly, of probably greater importance, is the repopulating potential of the donation determined by colony and cluster formation of the clonogenic assay [53]. Although a number of comparable in vitro techniques exist no practical advantage attends the choice of studying the more mature cells whether these be myeloid or erthyroid but rather using an alternative assay to document long-term colony initiating progenitors [54].

5.3. Allografts

Allografts run the risk of adverse side effects and in unfractionated procedures immunosuppressive regimens typically include methotrexate, cyclosporin A and additional corticosteroids [55]. As previously reported [10] ex vivo exposure to the Campath series of monoclonal antibodies to deplete T-lymphocytes has been confirmed as an effective manoeuvre requiring no additional immunosuppressive therapy [56]. Initially the older lytic immunoglobulin or IM almost totally removed these cells but with the switch to the opsonic variant there are additional considerations including in vivo consequences which are difficult to quantitate [57].

Autografts were shown to have a different pattern in which mononuclears and CD34+ cells appeared in the circulation. Here there was a bimodal distribution with most patients behaving similarly to the allografts but a second peak becoming evident on day 7. It is currently unknown what underlies this phenomenon. It can be speculated that release is disturbed by prior damage to the inductive microenvironment [58,59] but, acknowledging that numbers were small, no distinction was evident by disease category or class of cytotoxic drug. Not surprisingly this fact necessitated second or third collections necessary to meet the minimum requirements
for graft safety. Despite this restriction the requisite number of cells were obtained in all instances.

5.4. Recipient outcome

Recipient outcome is notable that, although differences were present in donors and quite striking in the collection characteristics, the response after infusion was indistinguishable. This raises two interesting points.

Firstly, it appears as though both the quantity and the quality of the progenitors recovered, whether from volunteers or after chemotherapy and irrespective of the diseases studied in the autografts, are indistinguishable in generating short-term recovery of phagocytic function reflected in numbers of circulating monocytes and neutrophils. Furthermore, since platelet regeneration was also comparable, it can be inferred that the committed myeloid compartment is not selectively damaged although it is conceded that the more sensitive evaluation of reticulocyte response was not specifically examined.

Secondly, and as part of this ongoing investigation, is the possibility of more subtle change in lymphocyte subsets that may unmask differences in immune function as humoral and cellular pathways are studied over longer periods of time. However, preliminary analysis of patient outcome shows no difference in early bacterial or viral infection between the allografted or autografted recipients. Nevertheless vigilance is mandatory to anticipate the risk of these complications [60] and reducing them as far as possible with appropriate vaccinations [61]. In similar context is the intriguing possibility that late-presenting grade I graft-versus-host disease limited to the skin and rapidly responsive to topical or systemic steroids, may favourably impact the incidence of tumour relapse.

The hypothesis is that enhancement of a desirable graft-versus-leukaemia effect may be separable from the more commonly recognised, but deleterious, inflammatory process [62]. For example it is suggested that cyclosporin A can upregulate, in the autologous situation, immunologically mediated recognition of foreign antigen and this pathway has the potential to be selectively modified and harnessed as a means for recognising and eradicating residual neoplastic cells [63].

6. Summary and conclusion

This ongoing prospective investigation has three goals. Firstly, to evaluate donor side effects and these were shown to be minor with the procedure having high patient acceptability. Secondly, to characterise the response to the stimulatory peptide with most allogeneic donors achieving peak mononuclear and CD34+ cell populations on day 4 at which time collections took place. Differences in autografts were thought to reflect prior chemotherapy and a second increment noted on day 7 despite which quantitatively adequate recovery was obtained in each instance. Thirdly, to define recipient outcome where it was demonstrated that, for both sets of donors, peripheral blood neutrophil and platelet regeneration was similar and consistent with published guidelines. It is concluded that the programme, standardised in this way, complies with international standards of practice. In the longer-term numbers and phenotypically distinct subsets of T-lymphocytes remain to be correlated with bacterial and viral infections as well as immunologically mediated events that included acute and chronic graft-versus-host disease and the possibility of a separate cell-mediated anti-tumour benefit.

The use of granulocyte-colony-stimulating factor in volunteer unrelated hematopoietic stem cell donors.

Pampillon D, Nacheva E, Navarrete C, Madrigal A, Goldman J.

The British Bone Marrow Registry and Institute for Transfusion Sciences, Bristol, UK. derwood.pampillon@nhsbt.nhs.uk

Granulocyte-colony-stimulating factor (G-CSF) is used for the mobilization of hematopoietic stem cells in healthy donors. It has a number of common side effects such as bone pain, which resolve rapidly after administration is discontinued. Recent publications have raised concern that it might act as a trigger for the development of hematologic malignancy in susceptible individuals, possibly by causing genomic instability, but to date there is no evidence that healthy volunteer donors who receive G-CSF are at any increased risk. Ongoing studies aim to confirm whether or not G-CSF can cause chromosomal abnormalities in healthy donors. In the UK, the British Bone Marrow Registry and Anthony Nolan Trust give G-CSF to donors who have agreed to donate peripheral blood stem cells. It is recommended by the UK Registries at present that all stem cell donors are given updated information explaining the current uncertainties with regard to the use of G-CSF before they give informed consent to its administration. This information is based on a statement agreed by the World Marrow Donor Association for use by individual donor registries. Further, it is our current practice that all donors who have received G-CSF, as well as marrow donors who do not, should be under regular review for at least 10 years to allow the occurrence of any long-term adverse events to be documented.

PMID: 18373639 [PubMed - indexed for MEDLINE]
Possible harmful effects of short course granulocyte colony-stimulating factor in normal donors

The initial success of haematopoietic stem cell (HSC) transplants, intended to reconstitute a patient's bone marrow function after high dose or 'supralethal' chemotherapy or chemoradiotherapy, was based on the use of bone marrow derived from either a related or unrelated volunteer donor. However, in the late 1980s it became clear that an alternative was to collect HSCs from peripheral blood following mobilisation with haematopoietic growth factors (HGFs), either granulocyte colony-stimulating factor (G-CSF) or granulocyte/macrophage colony-stimulating factor (GM-CSF).

To a large extent, the use of mobilised peripheral blood HSC has replaced marrow-derived stem cells as the preferred source of donor HSCs. The cells collected by prior treatment with cytokines include substantially more granulocyte/macrophage colony-forming units (CFU-GM), more CD34 cells and more lymphocytes than an 'equivalent' marrow harvest.

Peripheral blood HSC grafts are particularly useful in the setting of reduced intensity conditioning allografts where transfusion of large numbers of CD34 cells may be important. Whilst G-CSF and GM-CSF are very similar or identical to cytokines produced in the human body, investigators and clinicians have been aware since their first clinical use that their administration, even in a single short course, could possibly constitute a risk for healthy donors either in the short term or as a delayed effect. For this reason the healthy donors who receive them have been subjected to extensive follow-up evaluation and transplant centres and transplant registries on both sides of the Atlantic have attempted to maintain close contact with donors for many years after their respective donations. Thus the European Group for Blood and Marrow Transplantation reported five haematological malignancies from a database of 16,431 donors who had received G-CSF [A. Gratwohl (2004), personal communication] and the National Marrow Donor Program in the USA reported four cases of malignant disease out of 2,370 donors followed for varying periods of time [D. Confer (2005), personal communication]. In both cases, the incidence of malignancy was deemed not to have differed significantly from what would have been expected in a normal population that was not exposed to HGFs [Bacher et al., 2005]. Other smaller series failed to identify any increased risk of malignancy after G-CSF administration (summarised in Pulskipher et al., 2006). In summary of the available clinical data, it seems that the notion that HGFs cause or contribute to malignancy in a normal person is very far from established.

In contrast to the short-term treatment of HSC donors, G-CSF has been used for prolonged periods in patients with severe congenital neutropenia (Kostmann syndrome) and there does seem to be some definite risk. After treatment for 6 years the projected risk of progression to myelodysplastic syndrome or acute myeloid leukaemia was 2.9%, though after treatment for 12 years the risk had risen to 8.0%. However, it is likely that such patients are constitutionally at risk of their disease progressing to overt malignancy, which could simply mean that G-CSF is a co-factor or expedites this progression. The observation may or may not have any relevance for normal persons exposed to G-CSF for a single 5-day course.

At Tel Aviv University, Nagler et al. (2004) reported finding specific abnormalities in lymphocytes from normal people who had recently received G-CSF that were very similar to those seen in lymphocytes from persons with malignant diseases. Specifically, these abnormalities included loss of synchrony in allelic replication and aneuploidy. The abnormal timing of allelic replication was a transient phenomenon but the aneuploidy persisted in the longer term. The authors stated that these changes were characteristic of changes seen in lymphocytes from patients undergoing chemotherapy for malignant disease.

The paper by Bennett et al. (2006) that appears in this issue of the British Journal of Haematology reports five cases of leukaemia, three lymphoid and two myeloid, occurring in individuals who had received HGFs. Three patients had received a pegylated recombinant human megakaryocyte growth and development factor (hHuMIGDF), which has now been withdrawn from the market, and two patients, who developed acute myeloid leukaemia, had received G-CSF in the course of donating HSCs to siblings who were undergoing treatment for acute leukaemia. However, as noted in the paper by Bennett, large-scale studies in both Europe and the USA have not found increased levels of haematological malignancy in G-CSF-treated donors.

There is no doubt that the use of HSC transplants has offered a potentially life-saving procedure to many patients. However, it must be recognised there are established and also unknown risks for the volunteer donor whatever method is used to harvest the HSC.

How then, should the bone marrow transplant community respond to this latest paper and the reported remote, but presumably finite, possibility that G-CSF could be harmful in the long-term? Most would agree that currently to abandon use of G-CSF for normal donors would not be justified. In the
meanwhile, five measures warrant consideration by organisations involved with the provision and use of donors worldwide:

1. The international transplant community and donor register organisations need to reach a consensus as to the long-term risks that donors are being subjected to and what risk is acceptable. Transplant centres and donor registries should ensure that they follow normal donors postdonation with as much precision as possible. The duration of follow-up should arguably be a minimum of 10 years and perhaps lifelong. Such follow-up should apply equally to bone marrow donors.

2. Selected normal donors should be studied longitudinally with cytogenetic analyses of lymphocytes and other tests designed to detect persisting damage both to the lymphoid and, perhaps more importantly, to the myeloid lineage.

3. Donors should be exposed to the minimum amounts of cytokines, such that the maximal number of doses and the maximal number of courses are limited.

4. Consideration should be given to long-term (more than 1 year) insurance cover of donors following leucapheresis or marrow collection.

5. Prospective donors must be told of the somewhat uncertain situation regarding G-CSF for blood stem cell mobilisation so that they can balance the risks against those associated with bone marrow donation.

The continuation of this potentially life-saving treatment will depend upon the ability of the scientific community to monitor and evaluate on an ongoing basis the level of risk associated with G-CSF administration, so that donors, both past and present, can receive and assess for themselves the best available evidence.

CHAPTER 3

UNFRACTIONATED MARROW

THE WORLD STANDARD OF CARE
International experience was based on the use of marrow rich blood. This was obtained by multiple aspirations under general anaesthesia and generally with two teams working in parallel. The target was approximately 10ml/kg lean body mass of the recipient using appropriate anticoagulation. After ensuring that the recovered product was monocellular by gently passing it through a series of stainless steel screens, having decreasing pore size, samples were obtained for quality control and the graft infused intravenously. Attention was given to side-effects including changes in blood pressure and occasional oxygen desaturation.

Focus was maintained on local requirements. Nevertheless with accumulating experience each new observation or innovation was systematically tested in the laboratory utilising the established culture studies and exploration in animal models before introduction into ethics approved treatment protocols. Care was taken to integrate new information from international cooperative studies for both autografting and allografting. Examples were rejection and acute as well as the often consequential chronic graft-versus-host disease. Both generated substantial morbidity and mortality.

At this point it was appreciated that accountability was essential but such was nowhere available on the African continent. Accordingly there was the initiative of obtaining Ethics and Research Committee review and approval for scrupulously followed protocols. Clearly even this was inadequate on its own and, despite duplicating international methods, the seminal commitment was made to voluntarily report all information. This took place on every consecutive patient first to International, then autologous and latterly the Centre for International Bone Marrow Transplantation Research.

Such scrutiny with participation in these registries brings with it huge resource consumption but this is offset by three benefits. Access became constantly available to any changes that emerged with modifications by disease category. One example was severe aplastic anaemia where we had reported corresponding investigations.
It is also suggested that it is the saliva which is responsible for dental erosion and not acidic food and drinks. However, patients suffering dental erosion have been shown to have saliva of normal pH and buff ering capacity. Erosion which resulted from initial tooth decalcification was ascribed to the consumption of fruit juices, even though they were only in contact with the teeth for a short period of time before swallowing.  

The buffering effect of saliva is only modest — the pH value of the apple-saliva bolus typically ranges between 4.3 and 4.9. However, according to Jemiel, "The increased buffer capacity of saliva stimulated by chewing apples is clearly offset by their low (dietary) acid and their sugar content." The measurement of the stimulatory effect of apple products on the volume and quality of saliva has apparently not been investigated in depth, and it is not known whether the pH of the mouth reaches the critical level of 3.5. So while apples cannot be recommended as non-noticeable snack-food, they are claimed to be preferable to sticky confectionery because, gram for gram, they contain one-tenth the amount of carbohydrate, and also provide pomegranate (the fibre content), minerals and vitamins. Ascorbic acid (vitamin C), the most prominent vitamin found throughout the apple, is most concentrated under the skin.

Chewing a hard food or fruit, such as a carrot or apple, after a meal was once recommended as a way of preventing dental caries and gum (gingival) disease. This is no longer advised for carrots. As for apples, although the work of Slack and Martin in 1958 suggested that eating them slightly reduced the incidence of tooth decay, and that the gums of apple eaters were thereby improved, subsequent workers have concluded that eating apples does not enhance the health of gingival tissues. Instead, it removes plaque only from the smooth surfaces of the teeth, while inter-dental and gingival plaque is unaffected.

In a recent review it is recommended that "apples must be demoted from their position of prominence as foods good for teeth." We suggest that further investigations are needed into the properties of fresh and processed apples in order to establish whether the fruit, as a food, is in fact beneficial or detrimental to the mouth.

Bone Marrow Transplantation

Peter Jacobs

Both experimentally and in clinical practice the replacement of an irreversibly damaged organ offers a logical and life-saving approach to treatment in a number of threatening situations. Unfortunately, biological systems provide barriers far greater than the simple mechanics of removing, for example, a diseased kidney or heart and substituting this with its healthy counterpart. The most immediate problem encountered is that of rejection where antigenic disparity between donor and recipient may lead to loss of function in the foreign tissue. The administration of immunosuppressive drugs to try and avoid or suppress this complication frequently compromises the immunologic competence of the host, thereby predisposing it to lethal opportunistic infection.

In bone marrow transplantation the situation is more complex, since the graft contains a mixed population of cells. On the one hand are the haematopoietic stem cells, precursors of blood, that migrate to the marrow cavity, grow and eventually enter the circulation. On the other hand are contaminating, immunologically competent lymphocytes. The latter recognise the antigens of the recipient as 'non-self' and respond by mounting an inflammatory reaction directed against skin, gastrointestinal tract and liver—the unique syndrome of graft-versus-host disease.

Despite these two formidable challenges the last decade has seen progress in some aspects of bone marrow transplantation and there is currently increasing use of this procedure in a number of conditions previously considered to be uniformly lethal. Already there is clear need to extend the use of bone marrow transplantation, the extent of which will be determined by the success with which the technique is used.
rejection and other complications can be controlled.

Indications and results

The bone marrow is susceptible to damage by genetic, immunologic and toxic mechanisms. Where this is partial, recovery can occur and it is necessary diligently to seek out this possibility in each individual. However, where organ failure is total the term aplasia of the marrow is used. This is a more ominous situation since randomized prospective studies have established that bone marrow transplantation is the preferred form of treatment whereas response to the administration of male sex hormones, known to stimulate blood formation, has no statistically significant benefit.

In aplastic patients being considered for bone marrow transplantation the likelihood of the damage being reversible should be excluded by a two week period of observation during which time all the necessary preparations are being made. Persistence of severely impaired blood formation beyond this time, characterized by low red cell, white cell and platelet counts, identifies a patient population having a high mortality and here it is rational to proceed to transplantation.

In the marrow, developing blood cells are normally nourished from a scaffold of non-haematopoietic tissue known as the inductive microenvironment. Theoretically, therefore, haematopoietic failure may arise from defects in either of these two components. Convincing demonstration of environmental failure is based on animal studies; proof is lacking in man. Currently, most experimental evidence incriminates the haematopoietic stem cell. Recent interest has been centered on the possibility that impaired function may be immunologically mediated rather than due to intrinsic damage. To identify these individuals in vitro marrow culture is used; function may then be returned to normal by the administration of immunosuppressive agents. Unfortunately, the majority of patients require replacement of irreversibly damaged stem cells and transplantation offers a cure rate, in a previously lethal disease, of around 50%.

A similar situation prevails with children with severe immunodeficiency diseases in that, when a donor is available, transplantation is no longer a contentious issue. As in severe, acute aplastic anaemia, a plea is made for this form of treatment to be considered immediately on diagnosis. The well intentioned practice of instituting periods of blood transfusion or white cell and platelet support, in the naive hope that spontaneous remission may occur, is to be deprecated. Persistence with this unfortunate course of action leads to the development of isoinmunization and consequent loss of either the transplant option, substantially increased risk of rejection, or the development of graft-versus-host disease.

Depending upon circumstances, cure rates of over 50% are realizable. Leukaemia is a third case where bone marrow transplantation may be used. Initially, only patients who had failed to respond to conventional drug regimens or who had relapsed were referred for this form of experimental treatment. Many of these patients had been exposed to a wide variety of cytotoxic drugs over prolonged periods of time and were in the terminal stages of their disease. The salvage rate of between 10% and 15%, although low, is distinctly encouraging when the patient population is considered.

The latter results allow of two comments when considering transplantation in the leukaemic patient. Firstly, this procedure remains a viable therapeutic option even following relapse. However, it is essential that drug therapy should not be persisted with and that patients undergo the procedure immediately a second complete remission is achieved. By following this self-evident approach, complications arising from cumulative drug damage can be avoided.

Secondly, and of perhaps greater interest, is preliminary evidence to support the use of marrow transplantation, whenever a compatible donor is available, in adults achieving their first complete remission. In adults recent data demonstrate remission rates of just over 60% at two years, a figure which compares favourably with the best obtainable with drug treatment.

The same choice should be made available to children with acute lymphoblastic leukaemia in the presence of bad prognostic factors such as mediastinal or disease of the central nervous system. In both these groups chemotherapeutic regimens are generally acknowledged to be poor and no individual should be denied this alternative option. Results with these patients are presently inadequate for analysis because too few have been transplanted.

Marrow transplantation is possible in other situations but here even less clarity exists. For example, it is uncertain whether constitutional or familial anaemias would qualify in view of the possibility that siblings may share the genetically determined defect. Furthermore, because morbidity and mortality are substantial, patients with lethal genetic diseases and those with chronic granulocytic leukaemia should be evaluated for transplantation only on protocol study by groups committing their research and service resources to this form of treatment as a major priority.

Transplantation techniques

The transfer of marrow between identical twins, syngeneic transplantation, is the ideal practice since antigenic disparity does not exist. Understandably, rejection and graft-versus-host disease are not encountered, so that results obtained with aplasia and leukaemia are superior to those where the donor was not a twin.

In allogeneic transplantation, where the donor is a brother or sister, preoccupation is with selecting the sibling who, using laboratory tests, has the identical tissue type. This compatibility is defined by a set of genes carried on chromosome 6, which code for antigens on the surface of leucocytes designated as the major histocompatibility complex. Despite apparently perfect matching, rejection and graft-versus-host disease still occur and both phenomena may therefore reflect the influence of immune reactive genes located outside the strict confines of the HL-A system.

On the basis of such minor degrees of incompatibility, high doses of cytotoxic drugs are administered, with or without additional radiotherapy, in an attempt to suppress in the recipient immunologic responses to donor antigens. To some extent these increasingly aggressive regimens are offset by a higher incidence and greater severity of graft-versus-host disease and infection.

The transplantation procedure itself is relatively simple. Under general anaesthetic the donor has marrow collected from the pelvic and sternal bones by simple aspiration with a needle. A total volume of between 500 and 700 ml of marrow-rich blood is harvested, which contains between 1.5 and 5.4 x 10^9 nucleated cells and an adequate number of haematopoietic stem cells to reconstitute marrow function in most individuals. The adequacy of the graft can be monitored in vitro by bone marrow culture, although such a test is not a guarantee of engraftment.

Autologous bone marrow transplantation requires separate comment. Here the patient's own marrow is collected, stored and later reinfused intravenously when the necessity arises. Clearly this option will not exist in the patient with aplasia but it offers an approach for those with leukaemia having no suitable donor and for a variety of non-haematologic malignancies where treatment is limited by iatrogenic marrow damage. This treatment in patients with leukaemia is fundamentally defective since the graft is likely to be contaminated by members of the original malignant clone. However, if immunologic techniques can be developed for the recognition and removal of these tumour cells, then the possibility of infusing a 'clean graft' is attractive, since it carries with it no risk of rejection or graft-versus-host disease. These theoretical concepts are the basis for persisting with the evaluation and development of autologous bone marrow transplantation: the coming decade should see this technique placed in clearer perspective.

Cell support

In addition to the transfer of bone marrow stem cells from donor to recipient, the necessity to protect patients during the
period immediately following transplantation requires the availability of effective white cell and platelet support. Such facilities, involving the separation of blood fractions, are an integral part of the modern transplantation centre. The blood components must be readily available and derived from procedures where the highest degree of quality control has been established and is constantly maintained.

There is no doubt that the infusion of adequate numbers of functionally intact platelets has reduced morbidity from haemorrhagic episodes. As this problem has diminished so its place has been taken by infection, which emphasizes the need to provide reliable granulocyte support. The development of filtration and continuous flow techniques for harvesting sufficient number of white cells from donors remains the subject of intensive investigation. These are best considered research projects linked to carefully controlled protocols for bone marrow transplantation.

**Graft-versus-host disease**

This unique immunologic phenomenon occurs only in the recipient of a successful marrow graft and is thought to be mediated by surviving, immunologically competent donor lymphocytes. It remains the major stumbling block to the wider use of allogeneic bone marrow transplantation. Two clinical entities are recognizable. The acute syndrome characteristically occurs within four weeks of transplantation, runs a fulminating course and has a very high mortality. At present it is uncertain what role the lymphocytes present in the graft play in this variant of disease; the early onset suggests that they may be implicated in pathogenesis. In contrast, a more chronic inflammatory condition of skin, gastrointestinal tract and liver occurs later after transplantation and has been ascribed to cells, probably lymphocytes and monocytes, originating from the established graft. In either event failure to recognize the aetiological mechanisms has bedevilled management. Prophylaxis remains the cornerstone of treatment and on the basis of results obtained in syngeneic and autologous transplantation has focused attention on the need for more precise matching. Once established, attempts to modify severity of the graft-versus-host disease with immunosuppressive agents and antisera directed against the lymphocyte have met with only limited success and many theoretically hasten the progression of the inflammatory process. Of interest are experimental observations that, in animal models, the administration of immunologic adjuvants such as Cyclosporin A and Corynebacterium parvum both abrogate the phenomenon and prolong the survival of transplant recipients. It now remains to test their efficacy in man.

**Summary and conclusions**

Bone marrow transplantation is established as the preferred form of treatment for patients with severe aplastic anaemia and immunodeficiency diseases. This procedure is contingent upon the availability of a willing and compatible donor. It is impossible to over-emphasize the importance of referring potential patients early, before isoinmunization has resulted from blood transfusion and thus compromised the chances of success.

In both adults and children with acute leukaemia, cautious optimism is justified by available results. In both groups a small but significant salvage rate is possible even in patients with drug-resistant disease or following relapse. Preliminary data support the use of transplantation in first remission as the primary form of treatment, in both adults and children who have disease markers for poor prognosis.

Major problems still persist. On the one hand autologous complications such as isoinmunization should be reduced as the education of physicians results in a better appreciation of what early bone marrow transplantation will offer. In contrast, graft-versus-host disease, or 'reverse rejection', is not understood and stands out as the greatest obstacle currently preventing the wider use of this form of treatment.

Clearly, much progress has been made and there is every reason to persist with research programmes seeking to bridge the gap between what is theoretically and experimentally possible and what current clinical experience has shown can be realistically achieved.

**Crocodile Research and Conservation in Southern Africa**

**J. P. Loveridge**

In July this year the Crocodile Specialist Group (CSG) of the Survival Service Commission of the International Union for the Conservation of Nature (IUCN/SSC) will hold its fourth meeting in Miami, Florida, to review progress in the recent worldwide moves to conserve crocodilians. The first such meeting was held in New York in 1971, and now, nearly ten years later, seems an appropriate time to review progress achieved towards the stated aims of the CSG in Southern Africa. These aims include the review of existing knowledge of the status of the 21 species and subspecies of crocodilians, to determine national and international research, conservation and management priorities; and to devise a mechanism for co-operation and co-ordination of effort in these fields. In Southern Africa south of the Zambesi and Cunene rivers only one species of crocodilian, Crocodylus niloticus Laurent, now lives. The Nile crocodile is therefore the subject of this review.

**Distribution and present status**

Zoologists might be excused for expecting that the distribution of such a conspicuous species as the Nile crocodile should be well documented. In this they will be disappointed for four recent authors give distribution maps which differ substantially from another, and none of which is correct in the detail of distribution in Southern Africa. The probable former distribution of Crocodylus niloticus is given in Fig. 1, from which it can be seen that it was absent from Lesotho and the Orange Free State, and from the arid areas of Namibia, Botswana and nearly the whole of the Cape Province. Sizable populations formerly existed in Zululand, with fewer individuals in the larger rivers of the Natal south coast, Transkei and the eastern Cape. The species is now extinct in the Cape Province and, though never plentiful, was once found as far west as Uitenhage and occasionally in the Keiskamma river mouth. In the Transvaal, crocodiles were formerly numerous in the rivers of the eastern portion and in the Limpopo, Swaziland, Mozambique, Zimbabwe and Zambian rivers supported substantial populations of crocodiles and in Botswana, the Chobe and Okavango swamps were refuges which connected through the Caprivi strip with the Zambezi and Cunene populations. Since the last survey, the status of crocodile populations in all the Southern African countries must give in-
Overview of Bone Marrow Transplantation in South Africa

PETER JACOBS, MD, PHD
Emeritus Professor of Hematology
University of Cape Town, South Africa

Historical settings of present trends

The 30 million South Africans are as heterogeneous as the geography, climate, fauna, and flora that make up the southern part of this continent. This diversity is translated into substantial differences of cultural, political and delivery of health services. Historically the tribal or traditional healers functioned as primary care physicians and their practices currently continue to a greater or lesser extent. This influence is acceded varying recognition by those trained along western medical lines but, interestingly, there is a likelihood that statutory bodies will soon recognize and reimburse their contribution to all facets of contemporary medicine. At the other end of the spectrum are the conventional physicians working with a broad range of paramedical professionals that prominently include nurses. These multidisciplinary programs link the public and private sectors. Unfortunately, the latter are not yet participating appropriately in academic functions such as teaching and training although there are encouraging signs of an expanding role in good quality research.

It is against this background that the rapid and wide-ranging national changes taking place in this country need to be seen. There is now an overdue redistribution of available money under way to extend primary and secondary level services to peripheral areas. Inevitably there will be a reduction in commitment and size of tertiary activities which are, by nature of the sophisticated technology involved, disproportionately costly when the global needs of any community are considered. Debate rages on how best a shrinking budget can be reallocated to meet the present policies of the new government. An illustrative example of the ongoing exercise is that of bone marrow transplantation.

The stimulus to introduce these procedures into South Africa, nearly a quarter of a century ago, was 2-fold. The first was an appreciation of how experimental hematology was being transferred to the clinic. The melting-pot for these activities was a group that has become the International Society for Experimental Hematology. Amongst pioneers were E. Donnell Thomas, G. Santos, E. Cronkite, G. Mathe, and many other distinguished investigators. From this convivial environment emerged the demonstration that biological principles, such as histocompatibility testing, could be applied in a way that made possible the transfer of stem- and
progenitor cells to an individual with bone marrow failure to effect a cure. Projected techniques were cryopreservation and autologous grafting. Another visionary goal was the attempt to bridge immunologic differences between donors and recipients: this is being realized with the creation of registries for unmatched volunteers. A third area of effort was the attempt to control lethal toxicities such as graft-vs.-host disease (GVHD) and rejection.

Future requirements of hematology and BMT

Second, was the inescapable conclusion, from my years spent as a fellow at the University of Washington, that these procedures were soon going to become the focal point of hematology management. Here, noticeably, South Africa lagged behind the rest of the world.

The chance to capitalize on improving this shortcoming came, somewhat unexpectedly, with appointment to the newly created Chair of Haematology at the University of Cape Town. Although this school was known for studies in hemostasis through the prominence of Clarence Merkley and Hymie Nossal, the challenge was to anticipate and plan for future requirements, perhaps even at a national level. In so doing, it was necessary to avoid duplicating or even re-inventing the wheel. To avoid the academic and practical mistakes of the past, notably those of T. Bothwell and his group working on iron metabolism or A.R.P. Walker systematically investigating nutrition. What better way than to tackle the problem of bone marrow failure where a clinical need could be fulfilled in parallel with developing a role for marrow transplantation in seeking cure for leukemia, lymphoma, and myeloma. Additionally there was the attraction that, from such a patient-base, more fundamental aspects of hematopoiesis could be examined using experimental methods in the laboratory.

It is interesting to reflect on some of the steps taken to establish the program in Cape Town and then summarize the status of its counterpart developed in Johannesburg.

The first moves were into the unchartered field of radiobiology and took the form of allografting between 2 rabbit strains based largely on the work of B. Speck and A. Gratwold in Basel. Once the technique had been refined, the model was used to standardize methodology that had already been worked out elsewhere. Here variables included the cell dose needed for engraftment and an assessment of the repopulating potential that necessitated the establishment of clonogenic assays. Transplantation across histocompatibility barriers revealed the extent to which morbidity and mortality occurred from acute and chronic GVHD and led to early involvement in the use of cyclosporin-A.

As these procedures became established, challenges arose from other quarters. Of these the most daunting was a striking apathy amongst peers for what was widely regarded as a highly questionable procedure. Happily the day was saved by Dr. C. Barnard whose successful heart transplants and personal endorsement sustained our fledgling activities. Once access to this isolation facility was obtained, cell separator technology was introduced into the country, primarily to provide granulocytes for the neutropenic individual. The guidance of J. Porter Hester in this regard was invaluable. This has permeated other centers and also the commercial blood banks.

Initial problems in establishing transplant technology is SA

The scene was set and the anxiety as well as excitement at finally being able to join the international group of transplanteers remains a memorable recollection. Undoubtedly the same feelings occur as each new center is opened up, but, as opposed to the United Kingdom, Europe, and the United States where expertise is readily to hand, such was not the case in Cape Town on 11 December 1974 when the first allogeneic bone marrow transplant took place. Unfortunately this modest achievement attracted unwelcome media publicity that fuelled the animosity already existing for such new interventions especially as the first financial constraints were starting to appear on the horizon. Nevertheless, the learning curve had begun and very rapidly the problems common to all such procedures in the form of graft rejection, sepsis and the dreaded GVHD became strikingly evident. One tends to forget, with the passage of time, the many patients who died as a result of these complications but they were a constant reminder in those days, at morbidity and mortality rounds.

Another consequence was the difficulty in keeping nursing staff and the reputation grew that allografting was not much different from a death sentence. A second period became discernable when the addition of cyclosporin-A was aimed at blunting the severity of this unique immunologic phenomenon. Our animal studies had suggested that the fungal immunosuppressant had a role, perhaps in combination with methotrexate: this was supported by experience from a number of clinical centers. Nevertheless, and still true today, is the fact that the use of unmanipulated marrow, even from a matched sibling, has a significant incidence of GVHD with the attendant complications. Although we were the beneficiaries of visits from many experienced transplanters with encouragement always available from D. Thomas and B. Gale, a seminal event was the opportunity to become associated with H. Waldmann and G. Hale at Cambridge in studying their Campath monoclonal antibody; these efforts are still active and have already spanned close to a decade. Conceptually this protein, by binding to receptors expressed prominently on the T-lymphocytes believed to mediate GVHD, would provide an immunologic technique for purging the patient of the cytotoxic population. Initial studies with the mycotic variant confirmed these observations in the rabbit model, but clinical experience was relatively limited since it was superseded by the opsonizing form designated Campath 1G. My own effort was made largely in evaluating exposure of the graft to the antibody in vivo, or as it is popularly known, "in-the-bag" and this maneuver has virtually abrogated GVHD. Interestingly, when combined with in vivo administration there is a presently unexplained slow engraftment rate and when it is used only in the recipient, but without exposure in vitro, GVHD still occurs. These various permutations have the potential for different therapeutic applications. One very encouraging, but unex-
plained finding, is the low rejection and relapse rate with the *ex vivo* exposure, but small numbers and relatively limited follow-up require confirmation before this can be considered a clear benefit.

**Influence of changing national budgets on specialized health practices**

The Cape Town program center upon the multidisciplinary group that spans the various subspecialties. Only in the last few years has it been possible to commission a transplantation facility having laminar flow rooms with the influence of overseas colleagues again evident in that Dr. J. Sanders from the Fred Hutchinson Cancer Center in Seattle visited to share in the planning.

Until a few years ago our recipients have been limited to adults but children are now included. The most common indication is acute myeloblastic leukemia in first consolidated complete remission (CR): this is followed by idiopathic aplasia and Fanconi's anemia. Autografts are approximately equal in number and have comparable outcome to allogeneic transplant. The average rate is between 10 and 12 procedures per year, curtailed by histocompatibility matching particularly from the black population whilst financial constraints continue to limit availability of nursing staff needed to operate the protected environment to capacity. Given these limitations, matched unrelated sibling transplants with their higher complication rates, have so far not been undertaken. To this must be added the rapid change in philosophy where spending of the health budget should be targeted, which may further reduce the level of all high-tech programs. Consequently the interesting caveat, that, as is standard practice elsewhere in the world, expanding collaboration will be needed with the private sector. Thus, insured patients already have access to comparable management programs and this may release more public beds to indigents.

The second program is that commenced in 1983 and headed by Dr. W. Bezwoda in Johannesburg that within 5 years had reached an average of 10 procedures a year. This level is short of the anticipated 3-fold greater number that would be predicated on the basis of the patient population, but constraints include limited donor availability particularly amongst black nationals where matching is often only partial. As a result it may well be that 1 area for development is the expansion of the national donor program: again costs and the philosophy of mismatched or even matched unrelated allografting await clarification under the new health care scheme.

The team of physicians, nurses, and scientists operates out of a series of isolation cubicles and single beds supported by admission privileges to a large medical unit in the hospital. There has been a steady escalation in transplants which total 97 in 107 patients with the majority accounted for aplasia and acute granulocytic leukemia. Roughly half the patients are currently alive.

**Development of autografting since 1989**

A particular strength of this group has been their development of autografting where, since 1989, 346 procedures have been carried out in 309 patients mostly for Hodgkin's disease and breast cancer. Some 72%/ of 233 patients are alive and transplant-related mortality is low. Not surprisingly such an approach is attractive and here the source of stem cells has gradually shifted from marrow to the peripheral blood. A notable contribution is the cost-effective technology used for harvesting and reinfusion without cryopreservation when high-dose chemotherapy is used in patients with clinically localized breast cancer but with acknowledged poor outlook due to multiple node positivity. In contrast to conventional therapy with its high-relapse rate within 2 years, their current experience using escalated cytotoxic regimens with autologous salvage supports a benefit from the latter regimen. Notably the advance- ment of this program to young patients as first-line therapy, rather than rescue, has an increased response rate and superior survival. This appears to be the first such attempt to randomly compare the 2 treatment groups and the results continue to be encouraging.

In both Cape Town and Johannesburg the clinical services are complemented by laboratory studies. These are wide-ranging and include recognition of multiple drug-resistance, separation of malignant cell populations from normal as well as long-term marrow culture to expand suitable precursor populations. Other investigations focus on the use of cell lines with distinctive adhesion and growth promoting properties and in vitro studies of interleukins or different growth factors designed to elucidate benefits that can be transferred to the neutropenic or thrombocytopenic patient.

**Present status and future considerations of BMT in SA**

Considering the way these activities have evolved and, given the need to develop them in an essentially third-world setting, the present status of both program does credit to the directors and members of each team. The standards are endorsed by acceptance of data by the International Bone Marrow Transplantation Registry.

A logical conclusion would be that the areas represent distinct pockets of first-world medicine and efforts should be made to preserve them even as financial redistribution favoring primary health care is implemented. Thus, as never before, there is a need to broaden the working collaboration with the private sector and so bring these potentially curative therapeutic options within the reach of as many patients as possible. This will require the subjugation of personal and often self-serving perceptions to the wider need of the community. Specifically, both the Minister of Health and the Director General have emphasized their priority to see that those with appropriate insurance increasingly receive treatment in the expanding and readily accessible academic centers in private clinics. Only in this way can the limited slots available in state hospitals be properly allocated, with central and local government having the particular responsibility for the indigent community. This point needs strong reemphasis since calm judgement must prevail: for this to happen a
Autografting in Solid Tumors
Important Questions

CHR. JUTTNER
Clinical Director, Hanson Center for Cancer Research, Adelaide, Australia, Palo Alto, Ca., USA

Introduction
Breast cancer is currently the most common indication for high-dose therapy (HDT) and autologous transplantation in the United States, both in the poor prognosis adjuvant setting and as therapy for advanced local or metastatic disease. Other solid tumors, particularly ovarian, small-cell lung, testicular and brain cancer have been treated with HDT and autografting less consistently over the last 8-10 years. In preparing this brief introduction, I have chosen to focus on the important questions which relate specifically to the use of HDT and autologous transplantation in solid tumors.

To summarize:
1) What are the important questions?
2) What preliminary results are available?
3) Is the basic concept of dose intensification correct and proven in solid tumors or in other diagnoses?
4) What is the source of relapse after autologous transplantation and high-dose therapy in solid tumors?
5) What is the incidence, level, and nature of tumor contamination in autografts?
6) Which source of stem cells should be used?
7) What is the role of tumor purging either by positive stem cell selection or by negative selection of tumor cells?
8) Is a graft vs. malignancy effect important?
9) Will a single high-dose therapy be enough?

Preliminary Results
Much of this discussion will of necessity focus on breast cancer since most reported studies are in this disease. In metastatic breast cancer early and extensive studies of various types of HDT and autologous transplantation have yielded a high incidence of complete remission which has in general been poorly sustained. Studies began 8-10 years ago. A small proportion of patients, variously estimated between 5-15%, have become long-term survivors after HDT for metastatic breast cancer. Selection on the basis of relatively limited disease or complete response after conventional induction chemotherapy may increase that sustained disease free survival rate to 30 or 40%. This probably represents patient or case selection rather than overall efficacy. Other studies in the adjuvant setting suggest greater efficacy. This study by Peters, in poor prognosis Stage II breast cancer, is historically controlled with an attempt to use equivalent cases and suggests that disease-free survival may be improved from 30-40% to50-70%by using single HDT and autologous bone marrow and blood cell transplant. Two major prospectively randomized Phase III studies in the same adjuvant setting are in progress but results will not be available until 1999. Another small Phase III study of adjuvant therapy by Gianni, reported at meetings but not yet published, suggests a similar improvement in efficacy.

Future Prospects
There has been major debate whether or not HDT is justified, particularly in breast cancer. Some studies of intensification of conventional chemotherapy suggest no improvement with increased dose, but have been criticized because they may represent dose de-escalation in the low-dose arm rather than dose intensification in the high-dose arm. The dose intensification achieved with autologous transplantation is much higher than that achieved with conventional chemotherapy. There is no indication that transplantation is any more toxic than conventional chemotherapy, although it is more time consuming and expensive.

Introduction
The Zimbabwe ruins typify the mystery that surrounds the origin of advanced civilisations that existed in bygone centuries on the dark continent. Rock paintings of exquisite beauty and infinite detail tell stories that are recounted around camp fires and add to the mystique attributed to great traditional healers. Indeed, in 1997, the rural nature and cultural heritage of tribes across the length and breadth of Africa still center on the investigation and treatment of blood disorders by the “sangomas” with customs that are frighteningly alien to the western mind. But what of haematology in the traditional sense as it is perceived of in the so-called first world with a contrasting tradition of university training and degrees, clinical research, or laboratory-based studies? Nearly two years of intensive data-gathering have yielded precious little in the way of usable data. In many areas, despite persistence and repeated efforts, contact has been impossible. In others, information has been sparse and, with few exceptions, there emerges a depressing uniformity of gradual deterioration of those standards that had prevailed in earlier colonial times. However, a number of colleagues have gone out of their way to respond and it is these contributions that have provided the basis for this overview.

Perspective
Emancipation is a wonderful word, and independence as well as equality are highly desirable ideals. Realities are, however, different and a global picture of Africa, as anyone following world news on television or in newspapers can readily perceive, is one of escalating violence, political upheaval, and an instability that inevitably diverts attention away from interesting—indeed fascinating—clinical problems to a priority for survival of whole communities—let alone individuals. Superimposed upon this backdrop are the multiple agendas of political parties or governments. The latter frequently have shifting priorities so that infrastructure is under constant revision. One prominent example is the greater delivery of primary care and secondary services so that the high technology or tertiary centers are seen to be under threat. To compound the problem there are changes between the role of universities and technikons while everywhere there is a need for affirmative action incorporating the revamping of entire educational concepts. All this is taking place against an enormously wide spectrum of what constitutes even rudimentary health care. Thus in vast areas of the land mass, these facilities are primitive and focus on the management of casualties from massacres and genocide. As a result, expenditure of precious foreign exchange is earmarked for humanitarian considerations such as providing shelter and subsistence level feeding.

It is against this background that the existence of scattered pockets of first-world activity are observed. It is to these that we turn attention in the hope that they will be nurtured and survive to sustain undergraduate teaching as well as postgraduate programs. Additionally, they need to be developed to provide a suitable environment for technological growth and it is to be hoped that prevailing wisdom is such that resources will be assigned to protecting and ultimately leading to the regrowth of a few programs that, by international peer review, might contribute relevant knowledge to the investigation and understanding of hematopoiesis. Most of the ongoing research is at best descriptive patholog of or a clinical nature whereas research in cellular and molecular biology—the buzz-words of modern medicine in general and hematology in particular—is depressingly rare.

It is probably impossible to look at the African continent—or any other for that matter—and generalize. A more achievable alternative has been this attempt to indicate the status of training programs, the level of technology where this can be judged, and to draw attention to any research or development. Purely as a matter of convenience those areas where responses have been obtained are outlined by country.

Nigeria
Hematology training is provided at the university college of Ibadan, Lagos; Ilorin and teaching hospitals at Obafemi Awolowo, Ahmadu Bello, and Jos. Perhaps the best established of these is the university college hospital at Ibadan founded by Professors Luzatto, Essien, and Essen, who carried out their early work here on glucose 6 phosphate dehydrogenase deficiency and its interaction with malaria. Current interests center on thrombosis and hemostasis research on problems encountered in oncology and sickle cell disease. Training is by rotation through the four major pathology disciplines and a year in a field of interest before
writing the postgraduate examinations, which are in their traditional two parts. Successful candidates may register with the West African College or the Nigerian Medical College, both of which are postgraduate bodies. Sadly, like every other part of the public sector, there appears to be a gradual but progressive decline in standards and facilities. This is associated with the low morale and academic frustrations that have fueled the ongoing emigration. Few lecturers remain who try to maintain standards and these colleagues deserve all the support and encouragement that our society can provide.

**Kenya**

Professor Edward G Kasili, who recently died and will be sadly missed, wrote that there were no hematologists actively engaged in experimental work; indeed, he stated that their research capability was so restrained in scope that the country would be unable to participate in any collaborative project. At a recent psycho-oncology conference run in Nairobi, at which there were a number of overseas participants, it became clear that this was not an unduly critical viewpoint. Thus, after speaking to a number of colleagues, it emerged that post-graduate training programs in hematology were virtually nonexistent and any sort of investigation or management required referral of patients beyond their borders to either South Africa or not infrequently to the United Kingdom or the United States of America.

**Zimbabwe**

**Service**

Dr. McCleod E. Chityo, Dr. Alison M. Coutts and Professor Lorraine Levy report that there are currently three trained hematologists in the country and four physicians or pediatricians with an interest in hematology. Specialist services are not available outside Harare and Bulawayo. There are no specific hematology units in any hospital with care being provided in conjunction with the Department of Medicine at least at the Parirenyatwa Teaching Hospital in Harare.

**Undergraduate training**

**Medical**

Medical students have exposure to the subject in the second, third and fifth year in the M.B., Ch.B. course.

**Teaching**

The hematology establishment is one professor and six lecturers (with only two in-post at present) for 80 to 90 students with the intention of increasing the student intake to reach 200 annually. Chronic under-staffing constitutes a major problem.

The University of Zimbabwe runs a diploma course for medical laboratory technologists which is being upgraded to a Baccalaureate in science. Lecturers are few in number so that standards are difficult to maintain let alone upgrade.

**Postgraduate training**

There are currently no facilities or structured courses primarily for want of appropriate teachers. As a result, Zimbabweans train outside the country but it is uncertain how many are likely to return to provide clinical service. The university provides a 2-year postgraduate programme in general pathology with few hematologists emerging.

Nursing and paramedical professionals are not catered to at the present time.

**Research**

Cooperation between the university departments of hematology, medicine, and pediatrics focuses on epidemiological and clinical studies defining the incidence and pattern of hematological malignancies in the country but coordination and long-term projects are precluded by the staffing difficulties. Commendably, after initial difficulties, a cancer registry was started several years ago to better define the magnitude of the problem in this country, and is functioning well.

A heavy service and teaching load prevents the ample material from being utilized in any constructive way. Interestingly, there are adequate quantities of sophisticated equipment but is under-utilized because of staff shortages and limited funding. Despite this there is a home treatment programme for patients with hemophilia that is increasingly being run by their own association. More specialized management, such as bleeding or the presence of inhibitors, is centralized at a university clinic.

**Cancer**

Recognizing the existing constraints, a Committee for the Prevention and Control of Cancer has been formed to coordinate and strengthen existing activities and introduce new initiatives in a number of areas. Thus immunization for hepatitis B and educational programs about bilharzia and human immunodeficiency virus infections have been started although the tobacco industry remains a somewhat sensitive one.

Screening for carcinoma of the breast and cervix is projected but limited by inadequate funding. Early detection is being actively publicized but further investigation and management remain less than satisfactory.

Treatment with radiotherapy and oncology has focused primarily on achieving the best results with the machines available at the Parirenyatwa Hospital in Harare. A number of protocol studies have been carried out and one looks forward to the analysis and publication of data from these centers.

Palliative care through the Island Hospice, which is currently being expanded on a national basis, previously reached only a minute fraction of those requiring management and even the provision of morphine for pain control is a formidable challenge.

**Gauteng**

** Pretoria**

Professor Kenneth Stevens has commented that relatively little information is available other than that the training programs in pathology have been revised to include a larger clinical component and greater exposure to cellular and molecular biology.

Professor Geoffrey Falkson is the ranking oncologist in this country and spearheads an active group with two arms. The
first is in clinical pediatrics where the International Society of Paediatric Oncology protocols are followed and no particular free-standing projects are ongoing. In the adults there has been long association with the Eastern Co-operative Oncology Group and clinical data is incorporated in those trials but, again, no specific clinical or laboratory studies, particularly in hematopoiesis, are reported.

Johannesburg

Professor Barry Mendelow is active in a number of areas which include puromycin and cycloheximide-induced c-myc mRNA superinduction in which expression of this proto-oncogene is being manipulated to modulate regulation of the apoptotic cascade. Inherited hemolytic disorders continue to be studied, particularly at the level of abnormalities in the red cell membrane that are exemplified by hereditary elliptocytosis and spherocytosis. The work is collaborative with Dr. G Daniels of the Medical Research Council Blood Group in London and some of the projects include the identification of molecular defects, causing hereditary spherocytosis, a study of South East Asian ovalocytosis, the molecular biology of elliptocytosis in a South African kindred, spectrin and anchor binding defects as well as the molecular mechanisms involved in the invasion and growth of the malaria parasite Plasmodium falciparum in red cells. Molecular genetics focus on the mechanism of cancer initiation and progression in trisomy 12, t(3;14) in a B cell lymphoma and characterization of the 11p abnormalities in ovarian cancer. Platelets have long attracted attention and have been an area of special interest focusing currently on function, fatty acid, and cholesterol composition in type I and type II diabetes in terms of altered platelet reactivity in this context, thereby raising questions about higher platelet cholesterol levels, decreased membrane fluidity, and accelerated phosphoinositol metabolism.

With the retirement of Professor Thomas H. Bothwell, his highly respected iron metabolism unit has been disbanded. The very long years of relevant scientific contribution and innumerable publications, to say nothing of the many young scientists who received their fundamental training in his program, will be sorely missed. Clinical hematology, under the leadership of Professor Werner Bezwoda, has three major components. The first is the bone marrow transplantation service. Second is the employment of high-dose chemotherapy and autologous bone marrow or peripheral blood stem cell rescue—an area about which this group has published important controlled data demonstrating that, in the particular context of breast cancer in young women with poor prognosis, this cost effective approach increases remission rates and statistically improves relapse-free and overall survival. Third, at a basic research level, long-term marrow culture systems and adhesion to extracellular matrices, an immunobead method has been used to separate precursor cells as an approach to purging grafts of contaminating neoplasms.

KwaZulu Natal

Dr. Vinod Jogessar has reported that research is localized in two major areas. The first is the Natal Blood Transfusion Service studying gene polymorphisms in hemophilia and the use of human leukocyte antigen typing and cytogenetic analyses for inherited disorders, particularly Down's Syndrome.

Second, in the Department of Haematology, the major activities are the use of molecular techniques for documenting lymphocyte clonality in malignant lymphomas, minimal residual disease in chronic myeloid leukemia where patients are treated with interferon and in vitro interaction between hematopoietic growth factors and normal bone marrow cells. Flow cytometry is being applied to assess immune status in patients who have been infected with the human immunodeficiency virus, the phenotyping of lymphoproliferative disorders, and a study of DNA ploidy in malignant disease.

Two additional studies are the role of cytokines in the pathology of pulmonary tuberculosis and the problem of drug resistance to malaria in that part of South Africa.

Orange Free State

Professor Philip Badenhorst comments that the characterization of Fanconi's anemia is being studied since this is an area of high indemnity while there is a clinical survey in progress defining the incidence of acute leukemia and another characterizing immune thrombocytopenia in children to distinguish features that separate the acute from the chronic forms.

The Cape Province

Dr. Arthur Bird reports that the Western Province Transfusion service is studying the role of the abbreviated cross-matching in blood banking, the clinical and pathological consequences of finding hepatitis C virus antibodies in blood donors, the detection of T-lymphotropic in neonatal necrotizing enterocolitis as a basis for its management, and a tissue culture-based test for in vitro detection of pyrogens.

The University of Stellenbosch and Tygerberg Hospital were reviewed by Dr. Erna Mansvelt and Professor Peter Hesselink. There is a large routine service laboratory that includes the evaluation of patients with congenital and acquired hemostatic disorders while clinical and laboratory based research focuses on epidemiological and intervention studies in patients with nutritional disorders and contrasts population groups as a basis for iron fortification and the use of additives such as vitamin A in the pediatric population. A number of hematology projects include immunophenotypic comparison of acute lymphoblastic leukemia in children and adults, the demography and cytogenetic findings in patients with chronic myeloid leukemia, the systematic investigation of hematologic disorders in those with human immunodeficiency disease, with additional viral screening in leukemia and lymphoma. Hypercoagulability is being documented in patients with thrombosis and a short partial thromboplastin time while computer based anticoagulant control is being compared with the older manual method. Bone marrow trephine biopsies continue to be examined using microwave oven processing and the utility of sampling both iliac crests in patients with myeloma as opposed to the more traditional single biopsies is in progress.

The pediatric group headed by Professor Peter Hesselink has a well established registry (with data available for analysis from 1983 onwards) in which there are 50 or 60 new entries each year in the under 15-year-old age group. On this basis there have been a number of reports on the epidemiology of childhood cancer and perhaps the world's largest experience in the recognition, diagnosis, and treatment of onyai.
Professor Cyril Karabus reports from the Red Cross War Memorial Children's Hospital that a very heavy service load precludes major clinical studies but particular interests are in the management of hemophilia and a wide range of malignancies, including the leukemias.

The University of Cape Town established a department based in the Groote Schuur Hospital under the foundation headship of Professor Peter Jacobs in 1970. In order to support research activities, the Leukaemia Centre was created two years later. Since then it has, by common consent, played a leadership role in seeking the development of a unified discipline that incorporates clinical service, undergraduate teaching, postgraduate training and laboratory-based pathology and to further unite these through research where the theme has been the development of treatment programs that center on a multidisciplinary team giving equal weight to medical, nursing, and related professions. Attempts to propagate this concept at a national level, with standardized training and examinations, have not been successful and the current status quo of having hematopathology and clinical hematology as separate registrable disciplines has been perpetuated. Only the future will tell whether this decision, which differs from many developed countries, is the wisest way to train specialists in the changing third world that is South Africa. The feature of patient care has been the systematic study, through a series of carefully structured and peer-reviewed protocols, of hematologic malignancy with most of these culminating in bone marrow transplantation. In the latter sphere has been the cardinal observation, researched and reported in association with Professor Herman Waldmann and Dr. Geoff Hale, originally from Cambridge and now at Oxford, that T cell depletion of the graft by exposure to the monoclonal antibody Campath 1G ex vivo or in-the-bag, leads to rapid and universal engraftment, total abrogation of acute as well as chronic graft-vs.-host disease, and a promising low relapse rate in acute myeloblastic leukemia.

Cell separator technology was introduced into the country two decades ago in the same university department primarily to provide the necessary support for evolving chemotherapy programs; this technology has been expanded in a number of ways, including its adoption by the various blood transfusion services. A new observation is that serial procedures in familial hypercholesterolemia lead to the development of iron deficiency and additionally the use of inductively coupled plasma atomic emission spectrometry has shown that this reflects separator-linked extracorporeal hemolysis with iron loss in the exchange fluid and when chelated to citrate in the urine. This phenomenon was pursued using electrophoresis and it is speculated that a lipid-related acquired membrane defect, caused by high cholesterol levels, diminishes erythrocyte deformability and increases fragmentation so that shortened survival occurs as they traverse the microcirculation in vivo.

Laboratory based investigations range from demonstrating that the type of tissue plasminogen activator produced by leukemic blasts is a prognostic indicator in acute leukemia (collaboratively studied with Professor Lyn Wilson), to the introduction and development of in vitro bone marrow cultures, which have been applied to showing that exposure to chemoradiotherapy following transplantation is associated with residual damage to stroma and hematopoietic precursors. In parallel, a laboratory has been set up and equipped for cellular and molecular biologic techniques such as flow cytometry, cytogenetics, and DNA studies under the direction of Dr. Riva Rubinstein.

In the last two decades or more, postgraduate programs have been introduced and refined. These have provided training for residents in hematopathology and resulted in a steady stream of postdoctoral fellows graduating from Masters and PhD programs. An interesting and notable innovation has been, since retirement and relocation, the development of a similar university style department in a private academic complex with ongoing activity in a number of the programs previously initiated, including bone marrow transplantation using peripheral blood stem cells and laboratory-based research on the effects of T cell depletion with Campath antibodies, reporting an audit of results to the International, Autologous and European Bone Marrow Transplantation Registries, as well as the Campath Users' Group. Concurrently, flow cytometry and cytogenetics, now with fluorescence in situ hybridization, are being applied to the systematic study of hematologic malignancies.

**Hematology in a changing Africa**

These are sobering reflections that lead to two conclusions. First, where there remain vestiges of good science, such activities need to be thoughtfully nurtured. This will not be easy because available funds are increasingly redistributed to the delivery of primary health care; however, it could be reasonably hoped that careful planning will ensure a continuing role for academic programs in the context of universities and associated teaching hospitals as the indispensable guardian for standards and training in the future. Already there is an epidemic of managed health care sweeping through—at least—South Africa and it is unclear what the final composition and structure of this system, as well as research and development with its high cost and need for expensive funding, is going to be. One approach would be to favor much closer working relationships between the public and private sector where many active faculty are already relocating. In this swiftly changing environment, it is mandatory that there be cohesion in sustaining appropriate clinical and laboratory-based research programs and the time may well have arrived for private colleges and universities to be given serious consideration.

The second is in many ways an extension of the first and what is seen in Zimbabwe is a realistic reflection of the Third World, which is often quite beyond the comprehension of those trained or working in the United States and Europe. What exists is a valiant attempt by a few highly dedicated professionals to provide care with limited resources for the patients who reach central hospitals. The future is bleak since training facilities are limited, there is no incentive for well qualified, experienced staff to remain in university or government service and those who have the opportunity to study elsewhere seldom return. All this is compounded by the lack of funds needed to sustain continuity within academic departments. It is here that many of us can provide
constructive help. Some help could be at very low levels, such as donating last year’s journals to a department starved for current information, while others could offer to share in collaborative work. Also, we can use the existing patient material in association with the more advanced centers that remain to carry out cellular and molecular biology that is often needed to study unusual diseases. For larger institutions and established clinics an opportunity exists to invite colleagues to spend time participating in existing programs and to extend this through all professional ranks, whether they be doctors, nurses or technologists. Indeed the reverse is equally worthwhile and who knows what will emerge from time given up to teach a mini-course in another part of the world? Perhaps visitors will learn a little about the plight of others—a first small step that has the potential for constructive international collaboration.

Acknowledgments
My grateful thanks to colleagues who have provided information on which this overview is based. These include: A. Abayomi, Nigeria; Philip Badenhorst, Orange Free State; Werner Bezwooda, Johannesburg; Arthur Bird, Cape Town; McLeod Chitiyo, Zimbabwe; Alison Coutts, Zimbabwe; Geoffrey Falkson, Pretoria; Peter Hesseling, Cape Town; Lorraine Levy, Zimbabwe; Erna Mansvelt, Cape Town; Barry Mendelow, Johannesburg; Paul Rogers, Cape Town; Ken Stevens, Pretoria; Support was also provided by a grant from the Medical Research Council of South Africa.
Organ replacement, including the tissue from which immunohaematopoiesis is derived, continues to expand and many lives are saved. Unfortunately, not every procedure is successful with failures attributable to rejection and, in the case of bone marrow allografting, by varying grades of acute or chronic graft-versus-host disease. Furthermore, when used to support haematopoiesis following high doses of chemotherapy, relapse of the tumour being treated can occur. These problems persist to challenge the experimental haematologist and immunologist as much as the clinician. As with most advances in medicine improved understanding of physiological principles tantalizingly promise better outcome with much of the research focused on that enigmatic primitive progenitor – the true stem cell. Unraveling the genetic mechanisms that determine positive or negative regulation may, for example, permit ex vivo expansion of this target population and so make more realistic the use of other sources that include foetal liver and, perhaps more attractively, cord blood in adults. In the interest of safety one central issue has become the definition for what constitutes a standard graft with criteria being primarily haematopoietic reconstitution. Rapidly gaining momentum is a quest to understand, and then modulate, the closely associated immunologic recovery. Here challenges include morbidity and mortality that result from a wide range of infections and the potential to harness the formidable power of the immune system for its anti-tumour effect. In an extension of the latter phenomenon it is not surprising that much effort is being devoted to non-myeloablative conditioning regimens with their perceived lesser toxicity and benefits that may be linked to chimerism between donor and recipient or further manipulations that include a donor lymphocyte infusion.

For one brief instant, when sperm fertilizes ovum, all the genetic information for subsequent emergence of that particular individual is present in a single totipotential cell. Immediately, in ways still obscure, differentiation is initiated and pluripotential systems evolve to generate each different organ within the embryo. As technology has improved elegant studies continue to define the migratory nature of the anatomical sites in which blood formation takes place [1]. Such a march of events is exquisitely orchestrated and continues until function eventually resides primarily in the red marrow. Within this tissue subtle interaction takes place between receptors with their redundancy [2] and a wide range of pleiotropic cytokines, some of which are stimulatory and others inhibitory, to create the haematopoietic inductive microenvironment [3]. Achieving optimum outcome after transplantation necessarily rests upon an appreciation of the physiological interchanges within this latter compartment.

Morphology of the candidate stem cell places it within the family of small lymphocytes [4]. However, function remains the accepted way of defining this entity. Thus, the cardinal requirement is division into two daughters with one retaining the capacity to replenish the parent pool and a second committed to progress through increasingly more mature progenitors to morphologically recognisable precursors and eventually to mature progeny. Much impetus was given to understanding these steps by Till and McCullough using their in vitro mouse spleen assay [5]. The obvious validity of the
murine model is difficult to test in higher primates and humans but extrapolation is assumed.

Clonogenic assays were introduced to explore in the laboratory those phenomena that were inaccessible to molecular dissection in the intact animal. Two broad categories exist. In one area, stimulation of cytokine production by layering the mononuclear inoculum on a preformed and irradiated stroma. This is thought most amenable to recognising the earlier or long-term colony initiating cells [6]. For a long time it was assumed that this particular sub-category would be undetectable in some of the systems. Nevertheless, they appeared to grow when proper conditions are provided that include the absence of inhibitory molecules such as transforming growth factor β [7] and contact with plastic or connective tissue substrate [8].

Flow cytometry, focusing on expression of the CD34 antigen, has added a new dimension for separation of multipotential from pluripotential compartments [9]. Recent work examines self-renewal potential with evidence suggesting that segregation is possible into phenotypically distinct sub-types both of which have multipotential capacity but differ in that some can be successfully grafted and others, under normal conditions, lack this capacity [1]. Transplant studies, linked to in vitro colony-forming unit cultures, have demonstrated a discrepancy of approximately 300-fold more activity in the marrow than detected during cell transfer [1]. Extensions of this argument focus on varying expression, even lack of demonstrable membrane CD34, and cross-talk between haematopoietic with stromal cells within the micro-environment via molecules with cytoadhesive properties [10-13].

Further ways of looking at cellular haematopoiesis include determination of telomeric length [14] and already such information may have practical application through evolving abilities to manipulate the enzyme telomerase [15]. In addition, rethinking of haematopoietic hierarchy may be appropriate so as to incorporate recent appreciation that there exists a common progenitor able to generate macrophages and dendritic cells as well as segregation of erythroid and megakaryocytic lineages from other myeloid lines [16].

Sources from which grafts can be obtained vary and, perhaps not surprisingly, reflect the nomadic pathway from early sites in the yolk sac through reticuloendothelial organs that include the liver, spleen and to finally rest in the red marrow. These sequential steps are gradually being better understood and confirm the migratory nature of both stem and progenitor cells. Such behaviour, when linked to radiobiological studies that used the shielded femur in different adult animals, drew attention to the blood as a potentially practical donor organ. Thus, while mid-trimester foetal liver appears to be a rich source of cells for clinical transplantation [17], the use of cord or placental blood may well turn out to be a practical alternative if expansion of the appropriate components can be achieved [18]. Given these circumstances it is not surprising that the marrow is becoming less favoured and being replaced by a functioning graft derived from the circulation using apheresis technology [19].

Definition of graft adequacy is the cardinal issue that governs both practicality and safety. Much of the initial experience from different centres has been refined at meetings and gathered together in the Milan–Mulhouse guidelines [20] and more recently in the International Society of Haematotherapy and Graft Engineering or ISHAGE protocol [21]. Mobilisation methods need to take into account the effects of chemotherapy with, or without, additional haematopoietic growth factors [22]. Many of these aspects are brought into perspective by the incisive analysis provided in the accompanying review by Hester [23].

Ex vivo expansion then becomes an important consideration to increase at least progenitor cell numbers [24]. It is currently less clear whether these methods are able to induce and additionally maintain the pool that is needed to engraft and sustain long-term haematopoiesis. Thus, unless this crucial non-cycling component can itself be influenced, as opposed to lineage-committed progeny, cord blood, for example, may be insufficient to durably engraft large individuals.

Haematopoietic reconstitution has been the primary target in autografting as a manoeuvre pri-
mainly to permit dosage escalation with cytotoxic drugs [25]. Here particular problems relate to deterioration in the quality of the product recovered often after many cycles of chemotherapy. This approach has nevertheless proven realistic in protocol studies for treating lymphoma [26], myeloma, acute myeloid leukaemia [27] and, though controversial in some of its aspects, efficient in solid tumours including breast cancer [28]. Further confounding the issues is contamination by small numbers of neoplastic cells and a variety of methods for purging by positive or negative selection continue with increasingly sensitive technology applied to reveal cancer cells remaining in the harvest [29]. Another application is the use of these procedures for gene therapy [30] with preliminary results in sickle cell disease [31] and Fanconi anaemia [32] illustrating some of the persisting difficulties.

In allografting there are a rather different set of circumstances to be confronted irrespective of whether bone marrow or peripheral blood is the source of stem cells [33]. These include graft rejection that may be a function of variables that range from cell numbers infused through degree of histoincompatibility to the immunosuppressive effects of the conditioning regimen where we havefavoured the use of additional body irradiation [34]. However, concern has been expressed about damage to normal tissues from this modality and a model reported that identifies some of the factors subsequently capable of contributing to the development of graft-versus-host disease [35]. The latter syndromes may be acute or chronic and significantly impair quality of life particularly evident in children [36], with consequential decrease in survival [37]. Attempts to blunt the severity of cell-mediated attack on target organs that prominently include the skin, biliary endothelium and enterocytes of the gastrointestinal tract include cyclosporin A and methotrexate. In an entirely different approach a variety of monoclonal antibodies have been used in vivo. Contrastingly, encouraging progress was reported with T-cell depletion using the Campath series of immunoglobulins ex vivo or in-the-bag and uniform engraftment coupled with complete abrogation of GVHD achieved using bone marrow [34]. Subsequent studies with peripheral blood stem cells harvested by apheresis technique, after exposure to stimulatory peptides, showed a shortened period to engraftment that was directly related to the number of CD34 cells infused [38]. Of note is that the larger number of T-cells given did not increase this complication but, for the first time in our experience, led to a low-level reappearance of cytomegaloviral seroconversion [39]. Another intriguing feature has been the reappearance of erythrodema regarded as late presenting, rather than classical chronic, grade I graft-versus-host disease and limited to the skin with our switch to the humanised version or Campath 1 H [40]. These findings, are equally applicable to matched unrelated volunteer and mismatched sibling donors [40]. This topic is penetrating the reviewed in the accompanying paper by Bunjes [41].

Immunologic recovery is fast becoming the major challenge where, historically, unmanipulated marrow not only has a high rejection rate but is associated with substantial incidence of acute and chronic graft-versus-host disease. In those clinical settings, infections with bacteria, protozoa and fungi remain a tangible cause of morbidity and mortality [42]. Thus, cytomegaloviral seroconversion has resurfaced with a switch from marrow to peripheral blood stem cells and particular vigilance, regular screening and pre-emptive treatment with ganciclovir or, as appropriate, additional foscarnet are needed to prevent progression to pneumonitis that has a high mortality [43]. Another interesting observation is that the move from the opsonic Campath 1 G antibody to the humanised 1 H version for ex vivo T-cell depletion has reintroduced grade I graft-versus-host disease restricted to the skin [40]. Whether there will be an associated beneficial anti-tumour effect or perhaps even a different spectrum of natural killer cell expression awaits clarification [44]. It is against this background that a major new area of interest is attracting attention in the form of non-myeloablative stem cell transplantation [45]. This method, by creating mixed chimerism, opens new vistas for harnessing the enormous power of the immune system without necessarily exposing patients to the hazards of high-dose chemotherapy [46]. In what might be regarded as an extension of these
innovative approaches is the subsequent use of donor lymphocyte infusion and this is documented to achieve complete remission in relapsed haematologic malignancies exemplified by chronic granulocytic leukaemia [47]. Updated information in this field is provided by Schleuning in his contribution to this topic [48].

The conclusion is that haematopoietic stem and progenitor cell transfusion is established as a clinically viable procedure in a number of different disease categories. Progress has been evident in some of the major areas that include guidelines for defining a standardised graft. Under these circumstances the pattern of haematopoietic reconstitution is predictable with differences between bone marrow and the faster recovery using peripheral blood demonstrably shorter in the latter instance by approximately one week. In autografting the challenge remains that of quality of the product collected from patients exposed to chemotherapy with its cumulative damage to the target population. In addition, the role of contamination by malignant cells is not yet solved. However, the technology has proven of value in supporting high-dose chemoradiotherapy particularly in lymphomas. Another facet is the potential enhancement of an anti-tumour effect that might theoretically be achievable by interventions that combine interferon gamma and cyclosporin [49]. Considerable promise exists for applying this approach to gene therapy but much work remains to be done in this area before it is routinely transferable from the laboratory to the clinic. In contrast allogeneic material collected from siblings, matched unrelated volunteers or partially mismatched family members focuses on the need to overcome rejection and the persisting hazards of acute and chronic graft-versus-host disease. Here the pattern of immunologic recovery is a huge challenge but still in its infancy and even the criteria that defined return to normality remains controversial. Purely the number of T-cells and their sub-sets may be inadequate and a whole new field is developing to define the repertoire of the incoming lymphocytes. Recognising that cell-mediated competence is of central importance in diminishing infectious complications and mediating tumour eradication much effort is focused on whether it is possible to segregate the undesirable consequences of host damage from the benefits of eradicating malignant cells. One encouraging way of combining the best of both goals may yet prove to be a change in technique to non-myeloablative conditioning regimens with the latter further modulated, where necessary, by donor lymphocyte infusion.

Case report

Prolonged remission of severe refractory rheumatoid arthritis following allogeneic bone marrow transplantation for drug-induced aplastic anaemia

P. Jacobs, M.D. Vincent & R.W. Martell

University of Cape Town Leukaemia Centre and Department of Haematology, Groote Schuur Hospital, Cape Town, South Africa

Summary: Aplastic anaemia developed in a 33-year-old woman whose rheumatoid arthritis was refractory to the administration of many drugs, including penicillamine and gold. Allogeneic bone marrow transplantation reversed the haematological abnormality and simultaneously resulted in a 2-year period of relief from joint pain. Symptoms then reappeared and the serological tests for rheumatoid arthritis again became positive. The arthralgia has responded slowly to the administration of anti-inflammatory drugs and steroids. The protracted asymptomatic period may have been due to the intense immunosuppression required for marrow grafting and the subsequent administration of cyclosporin. Since she developed chronic graft-versus-host disease, the arthritis may be an unusual complication of this syndrome.

Rheumatoid arthritis may be a crippling disease in which severe symptoms require treatment with potentially myelosuppressive drugs, such as penicillamine and gold. Furthermore, prior gold therapy is described as a risk factor for subsequent development of serious penicillamine-induced adverse effects. Among the latter is marrow aplasia resulting from irreversible damage to the haematopoietic stem cells, particularly when histocompatibility antigens DR2 and 3 are expressed. The natural history of such drug-related myelotoxicity is unpredictable, but persisting aplasia may require allogeneic bone marrow transplantation, where such an option exists. Following this procedure, profound degrees of immunosuppression result from the conditioning regimens that are an integral part of allografting and this state may be compounded by the administration of additional agents for prevention of graft-versus-host disease (GVHD), including cyclosporin.

One therapeutic option in treating patients with rheumatoid arthritis, particularly when there are progressive and incapacitating symptoms, is the administration of immunosuppressive drugs. Since there is comparable but more intense impairment of both humoral and cellular mechanisms following allogeneic bone marrow transplantation, it was of interest to study an individual in whom this procedure was followed by prolonged and complete symptomatic relief of arthritis.

Case report

A 33-year-old female developed pain, swelling and morning stiffness in her knees

© The Macmillan Press Ltd, 1986
and proximal interphalangeal joints 6 months before presentation. A diagnosis of rheumatoid arthritis was established, using conventional criteria, including a titre of 1/512 for rheumatoid factor associated with radiological evidence for early erosive changes in her hands. Despite administration of non-steroidal anti-inflammatory drugs, prednisone and gold salts, the disease progressed gradually and joint function steadily decreased. Penicillamine was commenced in conventional doses and after 23 months the development of neutropenia necessitated discontinuation of the drug. One month later she presented with severe follicular tonsillitis and numerous petechiae; haemoglobin was 8.9 g/dl, white count was $1.5 \times 10^9$/l, of which 77% were lymphocytes, and platelets were $12 \times 10^9$/l. The bone marrow was aplastic. Because spontaneous recovery had not occurred after 3 months of adequate supportive therapy, she was conditioned with 200 mg/kg of cyclophosphamide and underwent allogeneic bone marrow transplantation from an HLA-identical brother. Prophylaxis for GVHD consisted of cyclosporin, adjusted to maintain whole blood levels by radiimmunoassay between 200 and 400 ng/ml.36 The marrow engrafted at day 14 and only donor cells were shown to be present by cytogenetic studies and red cell phenotyping. Within one month full blood count was normal, all symptoms of rheumatoid arthritis had disappeared, and serology had become negative.

At regular follow-up there was steady objective improvement in mobility and function of all her affected joints. At 18 months after transplantation she was able to cope with housework and shopping for the first time in more than 5 years. Cyclosporin, which had been without any side effects, was withdrawn one year after grafting. The immunological status as evaluated by multi-dose skin testing, and the in vitro response of lymphocytes to mitogens and alloantigens in the mixed lymphocyte reaction, were normal. Shortly after this, the patient developed limited cutaneous GVHD (Grade I).17 Some curtailment in joint movement recurred in the course of the following year and simultaneously rheumatoid and antinuclear factors again became strongly positive. These symptoms required control with titrated doses of non-steroidal anti-inflammatory drugs, prednisone and azathioprine. At 3 years of follow-up, the patient is fully mobile and has a Karnofsky rating of 90%; synovial swelling has not recurred and, on objective testing, joint movement is only slightly limited. Furthermore, repeated cytogenetic analysis confirms that autologous marrow reconstitution has not occurred.

Discussion

The pathogenesis of the marrow aplasia in this patient appears to be causally related to drugs taken for control of relentlessly progressive and incapacitating rheumatoid arthritis. Gold salts may predispose to the subsequent development of myelotoxicity with other drugs, notably penicillamine,17 which agent is the probable cause of the development of the aplasia.18-3 at the time, she was not on any other drugs known to be associated with marrow damage or to adversely interact with penicillamine. The explanation for marrow sensitivity to drug damage cannot be attributed to the HLA antigens DR2 and 3, which are statistically related to penicillamine toxicity,9 since the phenotype of the patient and the donor was A2, A28, B44(12), B15, CW7, DR1 and DR7.

The complete remission of her rheumatoid arthritis which followed allografting is attributed to the profound immunosuppression after conditioning with high-dose cyclophosphamide. This agent is effective in treating rheumatoid arthritis,18,19 although its effect would not have been expected to persist for such a long period. There may, however, have been a potentiating benefit from the cyclosporin administered during the first year following transplantation.

Of particular interest is the clinical and serological relapse of the rheumatoid arthritis which occurred 2 years after the marrow transplantation. It seems unlikely that this is a consequence of the late re-emergence of autoreactive host lymphocytes since there is
no current evidence for autologous reconstitution and only donor cells are demonstrable by appropriate cytogenetic studies. Alternatively, although less likely, it is possible that the joint symptoms represent a component of the chronic GVHD\(^2\) that emerged for the first time when the cyclosporin was withdrawn.

Acknowledgements

We thank Miss Lucille Wood, Chief Professional Nurse, for help with patient follow-up, Professor O.L. Meyers and Dr D. Hodson for assistance in the management of the patient's rheumatoid arthritis, Dr Jean E. Sanders (Seattle) for advice with diagnosis, Keren Edwards for bibliographic assistance, Jackie Davies for typing and the Chief Medical Superintendent of Groote Schuur Hospital for permission to publish.

This study was supported by the University of Cape Town Leukaemia Centre and Staff (Cancer) Research Fund, the Medical Research Council, the National Cancer Association, and the Kaliski and Micael Chanani bequests.

Allogeneic Bone Marrow Transplantation With a Fixed Low Number of T-Cells in the Marrow Graft

To the Editor:

Verdonck et al. have extended their earlier results on the above topic. Their approach is reminiscent of other experiences, in which T-lymphocytes are added back to a graft in which this population has first been removed using monoclonal antibodies. The reported feasibility and consequences of this manipulation have recently been commented on in some detail as a result of cumulative studies from the Campath Users' Group. Although theoretically attractive, this method undoubtedly has limitations and it therefore may be of interest that a slightly different technique, in which we expose the graft to Campath 1G in vivo, abolishes acute and chronic graft-versus-host disease (GVHD). Updated figures are given below. Thus, in 42 consecutive patients, engraftment was uniform and swift, in 30 with hematologic malignancy, rejection has not occurred and relapse rates are low. In 10 with aplasia and 2 with Fanconi's anemia, the pattern was similar, although grafts were lost in 3 requiring retransplantation (twice in 1 individual), but all are alive and completely well. Conditioning in this protocol includes 6 Gy total nodal irradiation, aimed at increasing immunosuppression. In the case of malignant disease, this modality may add an antitumor effect that, theoretically at least, might balance any graft-versus-host-leukemia (GVL) effect that could, otherwise, have been associated with GVHD.

Interestingly, the Dutch group still encountered the latter complication in 70% of their patients, although it was only grade I or II in 49%. In contrast, our experience is that even this is often unacceptable because it generates significant morbidity and, although generally underreported, a chronic performance status. Furthermore, the chronic variant is noted to occur in nearly one-third of those at risk, an additional, and far from significant, price that these individuals have to pay. Of note is a procedure-related mortality of 11%, which seems high when considering that none of the patients, in our present series, died as a result of the conditioning or transplant itself. It is possible that, in the high-risk category, these figures may be substantially worse.

Although quality of life is reported using a Karnofsky score at 1 year, this seems to refer only to standard-risk patients; again, presumably the remainder would have fared less well. Performance status is also notoriously underreported. Thus, even using well-established criteria, little real appreciation emerges for the social embarrassment created by the widespread skin lesions and the misery experienced by patients with what is euphemistically referred to as mild or limited. These issues are labored to emphasize, based on our reported data, that any degree of GVHD is necessary to achieve a GVL effect. This is certainly an area worthy of more investigation.

Thus, although the reported results are of scientific interest, we believe that the clinical experience, particularly when the substantial in-house mortality is added to the acute and chronic GVHD, needs to be seen in the light of alternatives, one of which is the much simpler procedure that we have used in Cape Town that seems able to circumvent complex immunologic manipulations of the graft and, especially if the results can be confirmed, would offer a much more practical approach to allogeneic bone marrow transplantation.

RESPONSE

The goals of our approach of partial T-cell depletion of the marrow graft (through a T-cell addback to the maximal T-cell-depleted graft, performed with a physical technique) were: (1) To prevent severe acute graft-versus-host disease (a-GVHD) but certainly not to abolish a-GVHD completely, rather to induce a mild a-GVHD and by that the graft-versus-leukemia (GVL) effect, and (2) to prevent the high incidence of graft failure occurring after maximal T-cell-depleted marrow grafting.1 Graft failure and loss of the GVL effect are the major drawbacks of maximal T-cell-depleted marrow grafting, occurring more often after T-cell depletion by monoclonal antibodies than by physical techniques.2 In our opinion, the high relapse rate occurring after maximal T-cell-depleted marrow grafting justifies the inconvenience to the patient of a mild GVHD, hopefully with maintenance of GVL. Indeed, our approach seems to have a relapse rate that is not different from that of non-T-cell-depleted marrow grafting, whereas severe GVHD has never been observed.

We do agree that the occurrence of grades I and II a-GVHD (only of the skin) in 70% of the cases and of chronic GVHD in 30% of the cases observed with our approach generates morbidity. However, the GVHD is always very responsive to corticosteroid therapy (if treatment is indicated), which is in contrast to the data of non-T-
A monoclonal antibody VCD-1, directed against the N-terminal intracellular part of the invariant chain (li) was used to show, by immunoprecipitation and Western blotting, the unprocessed and processed forms of li in chronic lymphocytic leukemia (CLL) cells, in Epstein-Barr virus–transformed normal lymphocytes (EBVL), and in cells of the Raji Burkitt’s lymphoma cell line. Terminal glycosylation and sulphation of li in the Golgi apparatus was shown in Raji cells and not in EBVL. CLL lymphocytes contain a higher concentration of p35 li than do EBVL or Raji cells.

© 1993 by The American Society of Hematology.

THE HLA CLASS II invariant chain (li) was first shown as a coprecipitant in immunoprecipitates of class II major histocompatibility complex molecules, and its expression, processing, and degradation by proteolysis have since been extensively studied. It is now known that li chains become associated with class II α- and β-chains in the endoplasmic reticulum (ER) and that this close association is maintained during intracellular transport until, in a late endocytic compartment, the li chain is digested, leaving the αβ complex free to bind exogenous, antigenic peptides for display on the cell surface.

The role of the li chain in these events is believed to be threefold. It blocks the αβ antigen-binding site, thus preventing display of endogenous peptides on class II molecules; it maintains the αβ chain complex in an immunologically effective conformation; and it targets the αβ chains to an endocytic compartment.

Thus, the invariant chain is a potentially important participant in B-cell function, particularly as this involves antigen presentation to CD4+ lymphocytes.

Electrophoretic studies have identified several forms of li that differ in charge and mass. These represent the products either of translation from two different AUG initiation codons (giving rise to 33-Kd and 35-Kd proteins) or of alternate splicing of the mRNA (giving 41-Kd and 43-Kd forms). During subcellular passage, glycosylation, and sialylation, limited proteolytic cleavage and sulfation (to form the core protein of a chondroitin sulfate proteoglycan) contribute further to the heterogeneity of li chain types that are encountered.

It is known that chronic lymphocytic leukemia (CLL) cells express large amounts of li chain, and it has also been shown that neoplastic cells may show abnormalities in glycosaminoglycan synthesis. For these reasons, we felt that it would be of interest to study the li chain synthesis in peripheral blood (PB) lymphocytes from patients with CLL and to compare it with that in Epstein-Barr virus (EBV)–transformed normal PB lymphocytes (EBVL) and neoplastic Raji cells derived from a B lymphoma.

We have developed an IgG2a monoclonal antibody (MoAb), VCD-1, that reacts with an epitope on the N-terminal intracellular region of li. In this study, we report on experiments in which we have used VCD-1 to show that processing of li does not follow the same pattern in all class II positive cells and that CLL lymphocytes express an unusually large amount of the minor p35 form of li.

MATERIALS AND METHODS

Antibodies. VCD-1 MoAb reacts with an intracellular aminoterminal epitope on li. It was produced in this laboratory by fusion of SP2 myeloma cells with splenocytes from a Ballyc mouse that had been immunized with CLL lymphocytes. Biotinylated VCD-1 was prepared according to the method of Stahli et al. Sheep anti-mouse Ig antibody and monoclonal mouse anti-horse-radish peroxidase were produced in this laboratory.

Cells. The Raji cell line was obtained from American Type Culture Collection (Rockville, MD); the EBVL cell lines were established by transformation of normal PB lymphocytes with EBV from the supernatant of B95-8 cells. CLL cells were PB lymphocytes from patients with CLL and were separated by Ficoll-Hypaque flotation. Cell lines were maintained in RPMI 1640 supplemented with 10% fetal calf serum (FCS) and antibiotics.

Reagents. The following reagents were obtained commercially from the indicated suppliers: formalin-fixed suspension of Staphylococcus aureus (SA); GIBCO-BRL (Grand Island, NY); sodium sulphate, H-thiouracil, Amplify, and Hyperfilm MP (Amersham, Arlington Heights, IL); endoglycosidase-H (endo-H) and long-arm bixin, Sigma (St. Louis, MO); Amphotelines, Pharmacon-LKB (Piscataway, NJ); urea, Schwarz-Mann (Orangeburg, NY); Immobilon P (polyvinylidene difluoride membrane), Millipore (Bedford, MA); and avidin/biotinylated peroxidase (ABC) reagent, Dako (Glostrup, Denmark). Peroxidase-antiperoxidase (PAP) reagent was produced in this laboratory; it contained monoclonal mouse antiperoxidase antibody (ascites at 1/100 dilution) and horseradish peroxidase (Serva, Cape Town, South Africa) at 100 μg/mL of phosphate-buffered saline (PBS).

Preparation of cell lysates. Cells were washed twice in PBS and
suspended in lysis buffer (PBS containing 0.5% Nonidet P-40 and 1 mmol/L phenylmethylsulphonyl fluoride (PMSF)) at a concentration of $5 \times 10^5$ cells/mL for B-lymphoblastoid cells and of $10^5$ cells/mL for CLL lymphocytes. After 20 to 30 minutes on ice, nuclei were pelleted at 1,000g; supernatants were stored at $-80^\circ$C until use.

**Western blotting.** Cell lysates were electrophoresed in polyacrylamide gels, in the presence of 2% sodium dodecyl sulphate (SDS-PAGE), using the Laemmli buffer system under nonreducing conditions. Blotting and labeling of the blot with VCD-1 was performed essentially according to De Blas and Cherwinski. Proteins were electro-blotted onto Immobilon P at 3.5 V/cm overnight. The membranes were blocked with 5% FCS in Tris-buffered saline and reacted sequentially with VCD-1 ascites (diluted 1/500 in blocking solution), with sheep antimouse IgG link antibody (whole sheep serum diluted 1/200), with PAP 1/20, with a second round of link antibody and PAP, and, finally, with diaminobenzidine (DAB) containing 0.03% cobaltous chloride.

**Metabolic labeling of cells with $^{35}$S-sulphate.** Sulphate-free medium was prepared by adding minimum essential essential medium (MEM) amino acid mixture (Flow Laboratories, Irvine, CA) and MEM vitamin mixture (International Scientific Industries, Cary, IL) to the salts of MEM with MgSO$_4$ replaced with 170.8 mg/L MgCl$_2$-6H$_2$O. Cells were washed twice in PBS and suspended at $10^5$ cells/mL in sulphate-free medium with 2% dialyzed FCS. After 30 minutes at 37°C, 30 μCi/mL of $^{35}$S-sodium sulphate was added; the cells were incubated overnight, washed, and lysed.  

**Pulse-chase labeling with $^{3}$H-leucine.** Cells were washed twice with PBS and suspended, at $2 \times 10^5$ cells/mL in leucine-free MEM containing 2% dialysed FCS and incubated for 30 minutes at 37°C.  

**Immunoprecipitation.** Formalin-fixed $S_A$ cells were washed twice in PBS containing 0.5% Nonidet P-40 + 2 mmol/L leucine + 0.02% azide ($S_A$ buffer) and resuspended at 10% in $S_A$ buffer containing 1 mg/mL ovalbumin. After 30 minutes on ice, 5 μL of VCD-1 ascites was added per 200 μL $S_A$ suspension. After 1 hour on ice, the $S_A$ were washed twice with $S_A$ buffer. For clearing lysates and for control immunoprecipitations, the $S_A$ were coated similarly with an irrelevant MoAb against $\beta$-galactosidase. Lysates were then cleared by incubating for 1 hour on ice, with $S_A$ coated with control antibody. The samples were centrifuged, and supernatants were immunoprecipitated with $S_A$ coated with VCD-1 for 1 hour. The $S_A$ were then washed 5 times with $S_A$ buffer, boiled with SDS-PAGE sample buffer (0.063 mol/L Tris-HCl pH 6.8, 10% wt/vol sucrose, 2.3% wt/vol SDS, and 0.002% bromophenol blue), and centrifuged. The supernatant solutions were loaded onto gels.

**RESULTS**

**VCD-1 immunoprecipitates all known monomeric forms of $\alpha_2$.** When EBV were incubated with $^{3}$H-leucine, lysed, and immunoprecipitated with VCD-1, two-dimensional electrophoresis and fluorography of the acrylamide gel (Fig 1) showed spots representing the p33, p35, and p41 forms of $\alpha_2^{123}$ as well as the p25 protolytic cleavage fragment. The most abundant form was that with molecular weight (M$_r$) 33 Kd (p33); p35, the product of translation from an alternative RNA initiation codon, and p41, which is encoded by the mRNA with alternatively spliced exons, were precipitated in lesser amounts.  

**CLL lymphocytes express a relatively large amount of the p35 form of $\alpha_2$.** In Western blots of EBV and Raji cell lysates, VCD-1 labeled a prominent band of the major p33 form of $\alpha_2$, the 66-Kd dimeric complexed form, and a faint band of M, 35 Kd that could have represented the p35 form or the sitidly, "processed" form of p33. However, in CLL lymphocytes, this higher M, form was abundant as the major p33 form (Fig 2A). When Western blots were performed with cell lysates of EBV from 5 different donors (Fig 2B) and of lymphocytes from 5 different EBV patients (Fig 2C), the same pattern was consistently observed. CLL lymphocytes contained more of the 35-Kd species, relative to the 33-Kd species, than do EBV.

To determine if the more abundant 35-Kd form in CLL cells represented p35 or the sialic acid-derivatized form of p33, we immunoprecipitated cell lysates with VCD-1 and separated the precipitated proteins by NPHEG and SDS-PAGE in two dimensions. These were then electrophoresed and detected with biotinylated VCD-1 and ABC reagent (Fig 3). Clearly, CLL lymphocytes expressed a large amount of the p35 form of $\alpha_2$ and very little processed p33 (Fig 3B); EBV (Fig 3A) and Raji cells (Fig 3C) produced only very small amounts of p35 and slightly more of the sialic acid-derivatized protein. Figure 3D shows an immunoblot with VCD-1 of CLL lystate precipitated with control antibody.

It is processed to form the core protein of significant amounts of chondroitin sulphate proteoglycan (CSPG) in Raji cells but not in EBV. When Raji cells and EBV were labeled with $^{35}$S-sulphate, lysed, immunoprecipitated with VCD-1, and analyzed by SDS-PAGE, the results, shown in Fig 4, were strikingly different. No CSPG could be precipitated from EBV (lane 4), whereas Raji cells had synthesized a polydisperse "smudge" of labeled protein.
ranging in M, from approximately 63 to 97 Kd (lane 3). The labeled, unprecipitated cell lysates were included in the gel (lane 1, Raji; lane 2, EBVL) to show that proteoglycans, although of different M, were produced by EBVL, but these did not bind to VCD-1. CLL cells produced no detectable CSPG (results not shown).

II is processed in the Golgi apparatus in Raji cells but only minimally so in EBVL. When Raji cells and EBVL were labeled with $^3$H-leucine, "chased" with nonradioactive leucine for varying times, and then lysed and immunoprecipitated with VCD-1, the immunoprecipitates were resolved into different patterns by SDS-PAGE. The fluorographs of the gels, run under nonreducing conditions, are shown in the left hand panel of Fig 5. In Raji cells, the immunoprecipitated II clearly increased in M, during the 2-hour chase, whereas, in the case of the EBVL, it was simply chased out of the pool without being modified. To see if this increase in pulse-chase pattern was due to processing in the Golgi apparatus, we treated VCD-1 immunoprecipitates of the chased Raji cells and EBVL with endo-H. Complex oligosaccharides generated in the Golgi apparatus are resistant to endo-H, whereas high mannose oligosaccharides generated in the ER are cleaved, resulting in lower M, forms. The fluorographs of endo-H-treated VCD-1 immunoprecipi-

tates of pulse-chased Raji cells and EBVL are shown in the right hand panels of Fig 5. In the Raji cells an endo-H-resistant band appeared after 30 to 60 minutes of chase; such a band was hardly detectable in EBVL. This difference in processed p33 is also shown in Fig 3A and C.

**DISCUSSION**

The results of these studies have shown that the MoAb VCD-1 precipitated the p33, p35, and p41 forms of the class II invariant chain and their sulphated and sialylated derivatives. Thus, the antibody could be used to estimate relative abundances of the different II species in lymphocyte populations representative of the transformed or neoplastic B-cell phenotype. It is from this application that two observations of interest emerged.

First, PB lymphocytes from patients with CLL were consistently found to contain larger amounts of the p35 form of the II chain relative to the p33 species. On the other hand, in the case of EBV-transformed normal B cells or Raji cells, a very faint 35-Kd band was seen, and p33 was the predominant species. Two-dimensional electrophoresis confirmed the identity of the 35-Kd band in CLL as p35.

Although CLL lymphocytes are known to express increased levels of II, this is, to the best of our knowledge, the
Fig 2. Western blots of CLL lymphocytes, EBVL, and Raji cells with VCD-1 MoAb. Lysates of lymphoid cells were subjected to SDS-PAGE in 11% acrylamide gels under nonreducing conditions. Separated proteins were electrophoretically transferred onto an Immobilon P membrane, and the membrane was reacted with VCD-1 MoAb, sheep-antimouse Ig link antibody, PAP, and DAB substrate as in Materials and Methods. (A) EBVL, lane 1; Raji, lane 2; and CLL, lane 3. (B) EBVL from 5 different donors. (C) CLL lymphocytes from 5 different patients. Arrows indicate positions and M, in kilodaltons, of marker proteins.

First report of the excessive accumulation in these cells of the b3 species whose translation is initiated from an AUG codon that is upstream from the p33 start codon. The abnormal p35:p33 ratios seen in all of the CLL cells that we examined suggests that this is a characteristic feature of this neoplastic disorder and, as such, merits further study. The fact that both p33 and p35 species are present, but in abnormal relative amounts, raises the possibility that mechanisms that control translation, and that have hitherto been characterized only in prokaryotic cells,27,28 may be deranged in CLL. The excessive accumulation of p35 in CLL cells is of interest because this molecule is known to have a strong N-terminal ER-retention signal16 and to form mixed trimers with p33. Therefore, in CLL cells it seems probable that both p35 and

Fig 3. Western blots of VCD-1 immunoprecipitates after separation by NEPHGE and SDS-PAGE. Unlabeled lysates of EBVL (A), CLL lymphocytes (B), and Raji cells (C) were immunoprecipitated with VCD-1, and the precipitated proteins were separated by NEPHGE and SDS-PAGE with the acidic end to the right as described in Materials and Methods. After electrophoretic transfer to Immobilon P membrane, the membranes were reacted with biotinylated VCD-1, ABC reagent, and DAB substrate. (D) A control blot, i.e., CLL lysate immunoprecipitated with control MoAb (anti-β-galactosidase) and reacted with biotinylated VCD-1 after NEPHGE, SDS-PAGE, and electrophoretic transfer. Arrows mark the spots representing the p35 form of b3. The significance of spots (i) and (ii) is not known.
p33 are retained in the ER without passing through the Golgi apparatus. This is consistent with our observation that glycosylation and sialylation of li chains was barely detectable in CLL cells.

In an elegant series of transfective experiments, Clements et al. were able to correlate li chain expression with tumorigenicity of Sal murine sarcoma cells. They suggested that overexpressed li chains blocked class II peptide-binding sites and so prevented presentation, via the class I route, of endogenous tumour-associated peptides. These observations, considered in conjunction with our findings, suggest that excessive li chain accumulation in CLL cells may contribute to the expression of the neoplastic phenotype by interfering with effective immune surveillance. Indirect support for this notion is to be found in a report by Sekaly et al. that showed class II molecules are able to present endogenous peptides in the absence of invariant chain.

Second, we have shown that Raji cells, derived originally from a malignant Burkitt lymphoma, differ from EBVL in that the malignant cells produced a CSPG with li as core protein and added endo-H-resistant complex oligosaccharides to their li chains, whereas the transformed cells did so to much less of an extent.

The significance of this finding is, as yet, uncertain. It may be related to the neoplastic nature of the cells, because it is known that intercellular glycosaminoglycans from mammalian tumour tissues differ significantly from those of the tissue of origin. Bono et al. have shown that M₆s of sulphated li chains isolated from malignant B cells are generally larger than those purified from normal B cells.

Furthermore, the in vitro killing of K562 target cells by natural killer cells is inhibited by complex carbohydrates; containing α(2 → 6)-sialic acid residues. Thus, the presence of such polysaccharides on the cell surfaces of B-lym-
Fig 5. Pulse-chase of II immunoprecipitated with VCD-1 and treated with endo-H. RAJ cells and EBVL were labeled for 10 minutes with 3H-leucine and chased for 0, 0.6, 1, and 2 hours in medium with nonradioactive leucine. Cells were lysed and immunoprecipitated with VCD-1. One-half of the SA with the immunoprecipitated proteins was treated with endo-H (right-hand panels), and the other half with buffer alone (left-hand panels) as in Materials and Methods. Proteins were solubilized in nonreducing sample buffer and separated by SDS-PAGE in a 11% acrylamide gel, which was treated with Amplify, dried, and fluorographed.

BONE-MARROW AUTOTRANSPLANTATION IN MAN

Report of An International Cooperative Study*

Summary Bone-marrow autotransplantation consists of the administration of extremely high doses of chemotherapy and/or radiation followed by “rescue” with autologous, cryopreserved, bone-marrow cells. This approach can produce responses unattainable with conventional doses of similar agents. Bone-marrow autotransplantation is relatively easy to do. This report summarizes data from 2570 patients receiving autotransplants at 43 centres worldwide for hematological malignancies and solid tumours; more than 50% of these transplants were done since 1984. Most transplants were performed for treatment of lymphoma, leukemia, lung cancer, melanoma, neuroblastoma, and breast cancer. Preliminary analyses indicate favorable responses in some tumour types and provide a basis for future investigations.

INTRODUCTION

Many types of tumours in man show a dose-response relation to antineoplastic drugs and radiation,1 but the amount that can be given is limited, primarily by toxic effects on the bone marrow. This limitation can now be circumvented by intravenous infusion of normal haemopoietic stem cells, either from the patient or a histocompatible donor. Infusion of the patient’s own bone marrow is referred to as an autologous bone-marrow transplant or autotransplant. Drug and/or radiation doses can be raised by 1.5-3 times when followed by an autotransplant.

There are two important considerations in selecting appropriate tumours for treatment in conjunction with bone-marrow autotransplantation. First, the tumour should show a dose-response relation to antineoplastic drugs or radiation. Secondly, the natural history of the tumour should be such that bone-marrow involvement is unlikely. Tumours that meet these criteria include acute leukemia, neuroblastoma, breast, ovarian, and testicular carcinoma, and certain lymphomas such as Hodgkin’s disease and aggressive non-Hodgkin lymphomas. In cases in which the bone marrow has been affected it may be possible to remove potentially contaminating tumour cells by immunological, pharmacological, or physical techniques.2-3 It may also be possible to use an alternative source of haemopoietic stem cells such as peripheral blood.4,5

There are considerable animal data to suggest that when the dose of drugs and/or radiation can be raised by doing bone-marrow autotransplantation a therapeutic response can be obtained in tumours resistant to conventional doses,6-7 and that the less extensive the disease, the better the response. Initial data in man indicate that high-dose chemotherapy, with or without radiation, followed by autotransplantation produces responses in patients whose tumours were resistant to conventional doses of these agents.8-10 Recent data suggest that response varies inversely with degree of spread,9-12 long-term, disease-free survival has been achieved in some instances.13,14

Bone-marrow autotransplantation is being used increasingly in man. There is no central registry of autotransplant data, as there is for allogeneic bone-marrow transplantation. Furthermore, much recent data is reported only at meetings or as abstracts. This report gives data from many centres active in bone-marrow autotransplantation. The objective of the study was to determine activity in this area and to obtain an indication of the types of tumours that respond to treatment with autotransplantation.

METHODS

Centres doing bone-marrow autotransplantation were identified by several means—for example, through international meetings or a review of publications indexed in the National Library of Medicine. Questionnaires were sent to 67 centres and answered by 43-15 centres, 24 (36%) in North America, and 4 (6%) elsewhere. Data were requested on 1-2 occasions to identify cases transplanted up to July, 1985.

Information was collected on number of new cases per year, in-vivo bone-marrow manipulation, cryopreservation, numbers of patients treated and tumour types, and drug and radiation regimens. Treatment outcome was classified as complete, partial, or less-than-partial response, by the use of standard criteria. Median duration of remission, duration of complete remission, and number of patients in continuous remission for more than 24 months were also ascertained. Data for January-July, 1985, were used to give a projection for rates for 1985.

RESULTS

Bone-marrow autotransplants were done in 2570 patients at the 43 centres. The annual and cumulative rates (fig 1)

Fig 1—Annual and cumulative frequency of bone-marrow autotransplants done by the participants in this study.

Data for 1985 have been obtained by projection.

show that more than 50% of transplants have been done since 1984.

In most cases the bone marrow was not manipulated in vitro to remove potentially contaminating malignant cells.

22 centres (51%) did so on more than one occasion, usually by the use of monoclonal antibodies (12 centres) or drugs (10 centres). All centres used cryopreserved bone marrow most of the time. At 11 centres some patients received non-cryopreserved bone-marrow.

935 transplants (36%) were done for lymphomas, including Hodgkin's disease (155, 4%), Burkitt's lymphoma (76; 3%), and other non-Hodgkin lymphomas (744; 29%) (fig 2). The non-Hodgkin lymphomas were diffuse large-cell or immunoblastic lymphomas. 588 transplants (23%) were done for leukaemias, including acute myelogenous leukaemia (246; 10%), acute lymphoblastic leukaemia (279; 11%), and chronic myelogenous leukaemia (83; 3%), 41% (1047) were done for non-haematological solid tumours.

Fig 2—Tumour types in patients treated with bone-marrow autotransplantation.

Fig 3—Preliminary response rates, expressed as percentage of the total number of cases, in patients treated by bone-marrow autotransplantation.

Because of range of patient characteristics and cytoreductive regimen, these data should be interpreted with caution.

Partly because the patients included in this study had diverse tumours at different disease stages and were treated with a wide variety of drug and radiation protocols, it is difficult to determine response rates accurately. Preliminary overall response rates are indicated in fig 3. Prominent among the responsive tumours are lymphomas, leukaemias, Wilms' tumour, neuroblastoma, breast, and ovarian carcinoma. Less commonly responses were observed in gastrointestinal malignancies and non-small-cell lung cancer.

DISCUSSION

Our international survey indicates that bone-marrow autotransplantation is increasingly being done in patients with cancer, mainly in those with lymphomas and leukaemias, but recently also in patients with solid tumours. The annual rate of autotransplantation is increasing rapidly; 50% of all procedures have been done since 1984, and more than 1000 will probably be done in 1986 alone.

Considerable experimental data suggest that high-dose chemotherapy and/or radiation with autotransplantation can be effective. Preliminary results of phase I-II trials in man are encouraging. The dose of antineoplastic drugs and radiation can be 1-5 times higher with bone-marrow autotransplantation than without, and although most autotransplants have been done in patients with advanced cancer resistant to conventional doses of antineoplastic agents, favourable results have been observed. Laboratory data clearly indicate that the earlier in the disease that autotransplantation is done, the better the response. Preliminary data in man support this finding. Some patients with tumours such as aggressive lymphomas that do not respond to chemotherapy and radiation can now be cured with high-dose chemotherapy and bone-marrow autotransplantation. The proportion of such patients who could be cured might be increased if transplants were done earlier.

Our data indicate certain types of tumours likely to respond to autotransplantation and high-dose chemotherapy/radiation. Prominent among these are lymphomas, leukaemias, breast and ovarian cancers, and neuroblastomas. In these instances, phase III trials would
be appropriate. Other tumours, such as gastrointestinal malignancies and non-small-cell lung cancer, seem less responsive. Yet other tumours have not yet been thoroughly investigated.

The response rates presented in this paper ought to be interpreted with caution since data are from heterogeneous groups of patients in different disease stages receiving different forms of pretransplant chemotherapy and/or radiation cytoreductive regimens. However, high-dose chemotherapy and radiation combined with bone-marrow autotransplantation seems to be a promising form of treatment for patients with advanced cancer in whom conventional approaches are unlikely to be successful.

Increasing Utilization of Allogeneic Bone Marrow Transplantation
Results of the 1988-1990 Survey

Mortimer M. Bortin, MD; Mary M. Horowitz, MD; and Alfred A. Rimm, PhD

Objective: To determine the pattern and frequency of allogeneic bone marrow transplantation from related and unrelated donors from 1988 to 1990.

Design and Setting: Survey of 342 institutions in 47 countries.

Measurements: Numbers of patients receiving bone marrow transplantation for specific disease categories at institutions with active allogeneic bone marrow transplant programs.

Main Results: Patients (14,745) received allogeneic bone marrow transplantation between 1988 and 1990; of these, 11,531 (8%) were from unrelated donors. Reasons for transplantation were acute leukemia (47%), chronic myelogenous leukemia (27%), lymphoma and other malignancies (10%), severe aplastic anemia (9%), and other nonmalignant diseases (7%). The number of allogeneic bone marrow transplants per million persons differed among countries, averaging 7.7 per million in North America and 5.7 per million in western Europe.

Conclusions: The use of allogeneic bone marrow transplantation continued to increase at a rate of more than 600 additional patients and 25 new transplant teams annually. This rise is due in part to increasing use of unrelated volunteers as donors. Resources allocated for transplants vary widely among countries.

Methods

We used the IBMTR Directory of Bone Marrow Transplant Teams (3) to identify all institutions at which allogeneic bone marrow transplantation was done. Several mechanisms ensure that all allogeneic transplant teams are included in this directory. First, most teams participate in the IBMTR research program and submit detailed information to the IBMTR Statistical Center regarding their consecutive patients receiving bone marrow transplantation. Second, the biomedical literature is screened monthly for articles on clinical bone marrow transplantation using the U.S. National Library of Medicine's MEDLINE to identify institutions not listed in the directory. Third, the IBMTR maintains a booth at meetings of various organizations including the American Society of Clinical Oncology, American Society of Hematology, International Society for Experimental Hematology, International Society of Hematology, and the UCLA Symposia on Bone Marrow Transplantation, where physicians who do bone marrow transplantation are encouraged to identify themselves and their institutions. Fourth, we reviewed a list of all teams submitting data to the European Bone Marrow Transplant Group (4) for 1990. Finally, members of the IBMTR Advisory Committee, representing 15 countries including the geographic areas where most bone marrow transplants are done, help identify institutions not found previously.

We identified 448 institutions in 52 countries in which allogeneic bone marrow transplantation was known or believed to have been done between 1988 and 1990. Although this list is complete to the best of our knowledge, allogeneic transplants may have been done elsewhere. Any such omissions are unintentional.

Questionnaires were mailed to leaders of transplant teams or heads of hematology-oncology departments at all 448 institutions. A duplicate questionnaire was mailed 2 months later to nonrespondents. Those not replying 2 months after the second mailing were contacted by telephone, telefax, or express mail.

Questionnaires requested information regarding the numbers of patients receiving syngeneic, allogeneic-related, allogeneic-unrelated, and autologous bone marrow transplantation for specific disease categories in 1988, 1989, and 1990. The category of acute leukemia included acute lymphoblastic and acute myelogenous leukemia plus a small number of patients with hybrid or dual-lineage leukemia. The category of chronic leukemia included primarily chronic myelogenous leukemia plus a small number of patients with chronic lymphocytic leukemia. Malignant lymphoma included non-Hodgkin and Hodgkin lymphomas. Other malignancies included myelodysplastic syndromes, multiple myeloma, and a variety of solid tumors.

Institutional data were requested including total number of beds, number of beds assigned for patients in the hematology-oncology unit, number of beds for patients having bone marrow transplantation, and the year that bone marrow transplants were first done.

Results

Response Rates to Questionnaire

Completed questionnaires were returned by physicians at 418 of the 448 (93%) institutions surveyed.

From the International Bone Marrow Transplant Registry and the Medical College of Wisconsin, Milwaukee, Wisconsin. For current author addresses, see end of text.

The International Bone Marrow Transplant Registry (IBMTR) collects, organizes, and analyzes data on allogeneic and syngeneic (but not autologous) bone marrow transplantation. The IBMTR is a voluntary, multi-institutional group conducting research aimed primarily at determining the factors that affect the success and failure of bone marrow transplants. In addition to these clinical epidemiologic investigations, the IBMTR conducts periodic surveys to assess the use of allogeneic and syngeneic bone marrow transplantation worldwide (1, 2). Previous surveys have covered the period from 1955 to 1987; we report continuing increases in the use of allogeneic bone marrow transplantation from 1988 to 1990.

Repeated attempts to establish contact with physicians at 30 (7%) institutions were unsuccessful. We assumed that most of these nonrespondents did few or no allografts between 1988 and 1990. We learned, however, that two teams with allograft programs did not respond because they did not wish to participate in the survey. From other sources (4) we determined that neither team did more than six allografts in 1990. We are confident that our study included all allograft programs worldwide with ≥ 30 patients annually.

No bone marrow transplants were done between 1988 and 1990 at 18 of the 418 institutions from which we obtained completed questionnaires. Physicians at most of these institutions reported that their transplant programs would begin in 1991 or later, whereas a few reported that their transplant programs were discontinued before 1988. Autologous, but not allogeneic, bone marrow transplantation was done at 58 of the 400 remaining institutions. Data from these institutions were excluded from our analysis. Of the responding institutions, 342 had allograft programs (Appendix 2). Data provided by team leaders at these 342 institutions formed the basis for our analysis.

Characteristics of Institutions

The median number of hospital beds at the 342 institutions where allografts were done between 1988 and 1990 was 600 (range, 50 to 3900 beds). The median number of beds specifically assigned for the care of patients in the hematology-oncology unit was 24 (range, 0 to 500 beds), and the median number of beds designated specifically for patients having bone marrow transplantation was 5 (range, 0 to 60 beds). As of 1990, the total number of beds designated for patients receiving bone marrow transplantation at these institutions was 2212. Of these 2212 institutions, 599 were in North America, 844 were in western Europe, and 373 were elsewhere.

Allogeneic and Syngeneic Transplants

Between 1988 and 1990, 14,745 patients received allogeneic or syngeneic bone marrow transplants at these 342 institutions: 4300 in 1988, 4916 in 1989, and 5529 in 1990. Based on data reported to the IBMTR from 1968 to 1990, we estimated that fewer than 2% of the donors and recipients were genetically identical twins. Unrelated donors were used for 1153 (8%) of patients: 212 (5%) in 1988, 392 (8%) in 1989, and 549 (10%) in 1990. At least one transplant from an unrelated donor was done at 167 institutions. The distribution of patients according to donor status (related or unrelated) and disease category is shown in Table 1. Eighty-three percent of transplants were done to treat malignant diseases and 17% to treat nonmalignant diseases.

506 15 March 1992 • Annals of Internal Medicine • Volume 116 • Number 6
Table 2 shows the geographic distribution of patients by disease category. Most transplants were done in North America (42%) and western Europe (42%). The remainder were done in Asia (7%), Australia and New Zealand (3%), the Mideast and Africa (2%), South and Central America (2%), or eastern Europe (including the U.S.S.R.) (1%).

Based on world population approximations for 1989 (5), we estimated that between 1988 and 1990 the number of allogeneic transplants per million persons annually was about 7.7 in North America and 5.7 in western Europe. The distribution of allogeneic bone marrow transplantation procedures by country is shown in Table 3.

Between 1988 and 1990, 35 institutions did an average of one or fewer allogeneic transplants per year. At 120 (35%) of the 342 institutions, five or fewer patients had allogeneic transplants annually, accounting for 6% (822) of the 14,745 patients. In contrast, an average of 50 or more patients had allogeneic bone marrow transplantation per year at 16 (5%) of the 342 institutions and accounted for 25% (3,714) of the patients.

Figure 1 shows the annual and cumulative numbers and percentages of patients treated with allogeneic or syngeneic transplantation from 1 January 1981 through 31 December 1990. The increases during this 10-year period were linear and averaged 495 additional patients each year (least squares regression). Between 1988 and 1990, however, the increase averaged 615 patients per year. Based on the results of the current survey and previous IBMTR surveys (1, 2), we estimated that the cumulative total number of allogeneic and syngeneic transplant procedures was at least 14,745 between 1988 and 1990, 32,582 between 1981 and 1990, and 35,077 from the mid-1970s through 1990.

Of the 342 institutions with active allogeneic transplant programs between 1988 and 1990, 76 (22%) started between 1988 and 1990, 170 (50%) between 1981 and 1987, and 96 (28%) between 1960 and 1980.

### Autologous Bone Marrow Transplantation

We did not conduct a survey of worldwide autotransplant activity; results of such surveys have been previously reported (6, 7). However, to obtain an estimate of the total size of their bone marrow transplantation programs, physicians at the 342 institutions with autotransplant programs were also asked to provide data about their autotransplant activity. Only autologous bone marrow transplants were done between 1988 and 1990 at 41 of the surveyed institutions. At the 301 institutions with both autotransplant and allogeneic transplant programs, 14,187 patients received autotransplants, and 13,139 received autotransplants. These data yielded an overall ratio of 1.08:1.00; this ratio varied widely among institutions.

The number of patients receiving autologous bone marrow transplantation by disease category is shown in Table 4. The number of patients who received autotransplants at these institutions (where autotransplants were also done) increased more rapidly than did the number of patients receiving autotransplants between 1988 and 1990: 3,506 patients in 1988, 4,479 in 1989, and 5,154 in 1990. The increase averaged 824 additional patients per year.

The geographic distribution of autotransplants by disease category is shown in Table 5. Most autotransplants were done in North America (50%) and western Europe (42%). The rest were done in Australia and New Zealand (3%), Asia (2%), the Mideast and Africa (2%), eastern Europe (including the U.S.S.R.) (<1%), and South and Central America (<1%).

Of the 301 institutions with both autotransplant and allogeneic transplant programs, 76 (26%) autotransplant programs began between 1988 and 1990, 176 (58%) between 1981 and 1987, and 48 (16%) between 1960 and 1980.

### Discussion

The use of allogeneic bone marrow transplantation increased at a rate of 615 additional patients per year.

It is now generally accepted that allogeneic bone marrow transplantation is superior to alternative therapies and offers the potential for cure in conditions such as the Wiskott-Aldrich syndrome (8), severe combined immunodeficiency disease (9), severe aplastic anemia (10), thalassemia major (11), and chronic myelogenous leukemia (12, 13). Although effective and widely used in the management of other diseases, such as the acute leukemias, its relative value in comparison with other approaches is less clear (14).

The increasing use of allotransplants may also be a result of increasing safety of the procedure. Recent improvements are reported in the prevention of graft-versus-host disease (15) and in the prevention and treatment of cytomegalovirus interstitial pneumonia (16, 17) (two major causes of treatment failure after allogeneic bone marrow transplantation).

One of the factors limiting more widespread use of allotransplants is the knowledge that results are generally inferior when a family member other than an HLA-

identical sibling is used as the donor (18, 19). Most patients (60% to 70%) who could benefit from a transplant do not have an HLA-identical sibling (20). Results much like those obtained with HLA-identical sibling donor transplants were recently reported using unrelated donors closely matched with recipients for HLA antigens (21-23). This finding has led to the development of large registries of persons who have volunteered to serve as bone marrow donors (24-26). The increasing use of unrelated donors (5% of all allografts in 1988, 8% in 1989, and 10% in 1990) accounts, in part, for the continuing increase in the use of allogeneic bone marrow transplantation.

Between 1988 and 1990 more allotransplants (14 187) than autotransplants (13 139) were done at the 301 institutions that did both types of transplantation. The rate of increase in autotransplants (824 per year), however, was higher than that of allotransplants (566 per year). Also, a more rapid increase occurred in new autotransplant programs compared with new allotransplant programs. Although we did not attempt to obtain data regarding all autotransplant programs worldwide, we are confident that the total number of patients having autologous bone marrow transplantation and the total number of institutions in which this procedure is done now exceed those of allografts.

Confirming a previous report (6), we found that more patients with lymphoma had transplantation at centers in North America than in western Europe and that more patients with acute leukemia had transplantation in western Europe than in North America. The reasons for these differences are not known.

The effect of center size on transplant outcome is an important issue for health care policy managers. A recent study from the IBMTR found that the number of allotransplants done to treat early leukemia annually at institutions was predictive of outcome (27). The adjusted probability of treatment-related mortality was higher (relative risk, 1.53; \( P < 0.01 \)) among patients having transplantation at centers in which five or fewer transplants were done per year than among those having transplantation at larger centers. It is therefore of some concern that 120 institutions in our survey averaged five or fewer allotransplants per year. Further study that takes into account other factors, such as annual number of autotransplants also done at these institutions, is needed to evaluate the influence of center size on outcome of allogeneic bone marrow transplantation.

Our data on the use of allotransplants in terms of

national populations is, to our knowledge, the first analysis of this kind. It is not surprising that this expensive, high-technology procedure is available in fewer than 50 countries. In those countries without an allotransplant program, patients who might benefit either do not have transplantation or are referred elsewhere. The estimates of annual transplants per million persons in individual countries do not take into account the possible referral of patients across national borders. Although the United States has the largest number of patients receiving allotransplants (5552 between 1988 and 1990) and 87 institutions in which the procedure is done, 16 of 50 states do not have an allotransplant program. Here, also, patients who might benefit either do not have transplantation or are referred elsewhere.

It is impossible to assess the impact that the 1990 Nobel prize award to Dr. E. D. Thomas of Seattle for his pioneering work in clinical bone marrow transplantation will have on the field's future growth. Little doubt exists, however, that the expert training programs for young physicians at large transplant centers will lead to further increases in new transplant teams and in the number of patients offered this exciting new therapy.

Current Status of Bone Marrow Transplantation for Severe Aplastic Anemia: A Preliminary Report from the International Bone Marrow Transplant Registry

E. Gluckman for the Advisory Committee of the International Bone Marrow Transplant Registry

Severe aplastic anemia (SAA) is a usually fatal disease manifested by markedly reduced or absent hematopoiesis. There are numerous causes, but most often the etiology is not known. In most series the etiology can be linked to agents such as drugs, chemicals, virus infections, or total-body exposure to high doses of total-body radiation in 10% to 25% of cases. In other cases, the disease appears to be autoimmune, with the patient's own hematopoietic stem cells as the target. Bone marrow transplantation from an HLA-identical sibling or from a genetically identical twin is generally recognized as a more desirable treatment strategy than alternative therapies. Administration of antithymocyte globulin has also resulted in improvement or cure of the disease, with autologous recovery of hematopoiesis in some cases.

This study was conducted to evaluate the present status of bone marrow transplantation for SAA worldwide. Further, we evaluated

Clinical Bone Marrow Transplantation Proceedings, Vol XIX, No 1 (February), 1987: pp 2597-2599
factors that may influence the probability of long-term, disease-free survival with stable engraftment.

PATIENTS AND METHODS

Comprehensive data regarding 455 patients with SAA treated with high-dose chemotherapy with or without radiotherapy and bone marrow transplantation from HLA-identical siblings between January 1, 1978, and June 30, 1985, were reported to the International Bone Marrow Transplant Registry (IBMTR) by 74 transplant teams worldwide. Thirty-four potentially important variables were analyzed to evaluate their effect on the probability of survival with stable engraftment and restoration of hematopoiesis. For this preliminary report we used univariate statistical techniques and standard life table methods to evaluate associations between prognostic and end point variables.

RESULTS AND DISCUSSION

Stable engraftment with partial or full restoration of hematopoiesis following the first transplant occurred in 87% (365/421) of the patients. The actuarial probability of graft failure/rejection at 5 years was 18% ± 5% (95% confidence interval).

Eight factors were associated with the probability of stable engraftment. The incidence of graft failure/rejection was higher ($P < .03$) among patients who received no radiation as part of the conditioning regimen, 17% (35/205) vs 10% (21/216) for patients who were irradiated. Patients treated in conventional isolation had a higher ($P < .05$) incidence (16%, 38/234) of graft failure/rejection than those maintained in laminar air flow isolation (9%, 17/181). A trend ($P < .10$) toward higher graft failure/rejection rates was observed for the following variables: male sex, female donors; multiple fraction vs single fraction radiation; higher pretransplant hemoglobin and platelet counts vs lower readings; longer vs shorter intervals between diagnosis and transplantation; and lower vs higher doses of bone marrow cells per kilogram body weight.

Five factors were identified that were significantly associated with the actuarial probability of 4-year survival following transplantation of bone marrow from HLA-identical siblings for SAA (Table 1). Each of these factors is discussed briefly.

As one might anticipate, a highly significant association exists between engraftment and the probability of survival. On the other hand, although 56 patients failed to achieve stable engraftment following the first transplant, 21 of them are currently alive: 13 had successful second transplants, three had partial restoration of hematopoiesis with improvement of the disease, and five had autologous recovery of hematopoiesis.

Among the patients in whom engraftment is achieved, graft-vs-host disease (GVHD) remains a formidable problem. The 31% (±10%) 5-year actuarial probability of survival for 169 patients who developed moderate-to-severe acute GVHD contrasts with the 80% (±5%) probability of survival among patients with no or only mild acute GVHD. The use of in vitro T cell depletion of donor bone marrow may prove to be an effective means to reduce the risk of GVHD in the future (only one patient in this series received T cell-depleted marrow). Thus far, reports from individual centers have failed to show an improved probability of survival in patients

receiving T cell-depleted marrow due to an increased incidence of graft failure/rejection. The 62% (±6%) 4-year actuarial probability of survival for 292 patients who received transplants since 1981 vs a 47% (±8%) probability among 163 patients who received transplants earlier suggests that teams and techniques are improving.

Patients receiving radiation as part of their retransplant preparative regimen had a higher \((P < .02)\) probability of survival than those who were not irradiated. This may have been due to the fact that engraftment rates were higher with radiation than without it.

Patients whose donors were of the same sex and a higher \((P < .03)\) probability of survival than when donors and recipients were sex mismatched. The explanation for this finding is uncertain. It is possible that in male-to-male transplants the H-Y antigen on the male cells serves as a target for rejection. In male-to-male transplants, the H-Y antigen may serve as a target for a graft-vs-host reaction. Multivariate analyses are in progress to dress this and other issues.

The analyses reported here provide information regarding the current probability, worldwide, of long-term survival with restoration of hematopoiesis for patients with SAA following treatment with HLA-identical bone marrow transplantation. Several prognostic factors were identified that appear to influence the probability of stable engraftment and disease-free survival.

Received 1 September 1988; accepted for publication 31 October 1988

Summary. Data from 547 patients with aplastic anaemia who received bone marrow transplants from HLA-identical siblings were analysed to determine factors associated with the risk of interstitial pneumonia (IPn). IPn developed in 92 patients (17%). 37% of cases were associated with cytomegalovirus infection and 22% with other organisms; in 41% of cases no organism was identified. The case fatality rate was 64%; the mortality rate due to IPn was 11%. In multivariate analysis, four factors were associated with an increased probability of interstitial pneumonia: use of methotrexate rather than cyclosporine after transplantation (relative risk, 2-8; P < 0-0008); occurrence of moderate to severe acute graft-versus-host disease (relative risk, 2-2; P < 0-002); inclusion of total body radiation in the pretransplant preparative regimen (relative risk 2-2; P < 0-004); and patient age > 20 (relative risk 1-7; P < 0-002). The probability of IPn ranged from 4% for patients with none of these adverse risk factors to 51% (relative risk of 13-4) for patients with all four. The incidence of IPn decreased significantly between 1978 and 1985, paralleling a decrease in the use of total body radiation pretransplant for immune suppression and methotrexate post-transplant for prophylaxis against graft-versus-host disease.

Bone marrow transplantation is an important therapy for severe aplastic anaemia (SAA). Recent data indicate cure rates of 40–70% after bone marrow transplantation from an HLA-identical sibling (Gluckman, 1987; Storb et al., 1980; Anasetti et al., 1986; Storb et al., 1986; Smith et al., 1985; Feig et al., 1983; McGlave et al., 1987). Transplant-related complications associated with failure of bone marrow transplantation in SAA include infection, graft failure and rejection, graft-versus-host disease (GVHD) and interstitial pneumonia (IPn) (Gluckman, 1987; Anasetti et al., 1986; Winston et al., 1984). IPn accounts for up to 40% of treatment failures (Gluckman, 1987; Meyers et al., 1982; Meyers, 1986).

IPn characteristically presents within the first 4 months post-transplant. Typical features include dyspnoea, non-productive cough, progressive hypoxia, bilateral interstitial infiltrates on roentgenograms of the chest and decreased diffusion capacity. Histologic examination of the lung shows oedema, fibrosis, a variable cellular infiltrate, and alveolar exudates (Meyers et al., 1983; Khouria et al., 1979; Sloan et al., 1983). Cytomegalovirus (CMV) is the most common organism associated with IPn: other viruses, Pneumocystis carinii and fungi are less frequent. No organism is identified in 30–60% of patients despite culture and/or histologic examination (Winston et al., 1984; Meyers et al., 1982, 1983; Meyers, 1986).

Previous studies indicate that severe GVHD, older age, and
Pulmonary radiation are important risk factors for interstitial pneumonia following bone marrow transplantation (Meyers et al. 1982, 1983, 1986; Weiner et al. 1986). A recent analysis of 932 patients undergoing allogeneic bone marrow transplantation for leukemia demonstrated that older age, moderate to severe GVHD, use of methotrexate to prevent GVHD, prolonged interval between diagnosis and transplant, poor performance status prior to transplant and, in patients receiving methotrexate as GVHD prophylaxis, higher doses of total body radiation were significant risk factors for IPn (Weiner et al. 1986).

Patients with SAA come to transplantation with medical histories significantly different from patients with acute leukemia. Characteristically, they have received no prior cytotoxic chemotherapy or radiotherapy and have not had many of the consequences of iatrogenic immune suppression. Moreover, the transplant regimen itself differs from that used to treat leukemia since the main thrust is immune suppression rather than antitumour cytotoxicity. It is of interest, therefore, to determine the risk factors for interstitial pneumonia in patients undergoing bone marrow transplantation for SAA.

Most previous studies of IPn after transplantation for SAA included fewer than 100 patients (Gluckman 1987; Storb et al. 1980, 1986; Anasetti et al. 1986; Smith et al. 1985; Peig et al. 1983; McClave et al. 1987). This analysis of 547 patients with SAA who received transplants from histocompatible siblings identified risk factors associated with IPn in this setting. Several significant risk factors were found and a decreasing incidence of IPn between 1978 and 1985 was documented. Hypothesis based on these data and biological principles are suggested to help explain the pathogenesis of this disease.

**Patients and Methods**

Comprehensive data on sequential patients were reported to the International Bone Marrow Transplant Registry (IBMTR) by 84 transplant centres worldwide for 673 patients with SAA transplanted between 1 January 1978 and 31 December 1985. The analysis was based on all data received by 2 December 1986, at which time the minimum follow-up time was 4 months, the maximum 9 years, and the median 2.5 years. Data from the 547 patients receiving bone marrow from HLA A and B identical and mixed leucocyte culture non-reactive sibling donors with no evidence of incompatibility at other HLA loci form the basis for this analysis. Of the 126 patients excluded from analysis, 105 received bone marrow from donors other than HLA identical siblings, 16 received transplants from genetically identical twins, and five were transplanted with tissue other than bone marrow.

Fifty patients received two or more transplants for the following reasons: non-engraftment, 24; incomplete engraftment, six; and late graft failure or rejection, 20. Characteristics of the 547 patients included in the study are presented in Table 1.

All patients were prepared for transplantation using cyclophosphamide. 106 patients also received total body radiation (median dose 3.0 Gy; range 3.0–8.0 Gy) and 165 received limited field radiation (median dose 6.8 Gy; range 1.5–12 Gy). The latter included total lymphoid and thoracoabdominal fields. Donor buffy coat transfusions were given to 148 patients post-transplant. Prophylaxis against GVHD consisted of methotrexate alone or with other drugs in 329, cyclosporine alone or with other drugs in 193, methotrexate in combination with cyclosporine in eight and a variety of other regimens in 17 patients.

In this report, IPn is defined as any nonbacterial pneumonia occurring at any time after transplantation with radiographic and/or histologic features commonly associated with the disease. Biopsy or autopsy findings were available for 51/92 (55%) patients who had IPn.

**Statistical Methods**

A total of 35 prognostic variables were studied (Table II). The association between each risk factor and the occurrence of IPn was tested in univariate analyses using χ² for categorical and Student's t-test for continuous variables. Factors associated with IPn with a P value ≤0.10 in univariate analyses were entered into a multiple logistic regression model in a forward stepwise fashion. Because of the multiple comparisons made, only variables that improved the model with P < 0.01 were considered significant. The probability of IPn for a patient with a single risk factor and with a specific profile of risk factors was derived from the logistic analysis.

The relative risk associated with a single risk factor or profile was computed as the probability of disease for patients with that risk factor or profile divided by the probability of disease for patients with none of the risk factors. All multivariate analyses were examined for possible centre effects in two ways. First, the probability of IPn for patients transplanted in smaller centres was compared with the probability for those transplanted in larger centres. There was no significant difference. Second, transplant centre was entered as a categorical covariate in the multiple logistic regression model. Its inclusion did not significantly improve the model nor did it substantially alter the relative risk or statistical significance of the prognostic variables. All P values are based upon the results of multivariate analysis, unless specified.

**Results**

**Incidence**

Ninety-two of 547 (17%) patients developed IPn. The 3-year

actuarial probability of IPn was 21 ± 4% (95% confidence interval). The interval between transplantation and onset of IPn was 79 ± 65 d (mean ± SD). 80% of cases occurred within the first 120 d after transplantation. Thirty-four (37%) of 92 cases were associated with CMV and 20 (22%) with other organisms (Pneumocystis carinii in six patients, Aspergillus sp. in six patients, and various other organisms in eight patients). No organism was identified in 38 (41%) patients.

Risk factors

Four of the seven variables associated with development of IPn in univariate analysis (Table II), were shown to be significant adverse risk factors in multivariate analysis: use of methotrexate as prophylaxis against GVHD, development of moderate to severe acute GVHD, use of total body radiation for conditioning, and older patient age (Table III).

Methotrexate was strongly associated with the development of IPn (Fig 1A, \( P < 0.0008 \)). The risk of interstitial pneumonia was 2-8 times greater for patients who received methotrexate with or without other drugs than for those who received cyclosporine with or without other drugs to prevent GVHD. The number of patients who received other regimens to prevent GVHD was too small to assess their impact upon the probability of IPn.

The effect of radiation on the incidence of IPn is shown in Fig 1B. Conditioning regimens that included total body irradiation were associated with a risk of IPn 2.2 times greater than conditioning regimens using either limited field radiation (total nodal, total lymphoid or thoracoabdominal irradiation) or no irradiation (\( P < 0.004 \)). While conditioning regimens that included limited field radiation were associated with a higher risk of IPn (relative risk 1.5) than those using cyclophosphamide alone, this difference was not statistically significant (\( P > 0.1 \)). For all further analyses, therefore, the patients receiving limited field irradiation were combined with those receiving no irradiation.

The patients receiving total body radiation did not differ significantly in age or incidence of acute GVHD from patients who were conditioned without total body radiation. Because both methotrexate and total body radiation were associated with an increased risk of IPn, we examined this interrelation-
ship in greater detail. Methotrexate was used in 79% (84/106) of patients receiving total body radiation as compared to 56% (245/441) of those who received limited field or no radiation (univariate P<0.001). In order to test the association between methotrexate and IPN in the absence of pulmonary irradiation, the 441 patients who received limited field or no irradiation were analysed as a separate subset by multiple logistic regression analysis. The 245 patients who received methotrexate had a relative risk of 2.5 compared to the 196 patients who received no methotrexate (P<0.004).
Pneumonia after BMT for Aplastic Anaemia

Moderate to severe acute GVHD was also associated with the risk of IPn (Fig 1D, P < 0.002). Fifty-five of the 92 patients with IPn had moderate to severe acute GVHD: manifestations of GVHD were documented to have preceded the onset of IPn in 51 (93%) of these 55 cases. Individuals with moderate to severe acute GVHD had a relative risk of IPn of 2.2 compared to patients with no or mild acute GVHD. The incidence of acute GVHD was not significantly different in patients who received methotrexate as opposed to cyclosporine for GVHD prophylaxis (37% v. 42%, P = 0.35).

Older patient age was a significant risk factor for IPn; age > 20 years was associated with relative risk of 1.7 (Fig 1E, P < 0.002). The incidence of moderate to severe acute GVHD was not significantly different between patients ≤ 20 and > 20 (36 v. 42%, P = 0.13).

Fig 2 illustrates the cumulative effect of these variables on the probability of IPn. The probability of IPn was 51% for the group of patients who received methotrexate, developed moderate to severe acute GVHD, received total body irradiation for immune suppression pre-transplant and were older than 20 years of age at the time of transplant. Among patients with none of these risk factors, the probability of IPn was only 4%. The total number of cases of IPn was too small to allow meaningful logistic analysis of risk factors for idiopathic IPn.

Case fatality and mortality rates
In 59 of the 92 patients with IPn, the complication was either a primary or contributory cause of death resulting in a case-fatality rate of 54%. The case fatality rate was 47% (18/38) for patients with idiopathic IPn, 74% (25/34) for patients with CMV IPn and 80% (16/20) for patients with IPn associated with other organisms. Overall, IPn accounted for 26% of the 228 fatalities in this study. IPn was the primary or a contributory cause of death in 11% of the patients (59/547).

IPn developing in the setting of GVHD was more frequently fatal. While 75% of patients with both IPn and moderate to

</table>
severe acute GVHD died with IPn as a primary or contributory cause of death. 51% with IPn and either no or mild acute GVHD died of IPn (univariate $P < 0.03$).

Decreasing incidence

The overall incidence of IPn decreased over the 8 years of this study. The incidence was 22% during the years 1978–81 and 12% from 1982 to 1985 (univariate $P < 0.01$). This decrease paralleled the significant decrease in the use of methotrexate for prophylaxis of GVHD and the significant decrease in the use of total body radiation for conditioning (Table IV). The association between decreased incidence of IPn with temporal changes in treatment is further strengthened by the fact that there was no change in the incidence of IPn during this period for patients who received both pulmonary irradiation and methotrexate nor was there a change in incidence of IPn for those patients who received neither pulmonary irradiation nor methotrexate. The incidence of moderate to severe GVHD, the age of transplanted patients, the spectrum of organisms identified and the case-fatality rate of IPn did not change significantly between 1978 and 1985.

DISCUSSION

This analysis of 547 patients transplanted for SAA demonstrates several important risk factors for the development of IPn. These include two major treatment variables: the use of total body irradiation in the pre-transplant conditioning regimen and the use of methotrexate for GVHD prophylaxis. Decrease in the use of total body radiation and of methotrexate were associated with a decreasing incidence of IPn during the 8-year study period.

Incidence and fatality of IPn

We and others reported previously that the incidence of IPn in patients transplanted for SAA is lower than among patients transplanted for leukemia (Meyers et al. 1982, 1986; Weiner, 1987). The actuarial probability of IPn was 21% in this study, significantly lower (univariate $P < 0.0001$) than the 35% probability among 932 patients with leukemia reported to the IBMTR by essentially the same transplant teams during a similar time period (Weiner et al. 1986). The case fatality rate of IPn was also lower in SAA than in leukemia (64% v. 84%, univariate $P < 0.0001$). This difference was due primarily to the lower case-fatality associated with idiopathic IPn in SAA patients: 47% v. 78%. CMV IPn was usually lethal in both SAA and leukemia (Weiner et al. 1986; Weiner, 1987). Both the higher incidence and higher case-fatality rates in leukemia patients might be explained by the chemotherapy given to leukemia patients during the treatment of their disease. Many of these drugs cause pulmonary toxicity and prolonged immune suppression (Ginsberg & Comis, 1982; Whitcomb, 1983; Haupt et al. 1981). Conditioning regimens for leukemia patients often use higher doses of radiation and drugs with antileukemia activity. As a consequence, conditioning regimens used prior to transplantation in leukemia may be more toxic to the lung than preparative regimens used in SAA (Haupt et al. 1981; Barratt et al. 1983; Pino et al. 1982).

Drugs to prevent GVHD

Most recipients of allogeneic bone marrow transplants receive prophylaxis against GVHD. Methotrexate or cyclosporine regimens are the most widely used. This study identified a highly significant association between the use of methotrexate-containing regimens and IPn. A similar association was found in our analysis of IPn in leukemia patients (Weiner et al. 1986). In the current study, this association was significant even in the subgroup of patients who did not receive total body radiation (and thus did not have pulmonary radiation), suggesting a direct toxic effect of methotrexate on the lung or perhaps one mediated through an interaction with cyclophosphamide (Chan et al. 1979; Demeter et al. 1979; Sostman et al. 1976). Two randomized studies comparing methotrexate with cyclosporine as prophylaxis against GVHD in patients receiving pulmonary radiation did not identify an increased risk of IPn in those patients given methotrexate (Deeg et al. 1985; Forman et al. 1987). This disparity may be explained by the inherent difficulty in identifying significant risk factors (high beta error) in small series of patients.

Effect of radiation

A number of studies have suggested that pulmonary radiation plays a role in the pathogenesis of IPn (Barrett et al. 1983; Pino et al. 1982; Chan et al. 1979; Keane et al. 1981; Peters et al. 1979; Bortin & Harts. 1988). We found no relationship in leukemia patients (98% of whom received total body radiation) between radiation dose and IPn with lung doses between 5.6 and 12.8 Gy (Weiner et al. 1986). However, dose-rates of radiation in excess of 5 cGy/min were associated with a significantly increased risk of IPn only if methotrexate was given as prophylaxis against GVHD. In contrast to leukemia, preparative regimens for bone marrow transplantation in SAA often do not include pulmonary radiation (Anasetti et al. 1986; McGave et al. 1987). Therefore, we were able to evaluate the effect of radiation on the risk of IPn.

The field of radiation made a significant difference regarding the risk of IPn in patients with SAA. Those receiving total body irradiation, i.e. a radiation field including the lungs, had a significantly increased risk of IPn. A dose response effect of total body irradiation; however, was not identified. The range of doses was relatively small with 75% of patients receiving between 3 and 4.5 Gy. Moreover, there was no effect on dose-rate of irradiation. It may be that dose-rate is not as important when the total dose is low. Eliminating pulmonary radiation from the transplant regimen would, it appears, reduce significantly the risk of IPn.

Interaction between radiation and drugs to prevent graft-versus-host disease

The patients receiving cyclosporine for prevention of acute GVHD did not demonstrate a significantly increased incidence of IPn when total body irradiation was part of the transplant regimen (Fig 1C). However, the number of patients receiving cyclosporine without total body irradiation was too small to exclude the possibility that an effect of total body irradiation might be present but not apparent. The use
of total body irradiation in patients receiving methotrexate, however, was associated with a significantly increased incidence of IPn in comparison with the use of methotrexate without radiation (Fig 1C). These data indicate that methotrexate is associated with a markedly increased risk of IPn and that this risk is even greater when methotrexate is used in patients who received total body irradiation. These observations are in accord with others that methotrexate and radiation act synergistically to increase pulmonary toxicity (Chan et al. 1979; Phillips & Fu, 1978).

The data support the hypothesis that injury to the lungs is an important pathogenic mechanism of IPn and that avoiding pulmonary toxins reduces the risk of IPn after allogeneic bone marrow transplantation. These findings suggest that the risk of interstitial pneumonia in severe aplastic anaemia patients undergoing transplantation would be reduced if total body irradiation were excluded from the conditioning regimen, especially for those patients who are to receive methotrexate as prophylaxis for acute graft-versus-host disease. Moreover, the risk of interstitial pneumonia could be reduced even for those patients not receiving pulmonary radiation if methotrexate were not used as prophylaxis for acute graft-versus-host disease. It must be borne in mind, however, that preparative regimens without radiation may be associated with an increased risk of graft failure in severe aplastic anaemia (Champlin et al. 1988). Further study is required before recommendations can be made with respect to the use of radiation for pretransplant conditioning of patients with severe aplastic anaemia.

**Effect of acute GVHD**

Acute GVHD is associated with an increased risk of IPn (Meyers et al. 1986; Weiner et al. 1986). This study also demonstrates that the risk of IPn is significantly higher in patients who develop moderate to severe acute GVHD. Several factors may play a role in this association. First, GVHD itself causes profound immune suppression and is often treated with drugs that may further decrease immune responsiveness (Ellenbein, 1983). Thus, GVHD may impair host defences against endogenous or exogenous CMV, as well as other microorganisms. Second, GVHD may activate latent CMV re-infection (Meyers et al. 1986). In addition to being more common, IPn was more likely to be fatal in patients with coincident moderate to severe acute GVHD. Only 25% of individuals had resolution of IPn in this setting compared to 51% of patients with nor or mild acute GVHD.

**The effect of age**

Increasing age had a significant adverse effect upon the risk of developing IPn. This age effect most likely reflects the increased probability of prior CMV infection in older patients, and, therefore, the increased possibility that endogenous CMV will be activated post-transplant (Meyers et al. 1986: Ho. 1982). Data on CMV antibody status pre-transplant were not available for patients in this study precluding an analysis based on positive CMV serology. Correlations between age, CMV seropositivity, and the risk of CMV IPn have been reported (Meyers et al. 1986).

The effect of age on risk of IPn does not appear to be mediated through GVHD. When the relative risk associated with age > 20 derived from the multiple logistic equation was adjusted for the effect of acute GVHD, the two covariates were not significantly correlated.

**Differences between leukaemia and SAA patients**

Many of the findings of this study parallel those in 932 leukaemia patients reported to the IBMTR during the same time period (Weiner et al. 1986). Methotrexate, acute GVHD and older age were significant risk factors for IPn in both populations. The role of radiation in increasing the risk of IPn suggested in the previous study, was more clearly demonstrated in the current study since a large number of patients who received no pulmonary radiation were available for comparison. The present results demonstrate that age, methotrexate and GVHD remained significant risk factors even in the absence of pulmonary radiation.

Two variables which were significant risk factors for IPn in leukaemia were not significant in this analysis: Karnofsky performance rating pretransplant and the interval from diagnosis to transplant. Since both of these variables are affected by the duration and intensity of pretransplant antineoplastic treatment, their significance in leukaemia patients may reflect cumulative pulmonary toxicity and/or prolonged immune suppression.

**Trends in the incidence of IPn and practice variables**

The incidence of IPn declined significantly between 1978 and 1985. Two changes in clinical practice which paralleled this decrease were identified. More than twice as many patients received methotrexate or total body irradiation in 1978–79 as in 1984–85. Other factors that might account for the decreasing incidence of IPn over the past 8 years were tested but none were identified. Further decreases in this important cause of morbidity and mortality following bone marrow transplantation for SAA may be possible on the basis of the findings reported here.

Pneumonia after BMT for Aplastic Anaemia

Qualitative Abnormalities Characterize Hematopoiesis that Restores Marrow Function after Therapy with Antilymphocyte Globulin and High-Dose Methylprednisolone in Aplastic Anemia

NICOLAS NOVITZKY, G. S. PILLY, JANET HALLETT, SALLY MONTAGU-FRYER, BASHIER KOOPMANN, VALDA THOMAS and PETER JACOBS

*The University of Cape Town Leukaemia Centre and the Department of Haematology, Groote Schuur Hospital, Observatory, 7925, Cape Town, South Africa; †Wynberg Hospital, Wynberg, Cape Town, South Africa

(Received 19 May 1995; In final form 12 February 1996)

Purpose: Antilymphocyte globulin (ALG) can restore bone marrow function in patients with aplastic anemia, but following recovery, hematopoiesis may be functionally abnormal. The extent of these defects was retrospectively characterized in a uniformly treated cohort of patients that had been followed up for between 1 and 8 years.

Patients and Methods: Thirty-four patients with a median age of 25.5 years (SD 15.66) received a standard regimen of anti-human lymphocyte globulin together with high-dose methylprednisolone on 5 consecutive days, followed by oxymetholone for 6 to 9 months. The initial response rate was 71%, but conditions of 6 patients deteriorated, 2 patients required a second course of ALG, 2 patients are cyclosporin-dependent and 1 patient continues to receive androgenic therapy. Standard techniques were used to assess peripheral blood and bone marrow morphology and bone marrow cytogenetic status. In 16 responders, function in the granulocytes was defined by phagocytosis, intracellular killing and superoxide generation. Lymphocytes were characterized by response to mitogens and alloantigen and immunoglobulin production and platelets by bleeding time and aggregometry.

Results: At a median of 4 years mild granulocytopenia and thrombocytopenia were detected, with dysplasia present in all but three patients. Two developed paroxysmal nocturnal hemoglobinuria. Chromosomal breaks and gaps were demonstrable in one-third of patients in 13 to 40% of metaphases studied. Neutrophil functions were normal in only one patient, while lymphocyte studies were adequate in all but two who were receiving cyclosporin therapy; bleeding times were abnormal in two-thirds of the patients while aggregometry was universally defective.

Conclusions: The combination of ALG and high-dose methylprednisolone produced variable hematologic responses in 71% of patients and although two-thirds of these are currently alive with only mild quantitative defects, considerable qualitative abnormalities are present in the majority. These findings reflect the persistence of a substantially abnormal hematopoiesis.

INTRODUCTION

Irreversible bone marrow failure[1] is usually idiopathic but may be associated with exposure to drugs,[2] pregnancy,[3] jaundice[4,5] and infections. The variable clinical expression reflects the extent of the hematopoietic damage and although mild or moderate hypoplasia may respond to andro-
genic steroids, these are ineffective in severe disease. Here patients will benefit from allogenic bone marrow transplantation, particularly young and unsensitized individuals.

Where this option is not available and based on observations that immune mechanisms may suppress hematopoiesis, antilymphocyte globulin (ALG) in combination with corticosteroids, cyclosporin and anabolic androgens elicits responses in more than 50% of patients. However, relapses occur even in the face of normal peripheral blood values. Furthermore, dysplasia, defective platelet function, alterations in T-lymphocyte subsets and reduction in the serum immunoglobulins have also been reported.

These morphologic features may be similar to those described in patients with myelodysplastic syndromes (MDS), who have hypoplastic bone marrow and who also respond to immunosuppressive therapy. This confusion is further compounded when patients with typical aplasia develop MDS, acute leukemia or paroxysmal nocturnal hemoglobinuria (PNH). To explore this interrelationship, we have studied a series of patients with aplastic marrow, who received uniform immunosuppressive therapy, and documented the morphologic, cytogenetic and functional characteristics of their hematopoiesis over 8 years of follow-up.

PATIENTS AND METHODS

From January 1985 to December 1991, 34 individuals with severe aplastic anemia and one with hypoplasia, 15 of whom had been previously reported, were referred for therapy. None had phenotypic features of Fanconi’s anemia; presentation had been during late adolescence and adulthood and without exception, the disease had been of a rapid onset. The median age was 25.5 years (range 13 to 72; SD 15.66) and 17 were female. Two had convalescent serology for hepatitis B; one was pregnant but recovered partially after a therapeutic abortion. One had been exposed to chloramphenicol in eye drops and another received chloroquine for rheumatoid arthritis, and neither recovered after drug discontinuation.

At presentation, the median value for hemoglobin (Hb) was 66 g/l (SD 20.9), the corrected reticulocyte count was 0.3% (SD 0.29), the mean red cell volume was 102 fl (SD 54.76), the granulocyte count was $0.50 \times 10^3/\text{l}$ (SD 0.44) and the platelet count was $11.5 \times 10^3/\text{l}$ (SD 5.37). Median bone marrow cellularity was 15% (SD 5.4) of normal. Vitamin B$_{12}$ and red cell folate status was normal.

Therapy

After confirmation of the diagnosis, individuals were entered into a standard protocol approved by the University of Cape Town and Groote Schuur Hospital Ethics and Research Committees, consisting of ALG (horse immunoglobulin without thrombocyte adsorption, Swiss Serum Institute, Bern, Switzerland) 50 mg/kg, and high-dose methylprednisolone, 500 mg daily on each of 5 consecutive days, followed by 30 mg of prednisone daily for 1 month. Response was defined as reversal of symptoms, freedom from transfusions, a stable rise in the platelet count above $40 \times 10^3/\text{l}$ and an absolute granulocyte count $1 \times 10^3/\text{l}$. Complete remission required Hb $>$120 g/l, granulocytes $>$2.5 $\times 10^9/\text{l}$ and platelet count $>$150 $\times 10^9/\text{l}$. Patients with inadequate responses or with fluctuating blood counts received oxymetholone 2 mg/kg for 6 to 9 months.

Laboratory Investigations

The current analysis was performed on a cohort of patients with severe aplasia who had responded to immunosuppressive therapy and who were investigated at a median of 4 years (range 1 to 8) from initial presentation.

Peripheral Blood and Bone Marrow Examination. Routine hematological studies were done
by standard methods. Bone marrow aspirates were stained with Romanowsky dyes and reviewed retrospectively, with special search for dysplastic features according to the French-American-British criteria. Trephine biopsies were sectioned and stained with hematoxylin and eosin and evaluated for inflammatory infiltrates, abnormalities in the stroma or abnormal localization of immature precursors (ALIP).

Cytogenetic Analysis. Bone marrow chromosome analysis was performed on trypsin (Difco, Detroit, MI) Giemsa banded metaphases. When necessary, phytohemagglutinin (PHA) (Murex Diagnostics Ltd, England)-stimulated blood cultures were carried out to establish the constitutional cell line.

Granulocyte Functions. Peripheral blood leukocytes were obtained from 13 patients with aplastic anemia and 9 concurrent control subjects by dextran sedimentation (dextran 6% w/v in 0.9% NaCl) of heparinized blood (20 U/ml) and divided in aliquots for the various assays. Determination of superoxide generation, and the combined measurement for phagocytosis and killing were performed following previously described methods. Chemotaxis was studied according to Addison and Babbage.

Lymphocyte Functions and Serum Immunoglobulin Levels. Peripheral blood mononuclear cells from patients with aplasia and control subjects were washed twice in RPMI-1640 (Gibco) and 0.1 ml of the suspension (5 x 10⁶/ml) was cultured for 3 days at 37°C in 96-well microtiter plates (Cel-Cult, Sterilin Ltd., Hounslow, UK) in the presence of 0.05 ml of concanavalin A (Calbiochem, La Jolla CA), PHA, pokeweed mitogen (Gibco) or heat-inactivated AB serum (WPBTS). Cells were then pulsed with 1 mCi of [³H]thymidine (Amersham, 1:200) at 37°C and harvested 18 hours later on to dry filter discs, and the radioactivity was counted. For the mixed lymphocyte reaction, allogeneic control lymphocytes were thawed and incubated at 37°C for 20 min in mitomycin (MO 0503, 1:8 dilution, Sigma, St. Louis, MO). After being washed twice in medium, 0.1 ml of the cell suspension (5 x 10⁶/ml) was cultured in triplicate with patient or control lymphocytes for 5 days and pulsed with 1 mCi of [³H]thymidine (Amersham) for 18 hr. Cells were then harvested onto filter discs, and radioactivity was measured on a beta scintillation counter (Beckman).

Immunoglobulin levels were evaluated by agar electrophoresis. Quantification of IgG, IgA and IgM was performed by single radial immunodiffusion using immunodiffusion plates, and the results were compared to a normal range.

Bleeding Time and Platelet Aggregometry. Platelet functional activity was determined only for patients with platelet counts > 100 x 10⁴/l and compared with control values. Both groups were instructed to avoid medications that could interfere with platelet function for 2 weeks preceding the study. Bleeding time was determined by the Ivy method and at the same time blood was collected for aggregometry into siliconized vacutainer tubes containing sodium citrate. Comparisons were carried out in platelet-rich plasma, using a Chronolog aggregometer (Chronolog Corp., Havertown PA) in the presence of agonists [ADP, 2 mg/ml of collagen or 1.5 mg/ml of ristocetin (Sigma) and epinephrine (May Baker, South Africa)], and the results were registered on a chart recorder (models 560vs and 707, Chronolog).

Statistical Analysis
Patient survival was measured by the Kaplan-Meier method. Median values and confidence intervals (confidence coefficient: 0.95) of the patient results were calculated and compared with control results. The significance was tested by two-way analysis of median values.
Response to Therapy

In the patient with hypoplasia, remission occurred after a therapeutic abortion, and as she was not treated, she was excluded from analysis of response to therapy. Responses were seen in 24 of the 34 subjects (71%), and were complete in 8. At a median follow up of 1320 days (SD 803), 22 subjects (65%) are alive in response (Fig. 1). Although hematological responses were seen at a median of 110 days (range 60 to 300), improvement in the blood counts continued for up to 4 years after therapy. Four patients received oxymetholone within a month of ALG infusion for a median of 6 months. However, another 9 required this androgenic steroid for a median period of 6 (range 1 to 18) months due to fluctuations in the blood values. In 4 patients, this hormonal therapy alone resulted in blood count improvements. Six of 24 patients (25%) had relapses; but 4 are alive. In one, disease improved following the delivery of a normal infant. Three other patients received oxymetholone and further immunosuppression and are in their second (1 patient) or third response (2 patients, with 1 being sustained on cyclosporin maintenance therapy).

None of the clinical findings at presentation predicted the response. Among the pretreatment laboratory data, only a mean corpuscular volume >95 fl was significantly associated with response (responders, median 109 fl, SD 10.1 versus nonresponders 91 fl, SD 7.6; median test p = 0.015, exact two-tailed).[12,28]

RESULTS

Morphological Assessment

Of 22 patients alive in response after immunosuppressive therapy and one after therapeutic abortion, at a median of 4 years from presentation (range 1 to 8), 16 were available and agreed to undergo the present study. At the time of this study, 2 patients were receiving cyclosporin and 1 oxymetholone therapies due to recurrence of pancytopenia. Review of the blood and marrow

![SURVIVAL OF PATIENTS WITH APLASTIC ANAEMIA](image)

FIGURE 1 Survival of 34 patients with aplastic anaemia after ALG + high-dose methylprednisolone. Thirteen patients received androgens for suboptimal response or falling blood values (see "Results"). Twenty-two patients remain in response at a median of 4 years follow-up.
morphologic findings from the initial admission of these 16 individuals revealed mild megaloblastosis limited to the red cell precursors in 13 patients, while in another, in addition, slight abnormalities in the granulocytic series with giant bands, were observed. Cytologic findings were entirely normal in 1 patient and in 2 patients there was no analyzable hematopoietic tissue.

Reassessment of this group of 16 subjects performed at a median of 4 years from therapy showed continued improvement of the blood values. However, considerable morphologic abnormalities were also detected, characterized by dyserythropoiesis, megaloblastosis, giant band cells and Pelger-Huet forms (Tables I and II). In the bone marrow no excess of blasts or inflammatory infiltrates or increase in mast cells was detected. Iron stores were absent in 1 patient while pathologic or ringed sideroblasts were not seen in any. Median cellularity was 40% on biopsy. Morphologically, trilineage dysplasia with ALIP was present in 3 patients (Table II), and in 2 of them, a patchy increase in reticulin fibrosis was also observed. Two patients developed a positive Ham’s test with clinical features of PNH.

Cytogenetics

Metaphases suitable for analysis were obtained in 15 of 16 individuals. One patient had an abnormal

TABLE I  Quantitative Evaluation of the Blood Parameters of Patients with Aplastic Anemia at a Median of 1 and 4 Years after Immunosuppressive Therapy

karyotype expressed as 47,XXX in 8 of 12 bone marrow metaphases, the remainder showing random chromosomal loss. PHA-stimulated peripheral blood analysis confirmed the constitutional nature of the trisomy X. Chromosomal breaks and/or gaps were present in another 5 of 15 patients, ranging from 13 to 40% of cells tested. No other cytogenetic abnormality was detected. In one patient in whom karyotypic analysis of lymphocytes was performed, it did not show such chromosomal breaks. However, the studies were not executed in the presence of clastogenic agents to exclude the diagnosis of Fanconi’s anaemia. At the time of the current study, none were receiving any therapy. The clinical data for these 5 patients are presented in Table III.

Granulocyte Functions

Only 1 of the 13 patients studied had normal granulocyte functions, while in 3, all assays were deranged. In the remaining subjects, results were below control values in at least one assay. As a
group, median values were significantly reduced for superoxide generation ($p = 0.007$) and phagocytosis ($p = 0.002$) (Table IV). No correlation was found between blood leukocyte counts and \textit{in vitro} granulocyte functions or any other laboratory or clinical data, including age, sex or time from therapy.

**Lymphocyte Functions and Immunoglobulins**

All functional measurements were normal in 12 patients, but subnormal in both patients receiving cyclosporin therapy. Serum immunoglobulins were determined in 14 patients, and values were found within the standard range in all, including both patients receiving maintenance immunosuppression.

**Platelet Functions**

The platelet count was $>100 \times 10^9/l$ (median 127, SD 80.44 $\times 10^9/l$) in 14 patients. However, the Ivy time was normal in only 5 of these individuals. For all patients the median bleeding time was 8.5 min (SD 3.4) (normal range 3 to 7 minutes) and in 3 it was $>15$ min. Aggregation studies were significantly abnormal, and this applied to each of the agonists tested (Table V).

DISCUSSION

This study confirms previous observations that ALG is effective in improving the pancytopenia associated with idiopathic bone marrow failure.⁷¹,² The number of variables including patient age,³⁵ differences in disease severity,²³ or the intensity of the immune suppression³¹-³³ may also explain the unpredictable outcomes reported with this modality. Macrocytosis was the only feature significantly associated with a favorable response.¹²,²⁸ However, mild megaloblastic changes progressed to bilineage (8 patients) and trilineage (3 patients) dysplasia and increased deposition of reticulin and even ALIP over the follow-up period. The significance of these observations remains unclear, although prominent dysmyelopoiesis has been associated with an increased risk of progression to leukemia.¹⁹ Whether within this group, patients with morphologic but not quantitative abnormalities should also be regarded as having myelodysplasia remains questionable.

Furthermore, karyotypic derangements may provide a clue to the possible link between aplasia and myelodysplasia,³⁴,³⁶ and the present demonstration that 13 to 40% of metaphases in 5 of 15 individuals were abnormal, supports the concept that disturbed DNA repair mechanisms may presage evolution to the preleukemic syndrome.¹⁸ Nevertheless, the natural history of MDS that follows aplasia may be different from the de novo variant, with reduced or delayed evolution to more advanced types or into acute leukemia.³⁷ Moreover, childhood MDS, although an infrequent malignancy, may present with hypoplastic marrow in a proportion that is not different from the adult variant³⁸-⁴¹ and may also respond to immunomodulation, thus further adding to the confusion.⁴² Similar to the adult experience, in responsive patients with aplasia, dysmyelopoiesis³⁹,⁴³ and progression into clonal disorders, have also been reported to occur in the pediatric population,⁴⁰ suggesting that analogous pathogenetic mechanisms may be operating. This is particularly relevant to this age group because of the extended period of life expectancy and therefore increased risk of clonal progression. Lastly, in the present group the diagnosis of Fanconi's anemia was felt to be unlikely, owing to the lack of somatic defects, the age of presentation and the acute onset of the disease. However, no patient was subjected to diepoxybutane testing.²⁵

Defective granulocyte function was reflected in significantly reduced superoxide generation and phagocytosis, although it was not associated with increased infective episodes. This may perhaps represent normal lymphocyte function and immunoglobulin levels resulting from a more complete immunologic reconstitution. We have also confirmed that despite continuous improvement in the cellularity during sequential testing, mild thrombocytopenia persisted in the majority. As in this disease platelet survivals were shown
to be normal, the reduction in the thrombocyte numbers possibly reflected decreased production or ineffective thrombopoiesis.\textsuperscript{14} However, despite platelet counts exceeding $100 \times 10^9$/l in 14 patients, a value not associated with purpura, the bleeding time was prolonged in 7. Not surprisingly, significant aggregation abnormalities were detected.

With the pathogenesis of idiopathic marrow aplasia remaining obscure, our findings are consistent with two broad possibilities. First, the initial insult may have irreversibly damaged hematopoietic stem cells, and this was reflected as qualitative defective mature progeny. Alternatively, the differentiating population was subjected to continuous aggression by subclinical immunologically mediated mechanisms\textsuperscript{15-18} in the hematopoietic microenvironment.\textsuperscript{19-21} The former hypothesis would appear to be more likely since we have demonstrated that the aplastic stroma supports the growth of normal selected progenitors adequately and that the defect resides predominately within the aplastic precursors.\textsuperscript{22,23}

It is concluded that while response may follow immunosuppressive therapy for severe marrow aplasia, this quantitative recovery is coupled with chromosomal abnormalities and trilineage morphologic and functional alterations. In some patients this reflects the persistence of an unstable progenitor cell population with considerable risk of evolution into any of the described clonal disorders.

Keywords: Aplastic Anaemia; Pathogenesis; Treatment

Under basal conditions approximately $10^{10}$ erythrocytes and roughly half as many granulocytes or platelets can be produced each hour, with the capacity to enhance output manifold in response to demand. This is achieved mainly through amplification of progenitors sustained by stem cell differentiation along combined stochastic and determinative pathways. Efficiency of such induced output reflects fine tuning of accessory populations in the stroma, with release of stimulatory cytokines and reciprocal negative regulators of haematopoiesis. These high generation rates and the relatively short lifespan of the more mature cells means that any compromise in normal function will have serious consequences. In aplasia, a partial or complete arrest in blood formation occurs due to loss of this regenerative capacity. However, in contrast to the pancytopenia that follows intensive chemotherapy or radiation treatment, even optimal support does not lead to marrow recovery. It has been hypothesized that such acquired irreversibility arises on the basis of heterozygosity for genes, leading to marrow failure.

Whether correct or not, environmental insults can be identified in less than half the patients and include benzene, chloramphenicol, viral infections and pregnancy.

Particularly in the pathogenesis of the idiopathic variants, mechanisms intrinsic to the stromal microenvironment have been postulated to exist on the basis of several observations. A third of the syngeneic grafts were unsuccessful without intensive preconditioning, while in one-fifth, appropriately prepared allogeneic transplants were rejected, although in some this was followed by autologous reconstitution. Furthermore, antilymphocyte globulin (ALG), used on its own or during preparation for mismatched grafting, can lead to recovery.

Further dissection of these phenomena rests on the prominence of lymphocytes amongst accessory cells of the stroma, where they participate in the control of haematopoiesis through cytokine-mediated effects on progenitors. Co-culture with peripheral blood lymphocytes derived from aplastic individuals down-regulate myeloid and
erythroid growth in clonogenic assays.\textsuperscript{14-16} The effector phenotype is E + Fcγ + OKT3 + Ia-OKM1-, and this activity is mediated through release of soluble products into the conditioned medium.\textsuperscript{17,18} The major contender for this negative regulatory function is interferon γ, which is usually secreted by these cells following lectin stimulation, but in patients, despite normal blood levels,\textsuperscript{19} it is spontaneously generated in high concentration, perhaps due to abnormal immunologic function or as a response to viral infection.\textsuperscript{20} This is seen even before sensitization to blood transfusion has taken place.\textsuperscript{21} Interestingly, in a subgroup who express autoreactive CD4 + /CD8 + immunocytes, gene rearrangement has demonstrated monoclonality for the β-chain of the T-cell receptor.\textsuperscript{22}

This line of argument is extended by demonstrating that, following haematopoietic recovery, lymphocytes that had been collected and cryopreserved before therapy with ALG were inhibitory in co-culture with autologous marrow. The suppressor effect appears to reside within the CD8 + fraction and is reversed by administering this product or antibodies to IFNγ.\textsuperscript{23} Additionally, exposure of these T-cells to ALG induces, in a dose-dependent fashion, release of several haematopoietic factors\textsuperscript{24,25} that exert antiproliferative effects on B-lymphocytes.\textsuperscript{26}

Laboratory studies have interesting clinical parallels. Thus, ALG combined with corticosteroids and anabolic androgens, correct the pancytopenia in over two-thirds of patients and in half of these blood count returns to normal.\textsuperscript{27,28} Although the mechanisms have not been clarified, response may reflect lympholysis or, as detected \textit{in vitro}, release of growth factors by accessory cells.\textsuperscript{29,30} These observations are therapeutically important in so far as the intensity of immunosuppression may determine optimal outcome, suggested in both retrospective\textsuperscript{31} and controlled clinical trials.\textsuperscript{32} Extended follow-up has shown that despite improvement in blood counts and myeloid reserve, bone marrow morphology remains abnormal,\textsuperscript{33,34} with widespread features of dysplasia and cytogenetic lesions detected.\textsuperscript{35-37} Notably, mature elements, in the form of platelets and granulocytes, were functionally defective \textit{in vitro}\textsuperscript{37} and in some, evolution to myelodysplasia, paroxysmal nocturnal haemoglobinuria (PNH) and acute leukaemia has been described.\textsuperscript{38}

When haematopoiesis in these individuals was characterised using standard bone marrow culture techniques, the clonogenic potential was found to be suppressed, consistent with reduction in the progenitor population, unbalanced interactions in the myeloid microenvironment\textsuperscript{39-42} or defective marrow stroma.\textsuperscript{43}

Attempts to explore the functional relationship between progenitors and bone marrow stroma have produced inconsistent data. Although the myeloid adherent layer appears to secrete adequate amounts of G- and GM-CSF, as well as IL-6, both constitutively and during induction with IL-1,\textsuperscript{44} some studies showed fibroblast growth to be subnormal and to support colony formation inefficiently.\textsuperscript{45-48} Similarly, monocytes and macrophages, which are prominent in the microenvironment, were also dysfunctional, and this persisted despite successful ALG therapy.\textsuperscript{49} The reported defects ranged from phenotypic disturbances to impaired production of IL-1.\textsuperscript{50,51} It is likely that these findings may well turn out to have relevance for the pathogenesis of this disease. However, data derived from long-term bone marrow cultures is not uniform (LTBMC),\textsuperscript{52,53} where irradiated stroma from aplastic patients who were responding to ALG was morphologically no different from controls and both supported equally the growth of normal progenitors.\textsuperscript{54-57} However, fewer numbers of cells expressing the CD34 antigen were detected and, predictably, had significantly diminished output on both the LTBMC and the mixed clonogenic assay.\textsuperscript{56,58,59}

These studies were extended in our laboratory, using cross-culture experiments in the blastic colony assay (CFU-b1) to exploit the adhesive properties of clonogenic cells to stroma, where
confluent layers derived from untreated patients or those responding to ALG supported colony formation to the same extent as normal controls. In contrast, stromal adherent and nonadherent aplastic precursors, selected for the CD34 antigen and cultured in a number of different assays, consistently grew less well. This population, greatly depleted of accessory cells, formed significantly fewer CFU-b1 on control stroma in a way that was unrelated to abnormalities in their adhesive properties. One interpretation is that the level of negative regulators in the aplastic stroma was not functionally higher than that of the control layers, since normal CFU-b1 formation was well supported.

In a further step, these CD34 progenitors from patients who had responded favourably to ALG were cultured and dose responses defined. It is demonstrated that low cytokine concentrations growth was poor, but with dosage escalation significant linear increments occurred, reaching control values. Such findings suggest a markedly reduced sensitivity to erythropoietin, interleukin-3 and GM-CSF.

These results contrast with earlier studies showing that when aplastic mononuclear cells were cultured in the presence of incremental concentrations of erythropoietin or GM-CSF, they were partially corrected, although this was limited to transfusion-independent patients. However, in those reports, positive selection for the CD34 population was not attempted and therefore clonogenic progenitors were cultured in unknown numbers and contaminated with accessory cells.

Studies from our laboratory have documented adequate responsiveness of aplastic precursors to the c-kit ligand when cultured in the presence of erythropoietin and IL-3. Despite suboptimal growth in the presence of more restricted stimulators, at effective concentrations, stem cell factor significantly corrected this inferior colony development. This resulted in yields not significantly different from those of control cultures, again suggesting that, in this disease, the clonogenic potential remains preserved.

Suboptimal proliferation may result from either abnormalities in the receptor densities or their affinity for cognate ligands. Additionally, corresponding soluble forms or binding proteins exist, being secreted naturally into the microenvironment or alternatively originating as proteolytic cleavage products from transmembrane molecules, that potentially may function as inhibitors to the action of their ligands in feedback regulation. However, we were able to demonstrate that clonogenic derangements in the presence of optimal concentration of growth factors ranged widely between the three cytokines, suggesting alterations in shared structures or pathways signalling for cell division.

Receptors for IL-3, IL-4, IL-7, GM-CSF, G-CSF and Epo, but not GM-CSF and c-kit, are members of a family with some structural similarities, forming part of the growing transmembrane GTP-binding group of proteins which control a series of second messenger molecules, including adenylylate cyclase, cGMP phosphodiesterase, phospholipases and ion channels. Recently, a specific 68 Kd calmodulin binding protein with nuclear localisation, common for G, GM-CSF, IL-3 and IL-6, but not for CSF-1, has been described. This glycoprotein appears to be associated with the progression from G1 to S phase of the cell cycle, and may well be important in the control of the terminal events required for the onset of DNA replication. It would be attractive to suggest that defective responses to these growth factors may have a common intracellular defect that could explain the subnormal signalling of the cytokines.

One explanation is that the lesion could be the result of persistent in vivo immune activation against target bone marrow cells, not detected by our in vitro modelling system, resulting in the morphological and functional abnormalities, the late recurrence of the disease and further response to immunosuppression. In some of these individuals the emerging population appears to remain
intrinsically abnormal, thereby predisposing them to later progression, to clonal hematopoiesis and leukemic transformation. In opposition, it could also be speculated that some of these findings in patients responding to immunosuppression, may either reflect a milder expression of the original damage to the hematopoietic stem cell or recovery of an intrinsically hyperproliferative oligoclonal escape population surviving the initial immunological attack.

Monoclonal recovery of the hematopoiesis has been described in aplasia67 and interpreted as representing a limited expansion of the stem cell pool after the first injury to the marrow, and this has similarities to that reported following intensive chemotherapy68 or experimental grafting.69 The hematopoietic progenitor cells could have been rendered kinetically disadvantaged by the preliminary insult or, alternatively, hyperproliferative clones, such as the PNH cells present in the normal polyclonal hematopoiesis that survived the attack, taking over the repopulating fraction after the damaging event.70 However, in only the minority of these patients is hematopoiesis clonal, while this is a significant feature of myelodysplastic syndromes.

These issues are of paramount importance because if the protracted autoimmune response leads to clonal evolution, considerations should be given to prescribing a more extended period of immunosuppressive therapy, administered until the reversal of the described morphological or functional markers is achieved. This approach is not unusual in patients with autoimmune haemolytic71 or ITP refractory to therapy,72 or for the treatment of graft rejection in solid organ transplantation.73

Finally, it may also be possible that the described effects happen in different clinical settings, representing virtually two different disorders, exemplified by the hypoplastic variant of myelodysplasia74 and idiopathic aplasia. Here, early discrimination between the two by molecular analysis of clonality or cytogenetics as a basis for prognosis and therapy assumes major importance.

CHAPTER 43

Hodgkin's Disease in Africa

Peter Jacobs, Werner Bezwoda, Geoffrey Falkson, and Dalila Sellami

Data from Africa regarding Hodgkin's disease is generally sketchy. This is, in part, a reflection of the priorities in underdeveloped countries, where imperatives are usually basic survival rather than the nuances of exacting disease classification. Data gathering by registries and attempts to treat lymphoma in a consistent and acceptable manner are often hampered by a shortage of resources. These range from a lack of trained staff to inadequate facilities for investigation and are aggravated by limited supplies of cytotoxic drugs or poor access to radiotherapeutic equipment.

There are vast population and cultural variations on the continent. It is thus impossible to give a comprehensive picture of differences in natural history and response to treatment of Hodgkin's disease in Africa. This is particularly true when the diverse populations, that include black, white, and those of mixed ancestry, together with others of Mediterranean stock, are considered. The available data are derived from relatively few centers, making generalization difficult.

Despite these daunting limitations, it has been possible to assemble an overview of this entity as reported during the last three decades and as presently seen by practitioners in those countries where there is access to medical records. With such observations in mind, five aspects are sufficiently circumscribed to allow more detailed analysis. Included are the issues of epidemiologic difference, if any, by race or geographic region; patterns of disease at presentation; childhood Hodgkin's disease; the association with retroviral or other infectious disease; and prevailing management programs. From this some global comments emerge.

First, there are significant differences in the pattern of Hodgkin's disease in the various populations. It appears to be less common in blacks, particularly in central Africa as well as those living in the northern and southern extremities of the continent. In addition, the mean age at diagnosis is highest in whites and lowest in blacks, with those of mixed ancestry occupying an intermediate position. Similarly, histologic subtypes vary: nodular sclerosis predominates in the Caucasian patients, whereas mixed-cellularity and lymphocyte-depleted disease are more frequent in blacks. Second, late presentation is more common among lower socioeconomic and less educated groups. This may, however, be caused more by perceptions and lack of access to medical care than by any unique or disparate disease biology. Finally, the coexistence of tuberculosis with Hodgkin's disease and the acquired immunodeficiency syndrome is widespread, thus distorting natural history and survival in this lymphoma.

Conclusions about Hodgkin's disease in Africa inevitably attract comparisons with findings in other economically underdeveloped populations, including black Americans. Such contrasts provide a chance to examine common genetic influences based on the slave routes of yesteryear and to explore those differences that may have an environmental basis. We have also had the opportunity to review experiences in the northern and southern parts of the continent and briefly to compare our findings with what is reported from other Third World countries. The conclusions are that, stage for stage, there are no fundamental disparities in regard to presentation or response to treatment. The constellation of environmentally determined adverse prognostic features that culminate in advanced stage when first seen, seem to be the major factors that impact negatively on outcome, rather than any genetically determined or ethnic differences in host or host response to the neoplasm.
The way in which these variables exert their influence leads to a perspective of poorly nourished patients who delay seeking medical attention for prolonged periods of time and, consequently, present with extensive disease. Superimposed on this is significant infectious comorbidity. Additionally, there is a lack of disciplined protocol treatment, except in a few centers where First World standards prevail. These circumstances combine to result in an outcome for this lymphoma in Africa that ranges from appallingly poor remission figures to those comparable with developed countries.

BACKGROUND

During the past three decades research in Hodgkin’s disease on the African continent has concentrated largely on epidemiology, with descriptions of clinical patterns of disease as reported in the different population groups. Pioneering studies, such as those of H. Falkson (1), focused on what was seen predominantly in white South Africans during the era before effective chemotherapy was available. Only more recently has information become available on black and other ethnic groups.

Over the last decade there has been a worldwide paradigm shift in understanding the spectrum of lymphoproliferative disorders. This was occasioned, in part, by emerging consensus in revised classification systems (2) that now include immunophenotyping and data from molecular genetics. This improved knowledge extends to Hodgkin’s disease and has led to better understanding of the entity. Wherever feasible, given the limited resources available in Africa, the newer concepts have been incorporated into classification (3,4), investigation, and treatment of these patients.

The most significant change, however, came from the introduction of effective drugs, rapidly culminating in the development of combination chemotherapy with resultant high complete remission rates. Consequently, cure is now possible in many, if not most, cases, given only that they are correctly staged and treated early. This, however, seldom happens in Africa, where a major determinant of prognosis remains high-bulk lymphadenopathy and organ involvement when patients are first seen. This phenomenon appears to be explicable by environmental factors rather than there being some unique or continent-specific difference in tumor biology. Additional adverse factors include rampant undernutrition and associated infectious disease, with human immunodeficiency virus and tuberculosis holding pride of place. To try to gain perspective on what the current situation is in Africa, five topics have been singled out for examination. In each of these a brief commentary is appended to highlight differences between data from more affluent Western patients and their counterparts from this continent. Furthermore, where possible, findings have been compared to those in blacks from other parts of the world because it is here that we have the opportunity to contrast populations with a common genetic pool but living under vastly different environmental conditions and variable levels of medical care.

EPIDEMIOLOGY WITH GEOGRAPHY AND RACE AS INDEPENDENT VARIABLES

Westernized Societies

Extensive publications, mostly from the developed or First World, show little variation in incidence when geographic areas are compared. There is a well-defined bimodal pattern of incidence and mortality with two distinct peaks evident, the first at 25 and the other at 70 years (5). These findings, which occur typically in North America, have parallels in Denmark and The Netherlands, but they are distinctly different from Japanese, Singaporean, and Indian reports.

One hypothesis advanced to explain this distribution is that the pathogenesis may differ with age. In young adults the disease has similarities to a chronic granulomatous or inflammatory process, with an extensive host reaction but paucity of malignant cells. By contrast, in the elderly, truly neoplastic behavior is more evident. This concept has precedent in the model for paralytic poliomyelitis. Here, infection with a virus of low virulence at an early age confers life-long immunity, but without such exposure, the subsequent manifestations are much more severe (6). This paradigm, however, fails to deal adequately with this lymphoma in childhood, which has a higher frequency in Africa than elsewhere, and where the predominant histologic subtype appears to be mixed cellularity with a relatively high proportion of neoplastic Reed-Sternberg cells.

An alternative hypothesis to explain these two peaks, based on Colombian studies, suggests that there is a common cause but that different presentations reflect different host and environmental factors.

African Experience

Whatever the explanation ultimately turns out to be, there are regional and socioeconomically based variations in incidence, age at presentation, distribution of histologic subtype, and therapeutic outcome when Hodgkin’s disease in different parts of the continent are compared (7–15).

Considerable geographic variation in the incidence of this lymphoma is evident in Africa, with the frequency increasing from the equator to more temperate zones. Age-standardized rates for men and women recorded in the Kampala (Uganda) Cancer Registry from 1964 to 1968 (16) were far below those from Europe and North America. Accounts from other African countries within the tropical zone are based largely on single-institution
findings from academic centers or large regional hospitals. In most of these, the prevalence of Hodgkin’s disease is low, except in childhood, when compared with other malignancies. Uniquely, a much higher incidence rate, approaching that seen in the Northern Hemisphere, was reported from the Ibadan Province of Western Nigeria (17). This may reflect intraregional variation related to undefined local factors. Relatively low frequencies are reported from Zambia (18), Kenya (19), and Zimbabwe (20). Similar data sourced from other sub-Saharan countries with cancer registries, such as Mali, Uganda, and Gambia, show figures less than 0.8 per 100,000 population (21,22).

From Algeria, based on the regional register at Sétif, rates are 2.4/100,000 in adults and 0.7/100,000 in male and 0.4/100,000 in female children, respectively (21). Tunisia has epidemiologic data from the Institut Pasteur going back to 1950 (23–25) as well as classification, clinical staging, and outcome data from 1969, when the Institut Salah Azaiz (ISA) was founded as a national cancer center (26) (Tables 1 and 2). There do not seem to be significant differences in the pattern of Hodgkin’s disease in Algeria and Tunisia, but incidence is difficult to evaluate precisely because there is no national cancer registry. The ISA figures show the disease to comprise 4% of all cancers in adults and 11% of those in children (26). In Tunisia, this lymphoma accounts for 7.4% of all cancers in both sexes (26). In Morocco the corresponding rate was 6.6% of all malignancies (27).

The pattern in the Maghreb thus appears to be that the disease affects children and young adults. Children under the age of 15 account for approximately one-third of the cases (23–27). In childhood the male-to-female ratio is approximately 3:1, whereas in adults it is greater than 2:1. Among adults, nodular sclerosing Hodgkin’s disease appears to be the most common variant. Stage distribution between stage I and II and stages III and IV is about equal. Delayed diagnosis seems relatively common, with 40% of people being seen more than 6 months after the onset of symptoms, thereby perhaps explaining the extensive disease at presentation. In children from this region, most have nodular sclerosing or mixed cellularity, with stages III and IV predominating.

In Egypt, epidemiologic data are based on studies conducted in ten different cancer centers that are attached to various universities. The major repositories for data are the Egyptian National Cancer Institute (ENCI) and the Cairo University Hospital Oncology Center, or NEM-ROCK. As a generalization, lymphoreticular tumors and leukemias in Egypt constitute between 7% and 15.9% of all malignancies. In a survey of 557 cases, high-grade lymphoma (previously designated as reticulum cell sarcoma) occurred most frequently, followed by Hodgkin’s disease. For Hodgkin’s disease, the highest incidence rate was in the second decade, and a male-to-female ratio of 3 to 1 was noted. Mixed cellularity was the most common subtype of Hodgkin’s disease, and nodular sclerosis was rare (28). In another report, differences were found comparing Egypt and the Gaza strip. In Egyptian men, lymphoma occurred more frequently than in men in the Gaza strip, whereas the inverse situation was found among women. The authors noted that this kind of comparison may provide improved approaches for discerning risk factors for cancer and advocate increased cooperation among participating countries (29).

Additional data from ENCI, analyzing a series of 4,382 newly diagnosed cancer patients, all reviewed by a single pathologist, yielded 526 cases of malignant lymphoma (7%) but only 193 cases of Hodgkin’s disease (2.57%) (30). Mixed cellularity accounted for 50.71%, lymphocyte predominant 23.78%, nodular sclerosis 17%, and lymphocyte depleted 8.29% of the patients with Hodgkin’s disease. Unfortunately, age and sex distribu
tion within the histologic variants was not recorded. In addition, at NEMROCK, 7,325 adults with cancer were reviewed between 1992 and 1995. There were 420 cases of non-Hodgkin's lymphoma (5.7%) and 107 with Hodgkin's disease (1.5%), giving a ratio of 3.8:1 (31). These data showed similar trends to the ENCI series, with 42% of patients having mixed-cellularity Hodgkin's disease. Here the male-to-female ratio was equal. Lymphocyte predominant Hodgkin's disease accounted for only 5.6% of cases with a male predominance in this subtype, and lymphocyte-depleted occurred in 7.4%, again with male predominance. Nodular sclerosis Hodgkin's disease accounted for 48 of the 107 patients over the age of 15 years, and within this subtype the male-to-female ratio was approximately 2 to 1.

Clinical staging in the Cairo University Hospital series (31) showed that 12% were in stage I, most of these without constitutional symptoms; 43% were in stage II, with half showing weight loss or other evidence of systemic involvement; 35% had stage III disease, and 10% stage IV disease: in both of the latter two categories, two-thirds to three-quarters were accompanied by systemic symptoms. Supradiaphragmatic presentation occurred in 73%, the mediastinum was involved in 20%; the liver in 30%, and only sporadic cases had disease demonstrable in bone marrow, skin, or nasopharynx (31).

The investigation of cancer patterns in migrant populations has been used as an epidemiologic tool. Migrants from North Africa to France provide useful insights into the changing pattern of lymphoreticular malignancy following relocation. When Egyptian-born settlers were compared to local-born French, with appropriate adjustment for confounding factors such as social status and areas of residence, there was a trend for higher risk of lymphoma among the migrants, although specific data on Hodgkin's disease are not available (32).

South of the equator, Hodgkin's disease in Zimbabwe shows a pattern similar to that found in North Africa, although the age split is slightly different. Approximately one-third of cases are seen before 20 years, with a male-to-female ratio of 1.8:1. A striking predominance of the lymphocyte-depleted variant was noted (Table 3).

South African data are available for the Gauteng (33) area (previously known as Pretoria and Johannesburg) and the Western Cape, and they show regional trends. Conversely, countrywide patterns are documented in the National Cancer Registry (34), which reflect a consistent pattern since the time of its establishment in 1989, with an age-adjusted rate of 0.81 for black women as compared to 1.42 for their white counterparts, and 0.95 and 3.27 for black and white men, respectively (Fig. 1). The apparently lower frequency of Hodgkin's disease in the black population may, in part, be related to underreporting because this is a pathology database. Nevertheless, these figures are consistent with that previously declared for this region (33).

*LP, lymphocyte predominant; NS, nodular sclerosis; MC, mixed cellularity; LD, lymphocyte depleted. Data from L. Levy (unpublished).

There is also a marked difference between the histologic subtypes found in blacks and whites in South Africa. In the former, mixed cellularity or lymphocyte depletion predominates, whereas in the latter, nodular sclerosing is most frequently encountered. This pattern, illustrated by the Gauteng data (Table 4), also occurs in Natal and in the Freestate. The Western Cape, however, has a different population mix. In the past the population in the Cape was predominantly white or of mixed ancestry. More recently there has been a large black population influx. These population differences appear to be responsible for changes in Hodgkin's disease subtypes seen in the Cape, the pattern previously conforming to northern European data but with a significant trend toward the more frequent African pattern becoming evident since 1994.

Points of Contrast

Prominent differences are seen in the epidemiologic patterns between Africa and Europe or North America. In the terminology recommended by the International Union Against Cancer (35), Hodgkin's disease epidemiology is seen to fall into one of four categories. Type I Hodgkin's disease occurs primarily in children and is associated with less favorable histologic subtypes. Type III Hodgkin's disease predominates in developed countries and prevails in young adults, where a better outcome is associated with more frequent occurrence of lympho-
cute predominant and nodular sclerosing subtypes. Type II is intermediate between type I and type III. The type IV epidemiologic pattern is largely limited to Asia and is not discussed further here.

Viewed in this way, the type I pattern appears to be predominant in the central part of Africa (16–20). A few additional studies do deserve mention here, although in general the data were considered too sparse to be included in our main analysis of geographic pathology. A report from Zambia showed that Hodgkin's disease accounted for 18.6% of malignant lymphomas, with 44% of the cases occurring in the first two decades of life. The patients were predominantly of more advanced stage and had either mixed-cellularity or lymphocyte-depleted subtypes (18). Similar clinical presentations are reported from Nigeria (17,36–39), Kenya (19,40–42), Uganda (33,44), Gabon (45), and Zimbabwe (46–48). One set of Ugandan (44) data that may represent intraregional variation, however, describes a bimodal age-specific incidence curve approximating the type III pattern.

The pattern of Hodgkin's disease in North African littoral and South Africa is mostly intermediate or type II (20). This epidemiologic pattern approximates that seen in North America during the 1950s and 1960s (50–52), where this lymphoma occurred less frequently in blacks than whites. Hodgkin's disease in the former group had aggressive histology and was of advanced stage. These features were attributed to socioeconomic rather than genetic factors. In this regard, indications are that there has been a shift during the last 25 to 30 years among the North American black population (51) to a pattern more closely approximating type III. Based on similar inferential reasoning, one may conclude that the intermediate pattern seen in South Africa represents a transitional phase in epidemiology. However, this postulate needs to be confirmed by direct investigation to establish whether HLA or immune response–linked gene frequencies, or other genetic factors, might still play a significant role in the incidence and/or subtype distribution.

It might also be debated whether a drift in epidemiologic pattern from a lower overall frequency to a higher incidence, albeit to one with better prognostic features, represents a step forward in cancer control. It may rather be argued that available studies have not, as yet, provided any real clues to suggest a strategy of prevention of Hodgkin's disease in any population group.

CLINICAL PRESENTATION, STAGING, AND PROGNOSTIC FACTORS

Westernized Societies

The clinical features reported in North American adults and children (50–53) provide a convenient orientation against which to examine intercontinental differences. Although, predictably, attention is drawn to this entry by the finding of enlarged glands, with diagnosis dependent on node biopsy, in both developed and emerging societies there are, nevertheless, contrasting features.

African Experience

Throughout the length of this continent, the four-stage Ann Arbor classification (54–56) with modifications, as proposed at follow-up meetings in the Cotswolds (57,58), is recommended and is in general use. The problems of applying this approach to individual patients are organizational rather than methodologic. A large rural population with a limited number of centers that offer sophisticated investigations, such as computerized axial tomography, lymphangiography, and nuclear medicine techniques, have made accurate staging difficult. However, because this is a potentially curable disease, it is felt that all patients should be referred to available specialist establishments, where full and adequate investigations can be carried out. Imaging facilities are accessible along the North African littoral; in southern Africa, including Zimbabwe and South Africa; and in Kenya in East Africa, Nigeria, Ghana, and the Francophone countries.

The significant frequency of chronic bacillary and parasitic infections throughout Africa that are capable of giving rise to granulomatous or other inflammatory processes that may coexist with the lymphoma needs to be taken into account when evaluating lesions detected either clinically or radiologically (59). Such complications include, in our experience, tuberculosis, with its associated lymphadenopathy; human immunodeficiency virus infections; amebic abscesses; lymphogranuloma inguinale; hydatid cyst; syphilitic gummas; and schistosomiasis. Delay in diagnosis and empiric treatment for tuberculous lymphadenopathy, particularly among patients from rural areas, has, in our experience, been a significant cause of delay in diagnosis of Hodgkin’s disease. Although these disorders usually demonstrate features that are sufficiently distinctive for separation from Hodgkin’s disease, this does require experience and awareness of the condition.

The absence of pulmonary involvement by typical tuberculous changes should alert the clinician to the possibility that lymphadenopathy may have a cause other than this common infection. Ultimately, however, the diagnostic problem can only be resolved by adequate investigation. Access to and provision of laboratories that can make diagnoses on microbiologic and histologic grounds, rather than reliance on empiric treatment, are urgent needs in many African countries.

Enlarged spleens from endemic malarial infestation give rise to the tropical splenomegaly syndrome. Here the question of staging laparotomy and splenectomy requires judgment. The risk of malaria and other infectious diseases, on the one hand, and the fact that the majority of patients have stage IIB or more advanced illness on the other, make removal of this organ inappropriate in most of our cases. Not surprisingly, splenectomy has virtually not been used for staging in southern Africa since 1985.

Stage at presentation and prognostic features have been examined in some detail in northern and southern Africa. Data from Tunisia and Algeria (Table 2) show striking similarity, with approximately half of the patients presenting with advanced disease, B symptoms, elevated erythrocyte sedimentation rate, and a significant delay in time to diagnosis. In addition, the experience of ISA, unfortunately repeated throughout the rest of the continent, is that as many as 20% of the patients are lost to follow-up or receive inadequate treatment. The experience

Adapted from ref. 63. Overall $\chi^2 = 60.52; \ p < .001$. NS, not significant.

Striking confirmation of these differences comes from an updated study (Table 7) that showed significant differences to persist in the relative frequency distribution of components of the prognostic index, particularly histologic subtype and age, between the two populations. Despite the black patients being younger (age was a significant factor with substantial weighting toward good prognosis in the Newcastle Index), the overall outcome in these patients remained similar to that of the poor prognostic group among Caucasians. One consideration, which may be a major one in assessing the relative impact of prognostic factors on outcome of Hodgkin’s disease between blacks and whites, is that economic and educational level may be more predictive than race. However, these socioeconomic factors are correlated with race. Patient education and better socioeconomic support networks will, it is hoped, improve this situation in the future.

Updated from Ref. 62.

SPECIFIC ASPECTS IN CHILDREN

Westernized Societies

Childhood Hodgkin’s disease is rare in developed countries (63–66).

African Experience

Pediatric Hodgkin’s disease occurring in Egypt has been analyzed in a consecutive group of 242 children treated at the National Cancer Institute in Cairo between 1975 and 1980. There was a male predominance of 3:1. The most common histopathologic type was mixed cellularity (accounting for 60.74%). Late stages (defined as III and IV) comprised 63.2%, usually with bulky disease. Not unexpectedly, staging laparotomy (which was done in 154 cases) revealed more infradiaphragmatic disease than was clinically evident. Although an association between infradiaphragmatic Hodgkin’s disease and schistosomal hepatic fibrosis was described, this is probably no more than coincidental (67).

Currently available data from South Africa suggest that, although there may be a peak incidence between the ages of 15 and 19 in black children (34), the overall frequency is lower in blacks of all ages, including the childhood years, relative to whites (Fig. 1).

In a study from the Western Cape, including 39 children under 15 years of age, there were seven black.

*MC, mixed cellularity; NS, nodular sclerosis; LD, lymphocyte depleted; LP, lymphocyte predominant.

Data from ref. 71. Nodular sclerosing was present in 59% of white patients, whereas mixed cellularity dominated in those of mixed ancestry at 40%, and lymphocyte depletion in blacks at 43%. Mixed cellularity was present in 37% of the children under 11 and 25% of the older group, while lymphocyte depletion occurred in 30% of the older group and only 12% of the younger cases. The incidence of nodular sclerosing histopathology in whites and those of mixed ancestry did not achieve significant differences, again probably because of small numbers.

Data from ref. 71.

White and 20 children of mixed ancestry (68-70) (Tables 8 and 9). The male-to-female ratio was 2.9:1, and the median ages were 147, 124, and 119 months in children of white, mixed, and black ancestry, respectively. The latter two groups came mainly from a poor socioeconomic background. Systemic symptoms were present in 51% of cases. Histologic subtypes included nodular sclerosis in 35% of white patients, mixed-cellularity in 40% of mixed ancestry patients, and lymphocyte-depleted in 43% of black patients. Five percent of the entire group had clinical stage I; 41% stage II; 28% stage III; and 28% stage IV disease. By contrast, the majority of white children presented with stages I and II.

Points of Contrast

A recent study in children (<13 years old) from Johannesburg (62) emphasizes the Capetown data (Table 10). Notably, in this group of 91 patients, of whom 61 were black and 30 were white, there was a clear demonstration of a difference in distribution of prognostic factors, with late-stage disease and lower hemoglobin levels among black children as compared to their white counterparts.

Similar observations were noted in Namibia (71). Significantly, here, the increased risk of developing tuberculosis was sufficient to lead to the suggestion that

VIRAL INFECTION AND HODGKIN’S DISEASE

Epstein-Barr Virus

Westernized Societies

Numerous studies have examined the role of Epstein-Barr virus (EBV) (73,74) in Hodgkin’s disease. Although initial serologic studies were unable to show any clear clinical relationship between this lymphoma and the virus, the advent of in situ hybridization studies revealed an integrated genome in the Reed-Sternberg cells in 35% of cases (75). Furthermore, at least one gene product, the latent membrane protein (LMP-1), can be found on the surface of the multinucleate tumor cells. The LMP may function as a target for cytotoxic T lymphocytes and thereby facilitate host control over the neoplasm. Conversely, if this surveillance mechanism is lost, the same molecule appears to have the capacity to enhance proliferation of the infected cells, leading to the emergence of a histologically aggressive tumor (73–75). These apparently opposing effects might underlie differences in the course of this lymphoid malignancy and raise the interesting possibility that prevention may be achieved by means of vaccination.

African Experience

The role of Epstein-Barr in Hodgkin’s disease occurring in different geographic areas has been investigated in a number of studies (76,77). Differences in the frequency of expression of EBV in neoplastic cells of Hodgkin’s disease have been noted when cases from Kenya and Italy were compared (78). In another study biopsy material from cases of childhood Hodgkin’s disease occurring in ten different countries were compared: LMP-1 was found in 50% to 100% of cases, with the highest rates of expression tending to occur in cases from underdeveloped countries. By a sensitive polymerase chain reaction–based EBV strain–typing procedure (76), EBV strain type I was shown to be predominant in childhood Hodgkin’s disease from the United Kingdom, South Africa, Australia, and Greece; EBV strain type II was predominant in Egypt. Both EBV strain types I and II were detected in some cases of childhood Hodgkin’s disease from the United Kingdom, Costa Rica, and Kenya, with the frequency of dual infection being highest in cases from developing countries. The authors speculated that the high incidence of EBV and the presence, especially in developing countries, of dual infections with both type I and type II may reflect socioeconomic conditions leading to malnutrition–induced immunologic impairment (76).

The Human Immunodeficiency Virus

Westernized Societies

The possible role of the human immunodeficiency virus (HIV) in Hodgkin’s disease is attracting increasing attention. A number of recent publications from Europe and the United States have suggested an association between the two (79–85). In this setting, at-risk individuals are homosexual men with HIV disease and/or intravenous drug abusers with low CD4 counts and with significant evidence of impaired immunologic integrity.

African Experience

High rates of immunodeficiency viral infection and clinical AIDS occur throughout Africa. A causal relationship could be expected to have a major impact on Hodgkin’s disease incidence. HIV seropositivity rates of approximately 7% to 10% have been recorded among antenatal clinic attendees in South Africa (86). Even higher figures have been reported from Central Africa.

However, no increased incidence of Hodgkin’s disease has emerged in cancer registry data. In a recent case-control study involving 913 blacks with malignant disease (87) conducted in Johannesburg, a notable correlation between HIV infection and neoplasia was observed only for Kaposi’s sarcoma, with 27 of 35 patients being seropositive (odds ratio 61.8, 95% C.I. 19.7 to 194.2), and for non-Hodgkin’s lymphoma (27 of 40 individuals seropositive for HIV, with an odds ratio of 4.8, 95% C.I. 1.5 to 14.8). This association is similar to that noted in several other sub-Saharan African communities (88–90), where HIV viral prevalence is high. The odds ratio for the association of HIV and non-Hodgkin’s lymphoma was, however, lower than that reported in developed countries. The reasons for these findings are not clear but may include early mortality from tuberculosis in African HIV cases. This infectious complication occurs at higher CD4 counts (about 300 to 400/μL) counts than those associated with the development of non-Hodgkin’s lymphoma. No other cancer observed, including Hodgkin’s disease, as well as those arising from liver, vagina, penis, esophagus, cervix, or the oropharynx (all of which may have an infectious etiology), showed a significant relationship to infection with HIV. The Johannesburg study showed an HIV seropositivity rate of 10.8% in patients with Hodgkin’s disease, giving an odds ratio of 2.0 (95% C.I. 0.6 to 6.6).

Although there was no notable correlation between HIV and Hodgkin’s disease, the coincidental occurrence of the two entities does exist, particularly because both occur in younger patients. Of the 37 patients with Hodgkin’s disease who were HIV positive, clinical data were available for 28. The identification of these individuals allowed some observations to be made regarding the clinical aspects of Hodgkin’s disease with HIV in black

TREATMENT OUTCOMES

Westernized Societies

Evidence from an expanding literature clearly demonstrates that Hodgkin’s disease is curable. Cardinal determinants are reliable diagnosis, accurate staging, and management with appropriate and well-tested multimodality programs that comprise combination chemotherapy alone or combined with irradiation (91-93).

There has been a major shift from the early days when clinical assessment was converted to pathologic staging by surgery (94,95). Currently favored are less invasive methods that center on technological advances, including high-resolution imaging procedures (96,97).

Despite the favorable outcome for most patients treated with conventional approaches, there are still a number of problems. The first is refractory, slowly responding, or relapsed disease, which does better with high-dose chemotherapy and myeloprotection using peripheral blood hematopoietic stem and progenitor cells (98-100). Equally important is the ever-increasing appreciation that, although conventional treatment has curative capacity in sensitive patients, late complications arise and adversely affect outcome. Safer but equally effective regimens are needed (101-102).

African Experience

Treatment has been modified to keep abreast of new advances. In summarizing contemporary practice, radia-

Data from L.M. Levy (unpublished data).
Radiation and chemotherapy have been somewhat artificially isolated, and children are considered separately.

Adults: Radiation Therapy

In a report from Johannesburg (62), the outcome after laparotomy, for stage I to IIIA Hodgkin's disease treated between 1976 and 1986 with total nodal irradiation, was much poorer for black patients than for whites. However, in this retrospective analysis, when patients with stage I disease and those with nonbulky stage II disease with normal hemoglobin levels were considered, the outcome in blacks did not differ from that in whites with corresponding early stage similarly managed. These results suggest that radiation treatment can play a significant role on this continent, as elsewhere, provided diagnosis is prompt and referral appropriate. One problem is, however, access to radiation therapy centers. To this end, the World Health Organization, in association with the International Atomic Energy Commission, has embarked on a project of installing the necessary equipment and providing oncology training.

Adults: Chemotherapy

Systemic treatment is based on the traditional MOPP combinations. With few exceptions, the response rates in blacks emerge as significantly poorer than those observed with similar treatment regimens in other parts of the world (103–106).

From the evidence available, patients with unfavorable histology and advanced disease have a better outcome following six or even eight cycles of multidrug therapy combining MOPP, or its variant, with one or another form of ABVD than following MOPP alone (107–111). A significant factor may be the higher dose intensity achieved with the hybrid regimens (112–114). There have, however, been no randomized studies to determine whether this observation applies equally to all population groups. Our own experience, based on a retrospective analysis, is that there may be a trend toward improvement in blacks when the MOPP-ABVD era (1985 to 1995) is compared to earlier experience (1970 to 1983), when MOPP alone was used (Figs. 2 and 3). However, despite some improvements, the discrepancy between black and white individuals with Hodgkin's disease, equivalently treated, remains evident (Fig. 4). Costs are also significantly higher for regimens containing anthracycline, such as ABVD.

Data from the Cairo University Center are instructive. The overall and disease-free survival is shown in Figure 5. Survival appears, in general, to be inferior by 10% to 15% to that reported for Western series except for those cases with stage I disease, treated with mantle or inverted-Y radiation therapy, where survival exceeds 88% at 5 years. The corresponding figures are 48% for stage II, 39% for stage III, and 33% for stage IV. As elsewhere, the explanation may be related to irregular treatment courses, with 47% being delayed more than 2 weeks because of social circumstances (31).

A significant dose–response relationship has been shown for Hodgkin's disease with favorable results for high-dose chemotherapy linked to autologous bone marrow transplantation for patients with recurrent disease (115–116).

Because both dose intensification and better treatment compliance might be achieved using high-dose chemotherapy with autologous bone marrow support for advanced poor prognosis disease, a trial was initiated in Johannesburg using this as the initial approach. Twenty-six patients are currently evaluable. The regimen consists
of melphalan (140 mg/m² IV) combined with etoposide (VP16, 2.5 g/m²). Hematologic rescue is effected using noncryopreserved autologous marrow (four patients) or G-CSF-stimulated peripheral blood stem and progenitor cells (22 patients). Not having to freeze and store the rescue products has made the whole procedure technically simpler and cheaper. All patients have reconstituted (to ≥1.0 × 10⁶/L neutrophils and ≥40 × 10⁶/L platelets, without transfusion dependency) with median recovery time of 17 days. Median hospitalization time was 19 days.

Twenty-four of the 26 patients achieved complete remission following one cycle of treatment. Only one patient had a partial response, and one failed, giving an overall complete response rate (24 of 26) of 92%. The first six patients in this study underwent only a single course of high-dose chemotherapy. There were three recurrences (at 18, 22, and 25 months, respectively) (117). All subsequent patients had the induction cycle repeated and were autografted (as outlined above) with the second cycle, administered 4 to 6 weeks after the first procedure. Time to hematologic recovery was not significantly different following the second course of therapy in comparison to the first. Among the 20 patients given double high-dose chemotherapy with peripheral blood stem-cell rescue, the complete remission rate was 100%. At a median follow-up of 30 months, there have been no recurrences among the patients who were treated twice (118). The disease-free survival for all 26 patients is shown in Figure 6.

Although this is not a randomized study, it is of interest to note that the single cycle of chemotherapy has an adequate cure rate, even though the disease is chemotherapy sensitive. The efficacy of a double induction cycle remains to be established on further follow-up. However, if successful, this approach is likely to provide an acceptable method because it is additionally associated with a reduction in total treatment time for patients with poor prognostic Hodgkin's disease in Africa.

Children

Although reported series are small, results suggest an outcome superior to that achieved in adults (119,120). Exceptionally good results have been reported with MOPP for childhood disease in Africa with initial complete response rates of 85% to 100% (67,68,121,122). This outcome is noticeably better than that achieved in adults using the same therapeutic regimen. In a series reported from the Tygerberg Academic Hospital, those under 15 years of age (Tables 8 and 9) treated with MOPP, or its equivalent, CHIVPP, or the MOPP/ABVD hybrid together with 20 to 30 Gy involved-field radiotherapy to bulky mediastinal disease (70) had a projected survival at 10 years of 85% for stage I and II disease and 82% and 48% at 5 and 10 years, respectively, for stage III and IV disease (Fig. 7). Survival in children was identical, irrespective of chemotherapy used (Fig. 8). Disease- and treatment-related complications were, however, frequent. Of the infections, tuberculosis was common in the Western Cape and caused significant morbidity; one-third of the patients required antituberculosis treatment.
CONCLUSION

Hodgkin's disease, as seen among children and adults throughout Africa, creates a sense of déjà vu among investigators working in First World centers. Our understanding of the available evidence is that there is a single causative pathophysiologic process, but the impact of environmental factors is much more profound than in the more uniform societies generally evolved in the Western World. Of these, the presentation and clinical course are profoundly and adversely influenced by malnutrition and by rampant and escalating human immunodeficiency disease positivity, with its linked epidemic of tuberculosis. Logic would dictate that, if these compounding factors could be corrected, little difference would be seen either between blacks and whites on the continent or in comparison with more affluent societies in other parts of the world. On currently available evidence, these appear to be unobtainable and even receding goals. Perhaps the most frightening reality to be faced is a continent-wide deterioration in medical standards, with reduction and restriction of available resources that range from unavailability of chemotherapy drugs to the nondelivery of radiation and radiation therapy equipment. If this is the truth, as seems to be the case, Africa will continue to provide a model for the study of differences between affluent and poor. This is a chilling scenario and the antithesis of what all dedicated doctors strive toward. The goal must be improvement in the investigation and management of these individuals. Only in this way can the outcome be elevated to levels that in the future will differ in no significant way from the standard-setting academic centers in the First World.

ACKNOWLEDGMENTS

The authors wish to thank many colleagues in Africa who provided data for this chapter. Included are Lorraine Levy, Associate Professor, Department of Medicine, at the University of Zimbabwe and the Zimbabwean Cancer Registry; Dr. Handy Azim, of the Cairo Oncology Center; Peter Hesseling, Professor and Head of the Department of Paediatrics and Child Health, University of Stellenbosch, who was particularly helpful in providing additional data from his own experience and records; Gary Culligan, Professor, Medical University of Southern Africa; Coenrad F. Slabber from the Department of Medical Oncology, University of Pretoria; Seditia Isaacs from the University of Cape Town, Groote Schuur Hospital; and Pauline Close, Department of Anatomical Pathology, University of Cape Town and Groote Schuur Hospital. We would also like to thank Christine Dölling for providing invaluable bibliographic assistance; and Deirdre Collins and Gillian Ganz, who prepared and typed drafts and the final manuscript.

Effect of age on the characteristics and clinical behavior of non-Hodgkin’s lymphoma patients

The Non-Hodgkin’s Lymphoma Classification Project*

*See page 977 for list of study participants

Summary

Background: The goals of this study are to describe the frequency, clinical characteristics, and outcome of the different non-Hodgkin’s lymphomas according to age.

Patients and methods: Patients included in the recently published analysis of the Non-Hodgkin’s Lymphoma Classification Project were analyzed. All patients had their slides reviewed and classified by five independent expert hematopathologists. Lymphomas were classified according to the Revised European–American Classification of lymphoid neoplasms. Sufficient data were available on 1283 cases. Five age groups were analyzed: < 35 years, 35–49 years, 50–59 years, 60–69 years, and ≥ 70 years.

Results: Few differences were observed between the age groups with regard to lymphoma types and clinical characteristics. Anaplastic large cell lymphoma, Burkitt’s lymphoma, and lymphoblastic lymphoma were observed more frequently in patients younger than 35 years, whereas small lymphocytic and lymphoplasmacytoid lymphomas were observed more frequently in patients older than 70 years. Mantle cell lymphoma and marginal zone lymphomas were observed more frequently in middle-aged patients. Poor performance status was more frequent in older patients, as was bone marrow infiltration, whereas spleen involvement was more frequent in younger patients. Young and older patients had a slightly worse age-adjusted International Prognostic Index score (P < 0.01). Complete response rates decreased with age from 68% in the youngest patients to 45% in the oldest patients (P < 0.0001). Median event-free survival and overall survival also decreased with age (P < 0.0001).

Conclusions: Elderly patients have a poorer outcome than younger patients but age alone is not sufficient to discriminate patients with a poor outcome. However, the histologic type of lymphoma and clinical characteristics may define a subgroup of patients with a poor outcome in each age category.

Key words: age, elderly patients, non-Hodgkin’s lymphoma

Introduction

Although the incidence of non-Hodgkin’s lymphoma (NHL) is steadily increasing, particularly in elderly patients [1–3], few studies have described the histologic and clinical characteristics of the elderly patients. In some diseases, such as diffuse large cell NHL, it is known that older age is associated with a poor outcome, and that elderly patients frequently have more clinical features associated with a poor prognosis, such as poor performance status (PS), B symptoms, or concomitant diseases [4–8]. Some lymphomas, such as mantle cell lymphoma, have been reported to occur more commonly in elderly patients, while other lymphomas, such as Burkitt’s lymphoma or mediastinal B-cell lymphoma, occur less often in older patients. While the relative frequency of the various diseases, as described in the recently presented Revised European–American Lymphoma (REAL) Classification [9], was recently documented [10] no analysis were for the different classes of age, nor have patient characteristics and outcomes been addressed in relation to their age.

Therefore, we have used the 1403 patients previously reported in a clinical evaluation of the REAL Classification [10] to describe the frequency of each lymphoma, the clinical characteristics, and the outcomes according to the age of the patients.

Patients and methods

The patients included in this analysis were described in the previous paper reporting this study [10]. Briefly, nine institutions in eight countries provided up to 200 consecutive cases of previously untreated NHL beginning from 1 January 1988. In all cases, tissues biopsies had to be adequate for diagnosis and classification using the REAL Classification, including immunophenotyping. Five expert hematopathologists (J. Diebold, H.K. Müller-Hermelink, K. MacLennan, B.N. Nathwani, D.D. Weisenburger) reviewed all cases. Clinical characteristics, treatment data, and follow-up were required in all cases. The clinical information for each case was abstracted from the medical record by a clinician or data manager and recorded on a standardized form. These data included coded patient and site identifiers, sex, date of birth, date and site of diagnostic biopsy, a tabulation of nodal and extranodal sites of disease, Ann Arbor stage, performance status (PS), and maximum diameter of largest tumor mass at diagnosis. Laboratory data were recorded including serum lactate dehydrogenase (LDH) level, absolute lymphocyte count, presence of circulating lymphoma cells, presence of a monoclonal immunoglobulin, a history of immunodeficiency, and viral (HTLV-I, HIV) status. The initial therapy and therapeutic response, details of remission, progression, or relapse, and subsequent therapies and follow-up were tabulated for each case. Treatment was coded using the following criteria: unknown therapy,
no treatment given initially; radiation therapy only, surgery only, single agent chemotherapy (e.g., chlorambucil), CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) or CHOP-like (containing cyclophosphamide and doxorubicin at the same dosage than the CHOP regimen plus other drugs) regimens, high-dose CHOP regimens (with doxorubicin administered at ≥ 70 mg/m² and cyclophosphamide at ≥ 1050 mg/m² plus other drugs).

One thousand four hundred and three cases were entered in this study. Twenty-five cases were found to have a diagnosis other than lymphoma after review and, thus, were excluded from further analysis. Of the 1378 remaining cases, 95 had incomplete clinical data or follow-up data and were not included in this analysis, leaving 1283 cases. To create homogeneous groups with approximately the same number of patients, five classes of age were chosen (Table 1): less than 35 years old, 35 to 49 years, 50 to 59 years, 60 to 69 years, 70 or older. Even with that the percentage of patients in the oldest groups were higher than in the younger groups.

Completed clinical and pathology forms were reviewed and edited to detect any inconsistencies, and additional information and/or clarification was obtained when needed. After completion of the editing, the clinical and pathology forms were entered into a computer for data analysis [10]. The International Prognostic Index [11] was used to stratify patients with various disease entities. Treatment outcome was measured using event-free survival and overall survival. Event-free survival was defined as the time from diagnosis to the first occurrence of progression, relapse after response or death from any cause. Follow-up of patients not experiencing one of these events was censored at their date of last contact. Overall survival was measured from diagnosis to death from any cause, with surviving patient follow-up censored at the last contact date. Estimates of event-free survival and overall survival distribution were calculated using the method of Kaplan and Meier [12]. Time to event distributions were compared using the log-rank test [13].

### Results

The distribution of the different histologic subtypes according to age of the patients at diagnosis is shown in Table 1. Anaplastic large-cell lymphoma (ALCL), Burkitt's lymphoma (BL), and lymphoblastic lymphoma (LL) were observed mostly in young patients (less than 35 years old). Mantle cell lymphoma (MCL), marginal zone lymphoma (MZL), and mucosa-associated lymphoid tissue (MALT) lymphoma were observed more frequently in middle aged patients (35 to 69 years). Small lymphocytic (SLL) and lymphoplasmocytoid lymphoma (LPL) were observed predominantly in older patients. Follicular lymphoma (FL), diffuse large B-cell lymphoma (DLCL), and peripheral T-cell lymphoma (PTCL) patients had a distribution comparable with the whole population, that is an incidence slightly increasing with age. Nevertheless, DLCL and FL remained the two most frequent lymphomas in all age categories, representing respectively 30% to 40% and 20% to 30% of all lymphomas by age category. SLL/LPL, MALT, and PTCL only represented between 5% and 10% of all lymphomas, and the other lymphoma types less than 5% in all age groups.

Table 2 shows the main clinical characteristics of these patients and the most frequent extranodal sites according to age distribution. The youngest patients were predominantly male and oldest patients predominantly female ($\chi^2 = 16.5, P < 0.005$). While poor

*All parameters were not known for each patient.*
involved in 33% to 4% of the patients in decreasing order of frequency (Table 2). Bone marrow involvement was observed in only 19% of the youngest patients compared to 30%-36% in older patients ($\chi^2 = 20.8$, $P < 0.0005$). Spleen involvement was observed less frequently in young and old patients (13% and 14% compared to 17%-24% for intermediate age, $\chi^2 = 12.9$, $P < 0.02$) and thyroid involvement was observed essentially in oldest patients (2.4% compared to <0.5%, $\chi^2 = 15.2$, $P < 0.01$). For all other sites of involvement there were no statistically significant differences among the different age groups. In summary, except for bone marrow involvement and poor PS, very few differences were observed among the different age groups.

Table 3 shows the distribution of patients by age group according to the International Prognostic Index (IPI) scores [11], index based on age ($\leq 60$ or $> 60$ years), stage (localized or disseminated), PS (0-1 or $\geq 2$), number of extranodal sites (0-1 or $\geq 2$), and LDH level (normal or increased); and according to the Age-Adjusted Prognostic Index (AAPI), index based on stage, PS, and LDH level. The IPI was largely influenced by the age of the patients: 60% of patients younger than 60 years had a good score and less than 20% a bad score, compared to 25% and 50% for patients older than 60 years, respectively ($\chi^2 = 224.2$, $P < 0.00001$). For the AAPI, the distribution of patients in each score was more homogeneous: slightly more youngest and oldest patients had a worse score compared to intermediate age patients ($\chi^2 = 28.8$, $P < 0.005$).

Table 4 shows treatments given to these patients, the response rates to these treatments, and the progression rates according to the age of the patients. Because of the heterogeneity of treatments, it is not possible to correlate response rates to the different types of treatment. The percentage of patients treated with CHOP-like or high dose regimens decreased with age. This may reflect in part the higher percentage of patients with SLL, however, predominantly, it is due to the natural tendency of physicians to decrease the intensity of the treatment in older patients since they have poor PS or associated diseases. Less than 40% of the patients with SLL, MZL, or MALTL were treated with anthracycline-containing regimen. No initial treatment was the choice at diagnosis for patients with MZL (28%), SLL (23%), and MALTLymphoma (13%) patients; in contrast, only very few patients had no initial therapy for other lymphomas (8% of FL, 6% of DLCL and PTCL, 5% of MCL patients). Surgery only was used in 10% of MALTLymphoma and 6% of MCL patients. Radiation therapy only was used in 12% of FL, 11% of BL, and 11% of MALTLymphoma patients. Complete response (CR) at the end of treatment decreased with age from 68% in youngest patients to 45% in oldest patients ($\chi^2 = 62.9$, $P < 0.0001$) accompanied by an increasing partial response (PR). However, as shown in Table 4, treatments differed with age groups and this decrease may witness either the refractoriness of the lymphoma or the inefficacy of the treatment.

Disease progression was observed slightly less frequently in the youngest patients ($\chi^2 = 10.1$, $P < 0.05$), but true relapse rate from CR did not increase with age (Table 4). Median event-free survival and overall survival as well as the percentages of patients free of disease or alive at three years or five years decreased with age (Table 4 and Figure 1). The number of patients who reached a CR then died in CR from a concomitant disease is more important in patients older than 70 years (8%) compared to 2%-5% in younger patients.

Patients with the most common lymphomas, diffuse large B-cell lymphoma, had a survival pattern that did not differ from that described for the entire study population, with median survival and event-free survival
Figure 1. Survival of the patients included in the International Non-Hodgkin's Lymphoma Classification Project according to their age at diagnosis ($\chi^2 = 80.87, df = 4, P < 0.0001$).

Figure 2. Overall survival of follicular lymphoma patients included in the International Non-Hodgkin's Lymphoma Classification Project according to their age at diagnosis (log-rank test, $\chi^2 = 23.95, df = 4, P < 0.0001$).

Figure 3. Overall survival of diffuse large B-cell lymphoma patients included in the International Non-Hodgkin's Lymphoma Classification Project according to their age at diagnosis (log-rank test, $\chi^2 = 42.72, df = 4, P < 0.0001$).

Figure 4. a) Overall survival according to the age-adjusted International Prognostic Index for patients younger than 60 years and with known parameters. b) Overall survival according to the age-adjusted International Prognostic Index for patients 60 years or older and with known parameters.

1108 patients had a known value for the age-adjusted IPI (Table 3). Event-free survival and overall survival for the whole group of these patients reflected that described for aggressive lymphoma patients (data not shown). Patients younger and older than 60 years had the same pattern of outcome according to the AAPI, but younger patients had an always slightly better outcome in all AAPI scores (Figure 4). Figure 4b clearly shows that elderly patients may have a good or a poor outcome in relation to the number of adverse prognostic parameters as described in the AAPI.

Discussion

This series of 1283 patients is the first with a modern description of histologic subtypes and a description of standard prognostic factors particularly for a comparison according to patient's age. As was pointed out recently, clinical prognostic factors are as important as the histologic subtype for proper management of patients [10, 14]. We confirm that age was one of the most important prognostic factors in diffuse large cell lymphomas [4, 5, 7, 11, 15, 16]. Our analysis confirm that age is also an important prognostic factor for response to treatment, event-free survival, disease-free survival, and
overall survival for DLCL patients; in addition, the importance of age is also applicable for all lymphoma subtypes. Why older age has an adverse effect on patient outcome is not completely understood: a low response rate and an increase in death rate may be due to the presence of poorer conditions in the elderly, mostly because of comorbid conditions [4–8]. In fact, 8% of the oldest patients died in CR from another disease compared to less than 5% in all the other age groups. Although, a decrease in immune surveillance has been suggested as a factor responsible for this poorer outcome, direct evidence of this defect as a contributory factor has not been published.

The increased proportion of some lymphomas at different ages has already been described, however our analysis shows some new findings. Nearly all lymphomas may be observed in any age category but SLL/LPL, MALT lymphoma, MZL, MCL, and PTCL are rare in patients under 35 years, whereas ALCL, BL, and LL are rare in patients over 70 years (Table 1). The preponderance of young patients with lymphoblastic and Burkitt’s lymphomas is confirmed in this study, but these lymphomas may also be observed in elderly patients. MCL was initially described in older patients, but can in fact be observed in patients younger than 60 years. These observations lead us to believe that even in the elderly patients any lymphoma can occur and that accurate histologic diagnosis is essential since different outcomes are observed for the different diseases and these patients require different treatments.

The clinical characteristics at presentation and the sites of involvement do not vary significantly with age (Table 2). Lymphomas are observed more frequently in elderly females, but this is probably related to the earlier mortality observed in males. Regardless of the age groups, localized NHL were more frequent in this study than it was previously reported: 19% for stage I disease and 20% for stage II disease. This may be due to the fact that such patients are less frequently included in prospective trials. Similarly, the type and frequency of sites of extranodal involvement did not change with age category (Table 2), the most frequent involved sites being bone marrow, spleen, gastrointestinal tract, head and neck, skin, and liver, as previously reported [17].

This study confirms the poor outcome observed in elderly patients with lymphoma. These elderly patients do not have specific histologic or clinical characteristics, nor they have more adverse prognostic features as shown in Tables 2 and 3. However, the outcome of elderly and young patients is clearly related to the number of adverse prognostic factors, as shown in Figure 4. Thus, age is not sufficient to discriminate patients with a poor outcome, but histologic classification and clinical staging are necessary to define a subgroup of patients with very poor outcome. As elderly patients do not have specific characteristics, treatment decisions must be defined according to histology and a clinical prognostic index as in all other age groups. This study was not designed to analyze the effect of the different therapeutic strategies used in the different centers, therefore, it is not possible to draw conclusions about the merits of the various treatment categories we have described (Table 4).

In summary, this implication would lead to the design of new studies addressing specifically patients older than 65 or 70 years wherein treatment protocols will be determined according to the histologic type and prognostic parameters specific for elderly patients such as PS, comorbid presence of other diseases, and the extent of the tumor.

*Study participants*

The pathologists and clinicians at each institution were, respectively, Wiq C. Chan and James O. Armitage (Omaha, NE), Randy Gascogne and Joseph Connors (Vancouver, Canada), Pauline Close and Peter Jacobs (Capetown, South Africa), Andrew Norton and T. Andrew Lister (London, UK), Ennio Pedroni and Franco Cavalli (Locarno, Switzerland), Françoise Berger and Bertrand Cöfler (Lyon, France), Faith Ho and Raymond Liang (Hong Kong), German Ott/Alfred Schauer and Wolfgang Hiddemann (Würzburg/Göttingen, Germany). The five visiting expert hematopathologists were Jacques Diebold (Paris, France), Kenneth A. MacLennan (Leeds, UK), H. Konrad Müller-Hermelink (Würzburg, Germany), Bharat N. Nathwani (Los Angeles, CA); and Dennis D. Weisenburger (Omaha, NE). James R. Anderson (Omaha, NE) and Pascal Roy (Lyon, France) provided statistical expertise regarding the study design and data analysis.

Epidemiology of the non-Hodgkin's lymphomas: Distributions of the major subtypes differ by geographic locations

Departments of Preventive and Societal Medicine, Internal Medicine, Pathology and Microbiology, University of Nebraska Medical Center, Omaha, NE, USA

* See page 710 for list of participants

Summary

Background: There has been no previous systematic study of the distribution of the major subtypes of non-Hodgkin's lymphoma (NHL) across geographic regions, although there have been isolated reports of such differences.

Design: As part of a clinical evaluation of the International Lymphoma Study Group (ILSG) classification of NHL, we classified 1386 NHLs from eight different geographic sites (Omaha, NE, USA; Vancouver, BC, Canada; Cape Town, South Africa; London, England; Würzburg/Göttingen, Germany; Lyon, France; Locarno/Bellinzona, Switzerland; and Hong Kong) using the ILSG classification.

Results: Substantial differences were found in the distribution of the major subtypes of NHL across geographic regions ($P < 0.0001$). A greater percentage of follicular lymphoma was seen in North America, London and Cape Town (31% versus 14% at other sites). Peripheral T-cell lymphoma was more common in London, Cape Town and Hong Kong (9%) than elsewhere (3%). In Locarno/Bellinzona, higher percentages of mediatrastal large B-cell lymphoma (9% versus 2% elsewhere) and mantle cell lymphoma (14% versus 6% elsewhere) were seen. Angiocentric nasal T/NK-cell lymphoma was only seen in Hong Kong (8%) and Lyon (2%).

Conclusions: Our study provides evidence that the distribution of NHL subtypes differs by geographic region. These findings suggest that geographical differences in etiologic or host factors may be responsible for the observed differences in the distribution of cases across NHL subtypes.

Key words: epidemiology, geography, histologic subtypes, non-Hodgkin's lymphoma

Introduction

In 1994, the International Lymphoma Study Group (ILSG), a group of mostly European and American pathologists, proposed a new classification of lymphoid neoplasms [1]. Their approach was an attempt to define diseases which they thought could be recognized with contemporary morphologic, immunologic and genetic techniques. The proposed classification defined non-Hodgkin's lymphoma (NHL) subtypes using these techniques, but included no original data on patient characteristics and outcome, or the distribution of the various NHL subtypes.

Thus, in 1995, a group of hematopathologists, clinicians and statisticians were assembled to conduct a retrospective clinical evaluation of the ILSG classification of NHL [2]. The primary focus of this research effort was to evaluate the ability of experienced hematopathologists to apply the ILSG classification to NHL cases collected at various sites around the world and to describe the clinical characteristics and treatment outcomes for the common NHL subtypes. Because the cases came from eight countries on four continents, we were also able to compare the distributions of the major NHL subtypes across geographic regions.

Design

The specific details of the conduct of this study have been published elsewhere [2]. Briefly, nine institutions in eight countries were chosen to participate in the study, in part, because they were thought to have a case base representative of their geographical region. Up to 200 consecutive cases of previously-untreated NHL diagnosed between 1 January 1988 and 31 December 1990 were to be studied at each institution. A tissue biopsy other than bone marrow was required for the diagnosis of NHL. An panel of five review hematopathologists (see Appendix) traveled as a group over a period of eight months to each site and classified each case according to the ILSG classification [1]. In addition, a consensus diagnosis was obtained for each case. The consensus diagnosis was reached when at least four of the five review pathologists agreed upon the ILSG classification. For a diagnosis of follicular lymphoma or peripheral T-cell lymphoma, any grade or subtype was considered an agreement. For cases where consensus could not be reached, additional studies were performed and a consensus diagnosis was assigned based on an agreed upon algorithm.

The chi-square test for contingency tables was used to

assess evidence that the distributions of cases among histologic subtypes of NHL differed across geographic areas.

Results

The distribution of cases by histologic subtype for each geographic area is shown in Table 1. There was strong statistical evidence that the distribution of the cases among the major histologic subtypes of NHL differed substantially by geographic site (P < 0.0001). The distribution across NHL subtypes was similar for Omaha and Vancouver, except that fewer cases of small B-lymphocytic lymphoma were diagnosed in Vancouver. A greater percentage of follicular lymphoma was seen in North America, London and Capetown (28%-32%) than at the other sites (8%-18%). Peripheral T-cell lymphoma made up a larger percentage of the cases from London (8%), Cape Town (8%) and Hong Kong (10%) than from the other sites (1%-6%). Primary mediastinal large B-cell lymphoma accounted for 9% of NHL in Locarno/Bellinzona, whereas at other sites the percentages were 0%-4%. Mantle cell lymphoma was also more common in Locarno/Bellinzona (14%) than at the other sites (1%-8%). Angiocentric nasal T/NK-cell tumors were only seen in Hong Kong (8%) and Lyon (2%).

Discussion

Previous studies have reported considerable variation in the overall incidence of non-Hodgkin’s lymphoma (NHL) worldwide [3, 4]. Differences in the incidence of specific subtypes of NHL have also been reported, but these studies have been hampered by the use of multiple NHL classification systems. As part of a clinical evaluation of the International Lymphoma Study Group (ILSG) classification of NHL, five review hematopathologists reached a consensus diagnosis on 1378 cases of NHL reviewed over an eight month period in eight countries. As a result, we were able to compare the distribution of NHL cases among the common histologic subtypes in different geographic areas. It was not possible to calculate incidence rates because the sizes of the populations from which these cases arose were unknown. Note that the proportion of cases of a particular subtype at a site may be low (high) compared to other geographic sites either because the incidence of that subtype is low (high), or because the incidence is the same but the incidence of the other subtypes is higher (lower). Nevertheless, our findings suggest that some real differences in the incidence of certain subtypes of NHL exist among the geographic sites studied.

The distributions of cases studied in Omaha and Vancouver were similar. There were fewer cases of small lymphocytic lymphoma (SLL) seen in Vancouver, but this was thought to be due to a difference in practice patterns. Vancouver patients diagnosed with chronic lymphocytic leukemia (the leukemic counterpart of SLL) on the basis of a bone marrow biopsy typically would not have had additional biopsies of enlarged lymph nodes performed. Since cases were eligible for this study only if there was a tissue biopsy other than bone marrow available for the diagnosis of NHL, these patients would have been excluded from the study. Similar patients seen in Nebraska and elsewhere were more likely to have had biopsies of enlarged nodes, and would have been included with a diagnosis of SLL with marrow involvement.

Follicular lymphoma was seen more frequently in North America, London and Capetown (31% of all cases) than at other geographic sites (14%). Lower rates of follicular lymphoma have been reported in Asian populations [5] and developing countries [6]. The percentage of follicular lymphoma in Hong Kong (8%) was the lowest observed at any study site, and similar to that previously reported for Hong Kong [7]. In a study of the incidence of non-Hodgkin’s lymphoma in San Francisco/Oakland, California and western Washington state, Chinese-Americans and Japanese-Americans both had a reduced risk of follicular lymphoma, and the lowest risks were seen in those born in Asia [8]. The risk of diffuse lymphomas was similar in Chinese- and Japanese-Amer-
icans, and US-born whites. In a study of 1391 cases of NHL in patients age 15 years or older who were treated at six major medical centers in four representative areas of Thailand, follicular lymphoma constituted only 3.8% of all cases [9]. Follicular lymphoma also appears to make up only a small minority of cases of NHL seen in Oman (17%) [10], Pakistan (8%) [11], Nigeria (13%) [12] and Gabon (2%) [13]. The percentage of follicular lymphoma cases seen in mainland Europe (11%–18%) was also substantially less than that seen in North America, London and Capetown. The reasons for these differences is unknown, but may reflect a true decreased risk of follicular lymphomas among mainland Europeans.

Peripheral T-cell lymphoma represented a greater percentage of the cases in Cape Town (8%), London (8%) and Hong Kong (10%), as compared to the other sites (2%–6%). Indeed, including angiocentric nasal T/NK-cell lymphoma and anaplastic large T/null-cell lymphoma, T-cell lymphomas comprised 21% of the cases reviewed in Hong Kong. The percentage of T-cell lymphomas in Hong Kong Chinese has been previously reported to be 25% [14], and the percentage reported in Shanghai is similar (28%) [15]. The increased percentage of T-cell lymphomas observed in Hong Kong is not thought to be related to an increased incidence of T-cell lymphoma, but rather due to a lower incidence of follicular lymphoma [14, 16]. Angiocentric nasal T/NK-cell lymphoma was only seen in Hong Kong (8%) and Lyon (2%). This tumor is known to have a higher incidence in Asian countries and is associated with a high incidence of Epstein–Barr virus infection [17], as are some peripheral T-cell lymphomas seen in Asia.

Mantle cell lymphoma was more frequently seen in Locarno/Bellinzona, Switzerland (14%) than in the other sites (1%–8%). Few cases of mantle cell lymphoma were seen in Capetown (1%). Interestingly, the National Cancer Institute-sponsored Non-Hodgkin’s Lymphoma Pathologic Classification Project also found that mantle cell lymphoma (centrocytic type in the Kiel classification) was much more commonly seen in Milan, Italy (located some 70 miles south of Locarno) than in the American institutions which participated in the project [18].

One unexpected result of this study was the increased percentage of primary mediastinal large B-cell lymphoma seen in Locarno/Bellinzona, Switzerland. These tumors are indistinguishable from other diffuse large B-cell lymphomas histologically. Nevertheless, they appear to be different clinically, since these patients are younger and more often female than patients with diffuse large B-cell lymphoma [1, 2, 19]. Because of their unusual clinical presentation and their apparent increased percentage in Locarno/Bellinzona, they may have a unique pathogenesis.

In summary, we have shown that the distribution of NHL subtypes differs in different geographical areas around the world, and suggest that these differences may well reflect differences in etiologic factors or the host response to these factors in these geographic areas. Epidemiologic studies focused on specific subtypes of NHL in areas with an increased incidence are needed to elucidate such etiologic factors.

New Approach to Classifying Non-Hodgkin's Lymphomas:
Clinical Features of the Major Histologic Subtypes

By James O. Armitage and Dennis D. Weisenburger for the Non-Hodgkin's Lymphoma
Classification Project

Increasing knowledge about the biology of the non-
Hodgkin's lymphomas has led to new approaches in
classification. Rather than grouping lymphomas simply
based on cell size, cell shape, and growth pattern, it is
now possible to identify distinctive clinicopathologic
entities. In many cases, the existence of specific immuno-
logic and/or genetic features has confirmed the exist-
ence of these distinctive types of lymphoma. Since
patients will be given these diagnoses by pathologists,
it is important that clinicians be knowledgeable with
regard to their clinical characteristics. The findings for
the 13 most common lymphoma types that will be
encountered in clinical practice are presented here.

J Clin Oncol 16:2780-2795. © 1998 by American
Society of Clinical Oncology.

NON-HODGKIN'S LYMPHOMAS are increasing in
incidence and will be diagnosed in more than 55,000
patients this year in the United States.1-2 These malignancies
have been increasing in incidence at a rapid pace, approximately 4%
year since 1950,3 and the mortality rate has been increasing in a parallel manner.

The classification of non-Hodgkin's lymphoma has been
modified several times in this century and has often been a
source of confusion and frustration for clinicians. Gali and
Mallory4 proposed the first widely used lymphoma classifi-
cation, but this classification was not useful clinically. In the
1950s, Rappaport et al.5 recognized the importance of
lymphoma-cell growth pattern and subdivided the non-
Hodgkin's lymphomas based on this characteristic, which
led to the clinically relevant classification that bears Rappa-
port's name. In the 1970s, it became apparent that non-
Hodgkin's lymphomas were tumors of the immune system
and were derived from T or B lymphocytes. This knowledge
led to the classifications of Lukes and Collins2 and Lennert
et al6,7 (Kiel classification). The Working Formulation was
proposed in 1982 in an attempt to unify the complex and
confusing lymphoma terminology and improve communica-
tion between pathologists and clinicians in different parts of
the world.8 The Working Formulation became the most
popular classification used in North America, whereas the
Kiel classification dominated clinical practice in Europe.

The 1980s and 1990s have been a time of rapid increase in
our knowledge of the biology of the immune system. New
insights into immunology and genetics have allowed the
recognition of a number of previously unrecognized types of
non-Hodgkin's lymphoma. In some cases, biologic observa-
tions confirmed the existence of entities that were suspected
on clinical and/or morphologic grounds. In 1994, the
International Lymphoma Study Group recognized the exist-
ence of these new entities and proposed a new classification
that has been referred to as the Revised European-American
Lymphoma (REAL) classification.9 These observations will
form the basis for a new World Health Organization classifi-
cation of lymphomas that will soon become available.

A recent retrospective study of the REAL classification
confirmed the clinical relevance of this approach.10 This
study was performed in eight countries throughout the world
and demonstrated that this new approach could be applied
more accurately than previous classification systems.10 The
data from that study form the basis of this report.

METHODS OF THE INTERNATIONAL LYMPHOMA
CLASSIFICATION PROJECT

The methods used have been published in detail10 and are
summarized here. Nine institutions in eight countries were
chosen to provide up to 200 consecutive cases of previously
untreated non-Hodgkin's lymphoma that were representa-
tive of the geographic region during the time between
January 1, 1988 and December 31, 1990. The first 200 cases
at each site that fulfilled the following criteria were selected
for the study. In all cases, tissue biopsy samples that were
adequate for diagnosis and classification were required and
all diagnostic pathology materials obtained before initial
therapy, including positive bone marrow specimens, were
included in the pathology review. Immunologic characterization as
to B- or T-cell origin, by whatever means in use at the institution,
was also required in all cases. Clinical data were also required in
all cases. The nine study sites provided a total of 1,403 cases.

At each institution, the pathology slides and reports for
each case were carefully reviewed by a designated site
CLINICAL FEATURES OF THE NON-HODGKIN'S LYMPHOMAS

pathologist. Five expert hematopathologists then traveled as a group to each of the nine sites to review and classify each case in each of the three major classifications. In each case, the expert was then presented with the immunophenotypic profile, along with any available cytogenetic and molecular genetic data, and the immunostains and/or flow cytometry report. After review, a second diagnosis was rendered in each classification. In addition to the independent diagnoses rendered by each of the expert pathologists, a consensus diagnosis was also reached in each case.

The International Prognostic Index was used to stratify patients within the various disease entities. Treatment outcome was measured using failure-free survival and overall survival. Failure-free survival was defined as the time from diagnosis to the first occurrence of progression, relapse after response, or death from any cause. Follow-up evaluation of patients who did not experience one of these events was censored at the date of last contact. Overall survival was measured from diagnosis to death from any cause, with surviving patient follow-up data censored at the last contact date. Estimates of failure-free survival and overall survival distribution were calculated using the method of Kaplan and Meier. Time-to-event distributions were compared using the log-rank test.

MAJOR LYMPHOMA SUBTYPES

The 13 most frequent clinical entities that are recognized in the new lymphoma classification are diffuse large B-cell lymphoma, follicular lymphoma, small lymphocytic lymphoma, mantle cell lymphoma, peripheral T-cell lymphoma, marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type, primary mediastinal large B-cell lymphoma, anaplastic large T/null-cell lymphoma, lymphoblastic lymphoma (T/B), Burkitt-like lymphoma, marginal zone B-cell lymphoma of nodal type, lymphoplasmacytic lymphoma, and Burkitt's lymphoma. These are the diagnoses that will be provided by pathologists to clinicians who care for patients with lymphoma for the ensuing years. Therefore, it is important that clinicians be acquainted with the clinical characteristics of these lymphoma types. Summaries of their frequency, clinical characteristics, biologic characteristics, and clinical course are presented in the following tables for easy reference.

The lymphomas are presented in order of their frequency of occurrence. Composite lymphomas are excluded, resulting in a total of less than 100%. A previous study has shown that expert hematopathologists can diagnose most subtypes accurately (ie, > 85%) when adequate material, immunophenotype, and clinical information are available. The exceptions are Burkitt-like lymphoma, nodal marginal zone lymphoma, and lymphoplasmacytic lymphoma. In these subtypes, lack of clear definitions are probably at fault. Burkitt-like lymphoma is probably a mixture of Burkitt's lymphoma and a variant more closely related to diffuse large B-cell lymphoma, with the former more frequent in pediatric cases and the latter more likely in older adults.

In conclusion, it is extremely important that clinicians recognize that the correct diagnosis of each of these lymphoma entities is only one of many important pieces of information necessary for planning patient care. The clinical prognostic characteristics as identified in the International Prognostic Index are also vitally important, since the prognosis of any particular patient is related to the biology of the specific lymphoma type and the patient's clinical prognostic characteristics. Combining this information will facilitate an accurate estimate of the prognosis and makes possible the development of a rational treatment plan for an individual patient.

This progress is not the last change in the classification of lymphomas we will see. New insights into the biology of lymphoma will continue to elucidate new clinicopathologic entities. Certainly, the large group of diffuse large B-cell lymphomas will be subdivided into more specific entities. The future for clinical investigation in the non-Hodgkin's lymphoma is promising. Hopefully, new insights into the biology of this group of disorders will lead to improved therapies.

APPENDIX

Study Participants

The pathologists and clinicians at each institution were as follows: Wing C. Chan and James O. Armitage (Omaha, NE); Randy Gassoyne and Joseph Connors (Vancouver, Canada); Pauline Cloke and Peter Jacobs (Cape Town, South Africa); Andrew Norton and T. Andrew Lister (London, United Kingdom); Enrico Pedrini and Franco Cavalli (Locarno, Switzerland); Françoise Berger and Bertrand Caillier (Lyon, France); Faith Ho and Raymond Liang (Hong Kong); German Ott/Alfred Schauer and Wolfgang Hiddemann (Würzburg/Göttingen, Germany).

The five visiting expert hematopathologists were as follows: Jacques Diebold (Paris, France); Kenneth A. MacLeannan (Leeds, United Kingdom); H. Konrad Müller-Hermelin (Würzburg, Germany); Bharat N. Nathwani (Los Angeles, CA); and Dennis D. Weisenburger (Omaha, NE).

Nancy L. Harris (Boston, MA) participated as a consultant regarding application of the International Lymphoma Study Group classification. James R. Anderson (Omaha, NE) and Pascal Roy (Lyon, France) provided statistical expertise regarding the study design and data analysis.
DIFFUSE LARGE B-CELL LYMPHOMA

This is the most frequently occurring non-Hodgkin's lymphoma. It contains predominantly lymphomas classified as diffuse large cell, diffuse mixed cell, or immunoblastic in the Working Formulation and lymphomas classified as diffuse centroblastic, diffuse centroblastic/centrocytic, and immunoblastic in the Kiel classification. In the Non-Hodgkin's Lymphoma Classification Project using histology, immunophenotyping, and clinical information, diffuse large B-cell lymphoma was diagnosed accurately 87% of the time. Immunophenotyping improved the accuracy of diagnosis by 14%. Diffuse large B-cell lymphoma is a chemotherapy-curable lymphoma.

*Abbreviations: LDH, lactate dehydrogenase; GI, gastrointestinal; IPI, International Prognostic Index.*
FOLLICULAR LYMPHOMA

The combined group of follicular lymphoma makes up the second most frequent type of non-Hodgkin's lymphoma. These lymphomas are classified as follicular small cleaved cell, follicular mixed cell, and follicular large cell lymphoma in the Working Formulation and predominantly as follicular centroblastic/centrocytic or follicular centroblastic lymphoma in the Kiel classification. In the Non-Hodgkin's Lymphoma Classification Project using histology, immunophenotyping, and clinical information, follicular lymphoma was diagnosed accurately 94% of the time. However, subtyping of follicular lymphomas was less accurate. Immunophenotyping improved the accuracy of diagnosis by only 1%. Although there was an overall 5-year survival rate of approximately 72%, patients with a high International Prognostic Index score had a poor survival.
SMALL LYMPHOCYTIC LYMPHOMA

Small lymphocytic lymphoma makes up 6% of all non-Hodgkin's lymphomas. Since this often is the tissue manifestation of chronic lymphocyte leukemia, if patients who present with leukemia and predominantly blood and bone marrow involvement are included, the actual incidence would be higher. It contains predominantly lymphomas classified as small lymphocytic in the Working Formulation, but is called chronic lymphocytic leukemia in the Kiel classification. In the Non-Hodgkin's Lymphoma Classification Project using histology, immunophenotyping, and clinical information, small lymphocytic lymphoma was diagnosed accurately 87% of the time. Immunophenotyping added only 3% to the diagnostic accuracy.

Oncogenes involved
MANTLE CELL LYMPHOMA

Mantle cell lymphoma is among the most frequent of the newly recognized subtypes of non-Hodgkin’s lymphoma. In the Working Formulation, mantle cell lymphoma is classified as diffuse small cleaved cell lymphoma most frequently, but also as follicular small cleaved cell lymphoma, small lymphocytic lymphoma, diffuse large cell lymphoma, and lymphoblastic lymphoma. In the Kiel classification, this lymphoma is most frequently classified as centrocytic lymphoma or centrocytodendroblastoid lymphoma. In the Non-Hodgkin’s Lymphoma Classification Project using histology, immunophenotyping, and clinical information, mantle cell lymphoma was diagnosed accurately 87% of the time. Immunophenotyping added 10% to the accuracy of diagnosis. Patients with mantle cell lymphoma have a striking male predominance, usually advanced disease, and a poor overall and failure-free survival, which belies the good survival usually anticipated with small cell lymphomas.

PERIPHERAL T-CELL LYMPHOMA

The subgroup of peripheral T-cell lymphoma not otherwise specified represents the largest group of T-cell lymphomas in the REAL classification. For this report, angiocentric nasal lymphomas and human T-lymphotropic virus type 1 (HTLV-1)--associated lymphomas were excluded, which makes the results typical for those seen in most western countries. Peripheral T-cell lymphoma includes lymphomas with a wide variety of histologic appearances. Tumors in this subgroup were classified as diffuse small cleaved cell, diffuse mixed cell, diffuse large cell, and immunoblastic in the Working Formulation. In the Non-Hodgkin's Lymphoma Classification Project using histology, immunophenotyping, and clinical information, peripheral T-cell lymphoma was diagnosed accurately 86% of the time. However, this was only true when immunophenotyping was available. Immunophenotyping improved the accuracy of diagnosis by 45%. Peripheral T-cell lymphomas have one of the lowest overall and failure-free survival rates.
MARGINAL ZONE B-CELL LYMPHOMA, MALT TYPE

This is among the most frequent of the newly recognized subtypes of non-Hodgkin's lymphoma. In this report, only low-grade MALT lymphomas are included. In the Working Formulation, MALT lymphomas were most commonly diagnosed as small lymphocytic lymphoma or small lymphocytic lymphoma with plasmacytoid characteristics, although some were called diffuse small cleaved cell lymphoma. In the Non-Hodgkin's Lymphoma Classification Project using histology, immunophenotyping, and clinical information, marginal zone lymphoma of the MALT type was diagnosed accurately 86% of the time. Immunophenotyping added only 2% to the accuracy of the diagnosis. MALT lymphomas have one of the highest survivals of any subtype and even patients with a high International Prognostic Index score have a 5-year overall survival rate of 40%.
PRIMARY MEDIASTINAL LARGE B-CELL LYMPHOMA

Primary mediastinal large B-cell lymphoma represents a diffuse large B-cell lymphoma that cannot be distinguished histologically, but presents as a clinical syndrome due to the presence of a large mediastinal mass. This syndrome is clinically distinctive in that it occurs predominantly in younger patients and has a female predominance. In the International Non-Hodgkin’s Lymphoma Classification Project using histology, immunophenotyping, and clinical information, mediastinal large B-cell lymphoma was diagnosed accurately 85% of the time. Immunophenotyping added 7% to the accuracy of diagnosis. The clinical course of these patients differed little from that of other patients with diffuse large B-cell lymphoma, although mediastinal radiotherapy may play an important role in their treatment.
ANAPLASTIC LARGE T-/NULL-CELL LYMPHOMA

Anaplastic large T-/null-cell lymphoma represents the second most common T-cell lymphoma in the REAL classification. Patients with anaplastic large T-/null-cell lymphoma were often classified as having anaplastic carcinoma or an undifferentiated malignant neoplasm before staining for the CD30 antigen and discovery of the characteristic chromosomal translocation between chromosomes 2 and 5 led to its recognition as a distinctive non-Hodgkin’s lymphoma. In the REAL classification, only anaplastic large-cell lymphomas with T or null immunophenotype are included in this category. In the Non-Hodgkin’s Lymphoma Classification Project using histology, immunophenotyping, and clinical information, anaplastic large T-/null-cell lymphoma was diagnosed accurately 85% of the time. Immunophenotyping contributed 39% to the accuracy of diagnosis. Patients with this subtype of lymphoma have a young median age and a male predominance, and have the best overall and failure-free survival rates of any large cell lymphoma.

![Graph showing survival rates](image-url)
LYMPHOBLASTIC LYMPHOMA (T/B)

The lymphoblastic lymphomas make up a small proportion of all non-Hodgkin's lymphomas and are associated with a low median age, male predominance, and advanced stage. In the Non-Hodgkin's Lymphoma Classification Project using histology, immunophenotyping, and clinical information, lymphoblastic lymphomas were diagnosed accurately 89% of the time. Immunophenotyping contributed 35% to the accuracy of diagnosis. This is an aggressive lymphoma with low overall and failure-free survival rates.
BURKITT-LIKE LYMPHOMA

Burkitt-like lymphomas could not be diagnosed accurately in the Non-Hodgkin's Lymphoma Classification Project. Using histology, immunophenotyping, and clinical information, the diagnostic accuracy was only 53%. The problem was the lack of precise definitions to separate this group from the diffuse large B-cell category or true Burkitt's lymphoma. The median age and clinical characteristics of this subgroup were intermediate between patients with diffuse large B-cell lymphoma and Burkitt's lymphoma, but more closely approximated diffuse large B-cell lymphoma.

MARGINAL ZONE B-CELL LYMPHOMA, NODAL TYPE

Marginal zone B-cell lymphoma of the nodal type is one of the new forms of non-Hodgkin's lymphoma not recognized in the Working Formulation. In the Working Formulation, these lymphomas were most commonly found in the small lymphocytic subcategory, but were also sometimes diagnosed as diffuse small cleaved cell lymphoma, small lymphocytic lymphoma with plasmacytoid characteristics, or diffuse mixed cell lymphoma. In the non-Hodgkin's Lymphoma Classification Project using histology, immunophenotype, and clinical information, marginal zone B-cell lymphoma of the nodal type was diagnosed accurately 63% of the time. Immunophenotyping added 8% to the accuracy of diagnosis. These patients had an overall and failure-free survival similar to small lymphocytic lymphoma. These lymphomas are often currently diagnosed as monocytoid B-cell lymphoma.
LYMPHOPLASMACYTIC LYMPHOMA

Lymphoplasmacytic lymphoma is an uncommon diagnosis in the REAL classification, and includes patients that might also be diagnosed with Waldenström’s macroglobulinemia. In the Non-Hodgkin’s Lymphoma Classification Project using histology, immunophenotyping, and clinical information, lymphoplasmacytic lymphoma was diagnosed accurately 56% of the time. Immunophenotyping contributed 3% to the diagnostic accuracy. The clinical characteristics of this lymphoma were similar to those of small lymphocytic lymphoma.

Bone Marrow Transplantation for Acute Leukemia:
A Preliminary Report From the International
Bone Marrow Transplant Registry

R. Champlin for the Advisory Committee of the International Bone Marrow Transplant Registry

Bone marrow transplantation is increasingly used for the treatment of acute myelogenous leukemia and acute lymphoblastic leukemia. Factors associated with remaining in remission and with survival were evaluated by univariate analysis in 1,413 patients who received transplants from related HLA-identical donors since 1978 from 105 reporting centers.

Acute Myelogenous Leukemia

Comprehensive data from 739 patients were analyzed. The actuarial probability of survival at 4 years was 45% ± 7% (95% confidence interval [CI]) for 447 patients who received transplants in first complete remission (CR), 27% ± 13% in 114 transplant recipients in second CR, and 21% ± 8% in 178 patients with more advanced disease (P < .0002) (Fig 1). The actuarial probability of remaining in remission at 4 years was 75% ± 12% v 41% ± 23% v 35% ± 15%, respectively (P < .0001).

For patients receiving transplants while in first remission, factors associated with a higher probability of survival were younger v older age (P < .004) and no or mild v moderate or severe acute graft-v-host disease (GVHD) (P < .0001). Survival following use of methotrexate or cyclosporine (Cs) as agents to prevent GVHD tended to be higher (P < .02) than the use of T cell depletion of donor bone marrow. The only factor associated with a higher probability of remaining in remission was French-American-British (FAB) subtype M5 v M1 to M4 (P < .006). The use of higher v lower dose rates of total-body irradiation (P < .05) and the use of

2626 Transplantation Proceedings, Vol XIX, No 1 (February), 1987: pp 2626 2628
methotrexate vs Cs were of borderline significance.

The probability of relapse was significantly higher in 23 identical twins who received transplants in first CR in comparison with the 447 HLA-identical sibling transplant recipients (P < .003); their survival rates were comparable, however, due to a reduced incidence of transplant-related complications in the twins.

ACUTE LYMPHOBLASTIC LEUKEMIA

Six hundred seventy-four patients with acute lymphoblastic leukemia (ALL) treated with high-dose chemoradiotherapy and bone marrow transplantation from HLA-identical sibling donors were analyzed. The actuarial probability of survival at 4 years was 43% ± 14% for 181 transplant patients in first CR,

35% ± 8% for 257 recipients in second CR, and 21% ± 8% for 236 patients with more advanced disease (P < .0001) (Fig 2).

The data were analyzed to evaluate outcome following transplantation in first or second remission among patients with ALL with features associated with a high probability of relapse if treated with chemotherapy. The results as summarized in Table 1 demonstrate that transplantation in second remission results in a significantly lower probability of 3-year survival and a higher probability of relapse than transplantation in first remission. Furthermore, among patients transplanted in second remission, those with ALL presenting with high-risk prognostic features have a significantly lower 3-year probability of survival and a higher probability of relapse than patients presenting at diagnosis with standard-risk features.

Summary
Data from 176 patients with acute leukaemia given allogeneic marrow transplants between Jan. 1, 1977, and Dec. 31, 1980, and reported to the International Bone Marrow Transplant Registry were analysed retrospectively for prognostic factors associated with the development of interstitial pneumonitis (IPn). The overall incidence of IPn was 20% (36/176), and the disease was fatal in 21 of the 36 cases (58%). Three of more than thirty prognostic factors studied seemed to be associated with a low risk of IPn—pretransplant total body irradiation at a dose-rate ≤5.7 Gy/min, when compared with higher dose-rates (p<0.001); post-transplant immunosuppression with cyclosporin-A, when compared with methotrexate (p<0.0003); and transplantation of cells from female donors into female recipients, when compared with female donors and male recipients (p<0.0005). The low dose-rate of total body irradiation and the use of cyclosporin-A were considered as independent variables, but were confounded to the extent that it was not possible to determine if one or both factors were associated with a decreased incidence of IPn.

INTRODUCTION
Interstitial pneumonitis (IPn) is a frequent complication of allogeneic marrow transplantation in patients with leukaemia, aplastic anaemia, and severe combined immunodeficiency disease (SCID).14 The disease is associated with a severe morbidity and is fatal in more than half of the cases. No effective treatment is known. This study was undertaken to investigate pretransplant and posttransplant factors which might have prognostic significance for the development of IPn.

METHODS
Comprehensive data were reported to the International Bone Marrow Transplant Registry (Registry) by 28 transplant teams throughout the world for 215 leukaemia patients who received marrow transplants between Jan. 1, 1977, and Dec. 31, 1980. Included in this analysis are data from 176 patients with acute lymphoblastic and acute non-lymphoblastic leukaemia who were conditioned for transplantation with high doses (28 Gy) of total body irradiation (TBI) and who received methotrexate (MTX) or cyclosporin-A (CsA) post-transplant to prevent or modify graft-versus-host disease (GVHD). At the time of transplantation 117 patients were in complete remission and 59 were in partial remission or relapse. Excluded were 14 patients with chronic myelogenous leukaemia, 15 patients who received grafts from genetically identical twins, 3 patients who were prepared for transplantation with chemotherapy but without TBI, and 7 who received both MTX and CsA, no treatment, or other treatments as prophylaxis against GVHD.

Data were analysed by the use of univariate and multivariate techniques to investigate prognostic factors which might be associated with IPn. Among the factors studied were age, sex of patient, sex of donor, sex-match of donor and recipient, disease status, number of remissions, number of pretransplant transfusions, presence or absence of infection at the time of transplant, pretransplant antibiotic decontamination, time of isolation, duration of isolation, AB, HLA-match, HLA mismatch, cell culture-matched, interval from diagnosis to transplantation, year of transplant, pretransplant administration of donor buffy coat, pretransplant chemoradiotherapy regimen, total dose of TBI, dose-rate of TBI, dose of marrow/kg body weight, number of posttransplant transfusions, severity of GVHD, and drug used to prevent or modify GVHD.

The diagnosis of IPn was based on clinical and radiological observations, supported in some centres by open lung biopsy. The high mortality rate often enabled the diagnosis to be confirmed at necropsy.

RESULTS
The overall incidence of IPn was 20% (36/176), and 58% (21/36) of the patients died from the disease. The median interval from transplant to onset of IPn was 75 days (range, 6–236 days). The actuarial incidence of IPn in the first year after transplantation was 25% as calculated by life-table analysis.

In univariate analyses, three prognostic factors were significantly associated with IPn—dose-rate of TBI, drug used for prophylaxis against GVHD, and sex-match donor and recipient. IPn occurred in 6% (4/69) of patients who received TBI at a dose-rate of 2.5–3.1 Gy/min. The incidence was 30% (32/107) in patients who received TBI at a dose-rate of 6–30 Gy/min (median 7.5 Gy/min; the difference is significant (p=0.0001). Although the incidence of IPn was clearly decreased at dose-rates of TBI below 5.8 Gy/min, there seemed to be a threshold at 6–6 Gy/min, after which the incidence did not increase with higher dose-rates (fig. 1). IPn developed in 7% (4/56) of patients treated with CsA and 27% (32/120) of patients given MTX (p=0.0028).

Although both the lower dose-rate of TBI and CsA seemed to be associated with a low incidence of IPn, it is uncertain whether both were involved. Patients treated with low dose-rate TBI generally also received CsA; patients treated with higher dose-rate TBI were also often treated with MTX. Thus, there was confounding (p=0.53, p<0.0001) between the variables of TBI dose-rate and drug used for prophylaxis of GVHD (table I). IPn occurred in 1 out of 31 female patients given marrow from female donors and in 44% (16/36) of male patients given marrow from female donors (p=0.0001) (table II).

Male and female patients given marrow from male donors had an intermediate incidence of IPn (17%, 19/109).
IMMUNOPHENOTYPIC CLASSIFICATION OF LYMPHOMA AND LYMPHOCYTIC Lymphoma — AN EXPERIENCE IN THE SOUTH-WESTERN AREA OF THE CAPE PROVINCE OF SOUTH AFRICA

PETER JACOBS

The University of Cape Town Leukaemia Centre and Department of Haematology, Groote Schuur Hospital, Observatory, The Cape, South Africa.

Abstract—Adequate tumour material was obtained for phenotypic classification using a standard library of monoclonal antibodies from 81 previously untreated patients with acute lymphoblastic leukaemia (ALL), chronic lymphocytic leukaemia (CLL), or lymphocytic lymphoma (LL). Sixty-one individuals were adults and 20 were children of 14 yr or younger. Fifty-eight of the patients (72%) had acute lymphoblastic leukaemia and the remaining 23 (28%) had chronic lymphocytic leukaemia or lymphocytic lymphoma.

Considering only the patients with acute lymphoblastic leukaemia (n = 58) the median age was 19 yr (range 2–69 yr); 9% were black, 43% were coloured, 48% were white, and the distribution between adults (n = 38) and paediatric patients (n = 20) was comparable.

Complete remission rate in the adults was 58% and in the paediatric group 85%. For the total group (n = 58) median duration of survival was 59 weeks for common, 39 weeks for null, 63 weeks for T-ALL, and 13 weeks for B-ALL subtypes. In both the common and the null groups overall and disease-free survival was superior in the children. In contrast, no difference was evident in the T-ALL group, which was also notable for its high incidence in young coloured males.

The 15 patients with CLL and eight with LL were adults and all the cells were phenotypically of B lineage: in view of the small numbers no comments are possible about ethnic differences. A multi-centre collaborative study is needed to define the epidemiology of haematologic malignancy in South Africa, with emphasis on differences among ethnically distinct subpopulations.

INTRODUCTION

The natural history and response to treatment of the haematologic malignancies varies between different races. Scientific information about these neoplasms is strikingly deficient from Africa. This is unfortunate in view of the unique opportunities that exist for such epidemiological study. In part, this may reflect reluctance of patients to leave their families and travel long distances to attend specialised clinics where the diagnostic and therapeutic expertise is available, and in part to the formidable problems of maintaining records when follow-up is unreliable, particularly once any improvement in symptoms has occurred [1]. Superimposed on these difficulties may be local cultural influences, including those of traditional healer or medicine-man, low-level of medical information, and a generally accepting philosophy to symptoms and signs of disease.

Systematic protocol studies since 1972 have been used to explore the presentation and management of haematologic malignancies at our institution. In view of the unique composition of our patient population, data has been accumulated on ethnic differences during the course of studies on acute leukaemia [2–4], chronic granulocytic leukaemia [5], myeloma [6], chronic lymphocytic leukaemia and the indolent lymphomas [7], and diffuse large cell lymphoma [8]. In general terms, three observations occur consistently. Firstly, median age at presentation is between 10 and 15 yr lower in blacks than in whites with the coloured population being intermediate. Secondly, from a catchment area of between 3 and 4 million people, of whom 12% are black, 53% are coloured, 33% are white, and 2% are Indian or Asian, the attendance at the specialised haematology clinic is approximately 10% for black, 40% for coloured, and 50% for white. This small but significant deviation from the composition of the overall population is probably attributable to limited availability of specialised services for haematologic disorders. Thirdly, many of our patients present late in the course of their disease with high tumour bulk and suboptimal nutritional status: such fundamental differences make direct comparison of results from other centres having a more affluent patient load and earlier stage disease unreliable. These factors can only be con-
MATERIALS AND METHODS

The reference population

The Groote Schuur Hospital drains between 3 and 4 million people, of whom approximately 12% are black, 53% are coloured, 33% are white and 2% are Asian. The average annual admissions approximate 75,000 and outpatient visits close to 1 million; in general medical or surgical beds approximately 10% of patients are black, 63% are coloured and 27% are white. The Department of Haematology admits, on average, 360 patients and sees 7200 outpatients annually, of whom 10% are black, 40% are coloured [9], and 50% are white. This latter pattern has been constant over the past decade and the differences between it and both the overall population and that for patients on the general hospital services probably reflects a referral pattern which has developed around the special interest and provision of diagnostic and therapeutic services for patients with haematologic problems, including myeloma, lymphoma and leukaemia.

No reliable national or local figures are available for the overall incidence of the major categories of haematologic malignancy. An approximation can be derived from the population in the catchment or drainage area and the statistics for the hospital department for the period January 1980 through June 1984 with an average annual new patient accrual rate for patients over the age of 14 yr being 30 for non-Hodgkin's lymphoma, 12 for Hodgkin's disease, 14 for chronic lymphocytic leukaemia, 6 for chronic granulocytic leukaemia, 30 for non-lymphoblastic leukaemia and 13 for acute lymphoblastic leukaemia. Within each of these disease-types, the ratio of black to coloured and white patients was 9:43:48, with an additional 1% Asian patients, with these figures being relatively constant. Furthermore, within each of these ethnic groups, the male to female ratio was 3:4:1, 1:2:2:1, and 1:24:1. The predominance of black males may reflect local cultural practice where larger numbers of males make up the work force and there is generally greater reticence of the more conservative rural black woman to leave her family, even to attend regional hospitals.

Study population (n = 81)

Fifty-eight patients with previously untreated ALL, 15 with CLL, and eight with LL were phenotypically classified using a standardised library of monoclonal antibodies provided by the LRF Centre as part of the collaborative group study of leukaemia subtypes (see paper by Greaves et al., in this issue).

All patients were previously untreated and entered onto study with informed consent. Fifty-eight had ALL, 15 had CLL and five had miscellaneous lymphocytic lymphoma.

Patient evaluation

All patients had detailed history taken and underwent full physical examination. Complete blood counts were carried out on the Coulter Counter Model S Plus [10] and using May–Grünewald–Giemsa staining were classified as ALL on the basis of the French–American–British (FAB) Co-operative Group’s proposal [11–13]. The diagnosis of chronic lymphocytic leukaemia was based on established criteria [14] and staged according to the Rai recommendations [15]. Lymphocytic lymphoma was classified according to the recommendations of the International Working Formulation [16]. Biochemical profile was determined using established methodology [17]. In vitro bone marrow culture studies were performed on aspiration samples. Blasts were examined by sheep erythrocyte rosette formation [18] and by direct and indirect immunofluorescence using antibodies against terminal deoxynucleotidyl transferase (TdT) [19] and a standardised library of monoclonal antibodies, including demonstration of surface immunoglobulin [20, 21], Dr and cALL antigens [22, 23].

Patient exclusions

The 15 patients with CLL are excluded from further analysis but are reported elsewhere [7, 24, 25]. The eight patients with miscellaneous lymphocytic lymphomas are not suitable for further analysis because the numbers are too small.

Chemotherapy programme

The adults were managed with conventional doses of vincristine, prednisone, L-asparaginase and Adriamycin. Those achieving complete remission underwent craniospinal prophylaxis and entered a three-year maintenance programme of oral 6-mercaptopurine and methotrexate with monthly drug intensification. The children were stratified into low or high risk; the former were treated with a St Jude regimen [26] and the latter with a modified LSA-L2 protocol [27].

Statistical analyses

These were carried out using established methods [28, 29].

RESULTS (TABLE I)

Age

The median age of the patients with ALL (n = 58) was 19 yr (range 3–69). There were 38 adults with a median age of 24.5 yr (range 16–69); the corresponding figures for blacks were 24 yr (range 19–48), coloureds 20.5 yr (range 16–62), whites 28 yr (range 16–69), and Asians 37 yr (range 34–64). Twenty of the patients were 14 yr or

</table>

Comparison of patient population, complete response, and actuarially predicted survival by phenotype between adults and children aged 14 yr or younger. The small numbers make statistical analysis unreliable but children are seen to generally have higher response rates and better survival than adults. A notable exception is T-ALL where, despite higher response rates in paediatric patients, survival is comparable to that found in the adults. B-ALL is an uncommon group but patients do uniformly poorly.

Editors note: Several of these cases were re-classified by the reference centre (see Table 2 in the paper by Greaves et al.). In particular 5 of the 17 cases of Null-ALL were classified as ALL of uncertain subtype. Three additional cases were considered unclassifiable ALL subtypes.
younger with a median age of 6.5 yr (range 3-14); the corresponding figures for blacks were 11 yr (range 9-13), coloureds 6 yr (range 3-12), and whites 6.5 yr (range 4-14).

**Race**

The 58 patients with ALL were made up of five (8%) blacks, 22 (40%) coloured, 28 (48%) white and three (4%) Asians. When subdivided into adult and paediatric individuals this distribution was constant.

**Common acute lymphoblastic leukaemia (Table 2)**

The median age of these 17 patients was 27 years; two were black, two were coloured, 12 were white and there was one Asian. There were 12 adults having a median age of 37.5 yr; one was black, one was coloured, nine were white and there was one Asian. Five of the patients were children, having a median age of 5 yr; one was black, one was coloured and three were white. The male to female ratio was 12.5; for the adults it was 9:3 and for the children 3:2.

The complete response rate for adults was 50%, and median survival was 23 weeks; for the children complete remission rate 100% and median survival was 76 weeks.

**Null acute lymphoblastic leukaemia (Table 3)**

The median age of these 17 patients was 19 yr; one was black, five were coloured, nine were white and two were Asians. There were 10 adults having a median age of 28.5 yr; there were no black patients, three were coloured, five were white and two were Asian. Seven of the patients were children, having a median age of 9 yr; one was black, two were coloured and four were white. The male to female ratio was 6:11; for the adults it was 5:5 and for the children it was 1:6.

The complete response rate for adults was 70% and median survival was 30 weeks; for the children complete remission rate was 86% and median survival was 62 weeks.

**T-acute lymphoblastic leukaemia (Table 4)**

The median age of these 18 patients was 18 yr; one was black, 12 were coloured and five were white. There were 12 adults, having a median age of 22.5 yr; one was black, eight were coloured and three were white. Six of the patients were children, having a median age of 6.5 yr; there were no black patients, four were coloured and two were white. The male to female ratio was 14:4, for the adults it was 9:3 and for the children 5:1.

The complete response rate for adults was 67% and median survival was 46 weeks; for the children complete remission rate was 100% and median survival was 47.5 weeks.

**B-acute lymphoblastic leukaemia** (Table 5)

The median age of these six patients was 19.5 yr; one was black, three were coloured and two were white. There were four adults, having a median age of 33.5 yr; one was black, two were coloured and one was white. Two of the patients were children, having a median age of 7.5 yr; one was coloured and one was white. The male to female ratio was 2:4; for the adults it was 2:2 and for the children it was 1:1.

The complete response rate for adults was 25% and median survival was 4 weeks; in the children there were no responders and median survival was 7.5 weeks.

**Survival by phenotype**

Pooling the data from adults and children (Fig. 1), median survival is 59 weeks for common ALL, 39 weeks for null ALL, 63 weeks for T-ALL, and 13 weeks for B-ALL. Disease-free survival is 56 weeks for common ALL, 20 weeks for null ALL, and 66 weeks for T-ALL.

**DISCUSSION**

Ethnicity is a powerful prognostic factor influencing the natural history and response to treatment of patients with haematologic malignancy. Thus, comparisons between blacks and whites in New York State with Reef Towns in the Southern Transvaal reveal differences, suggesting that disease expression may be strongly influenced by the social milieu [30]. In a period now exceeding a decade, striking consistent differences have emerged between black, coloured and white patients at our institution. Of these, age has been most clearly documented, with the median for black being between 10 and 15 yr lower than white patients with the same disease, and the coloured population generally occupying an intermediate position.

Furthermore, although response rates for standardised management protocols are not different for race groups matched for other variables, late presentation with high bulk disease, often with sub-optimal nutritional status, show a trend to more frequent occurrence among referred black patients, although similar features may be found in less sophisticated individuals from the coloured and white race groups. In addition, sex distri-
distribution is a less striking but clearly demonstrable variable and, as in chronic granulocytic leukaemia, cytogenetic differences also appear to exist [5], although clinical presentation, haematologic features, response to treatment and survival rates could not be correlated with this finding.

Conventional morphology is insufficiently sensitive to reliably separate immunobiologically distinct subtypes of lymphoid neoplasia within the French-American-British (FAB) classification [12]. Monoclonal antibodies were used for this purpose to prospectively study the influence of age and race on remission rate and survival using standardised protocols for treatment in patients stratified by phenotypic subtype.

In the patients with common and null ALL the phenotype was distributed similarly, both between the adult and the paediatric age groups and, furthermore, there was no significant variation between black, coloured and white patients. Two additional points require comment. Firstly, both complete remission rate and median duration of survival is already showing a trend in favour of patients expressing the common acute leukaemia antigen. Secondly, age is predictably emerging as a favourable prognostic factor for both these immunophenotypic subgroups.

T-ALL is a particularly interesting cohort. Thus, while the age distribution is comparable to the other immunologically defined subgroups, the value of immunophenotypic classification is reflected in an unexpected finding with a clear predominance in young coloured males. Unlike other series reporting a prominence of mediastinal tumour, this finding was unusual in these patients. The complete response rate to standard chemotherapy was also not significantly different from common and null ALL patients, with adults achieving this status in 67% of cases and the children in 100%. However, survival shows two important differences. Firstly, as generally expected, in the paediatric age group this is inferior to the common and null ALL variants; a finding consistent with reports that the T-cell phenotype is an unfavourable prognostic factor in this age group [31]. Secondly, and by way of contrast, adults survive better than any of the other subtypes. To pursue this latter difference in more detail, comparative analysis has been

Fig. 1. Acute lymphoblastic leukaemia. Actuarially predicted survival by phenotype for pooled data from adults (n = 38) combined with children aged 14 yr or younger (n = 20). The notable feature is similarity in the curves for patients with common and T-ALL; the major influence being that of an unusually high occurrence of T-ALL in a subgroup of young coloured males. It is also notable that no plateau is yet evident for the overall population. Separate analysis by age is precluded by small numbers of patients in each immunophenotypically distinct subclass.
undertaken against a control group of patients immunologically classified as common or null-ALL [32].

In this study the complete remission rates were 71% for the T-ALL and 75% for the common or null group while actuarially predicted median duration of survival is 49 and 39 weeks, respectively. While these differences may reflect geographical and racial factors, they may equally well be explained by the thymic phenotype becoming a less reliable marker of poor prognosis with increasing age, and this is likely to be the result of the more aggressive clinical course of all phenotypic subgroups of acute lymphoblastic leukaemia in the adult.

CONCLUSION

Three points are emphasized by this study. Firstly, apparently homogeneous tumour morphology in lymphoproliferative disorders can be misleading and immunologic techniques provide a suitable methodology to more reliably define phenotypically distinct sub-populations. Secondly, the unexpected high incidence of T-ALL in young coloured males is in keeping with other evidence that ethnicity can exert an important and distinctive influence on disease expression. Thirdly, irrespective of race, age emerges as a favourable prognostic factor. Finally, there remains a striking paucity of properly assembled scientific data from countries in Africa, where a unique opportunity exists to define the potential impact of ethnic differences upon the natural history of different disease categories. The importance of the latter information is becoming increasingly appreciated as the role of viral infections and oncogene activation in the pathogenesis of human tumours such as the T-cell leukaemia–lymphoma syndrome is clarified [33]. All these cogent reasons for centres having the necessary expertise and patient populations collaborate in studies to explore this relatively neglected but important facet of geographical haematopathology.

Summary

105 patients with acute lymphoblastic leukaemia (ALL) who received bone-marrow transplants from HLA-identical siblings during first or second remission had an actuarial survival rate at 4 years of 43±12% and an actuarial relapse rate of 32±12%. 98 patients with more advanced disease had a significantly lower probability of survival (15±5%) and a significantly higher probability of relapse (67±14%). Among high-risk patients, those transplanted in first remission had a higher survival probability (55±22%) than those transplanted in second remission (41±15%). Relapse rates in the two groups were comparable (28±24% and 31±19% respectively). Standard-risk and high-risk patients transplanted in second remission had comparable relapse rates, but there was a trend towards higher survival probability in standard-risk patients. Thus long-term disease-free survival in ALL can be achieved with bone-marrow transplantation. It is not yet certain whether transplants in first remission will result in higher survival rates than transplants in second remission; relapse rates were similar in the two groups.

INTRODUCTION

During the past 30 years substantial progress has been made in the treatment of acute lymphoblastic leukaemia (ALL).1-4 Modern intensive chemotherapy can produce remissions in more than 90% of children and more than 70% of adults with ALL.5-7 Long-term disease-free survival is achieved in up to 70% of children with the common form of ALL, and many are cured.8-14 There is, however, a subset of children with ALL with "high-risk" features, such as a high white-blood-cell (WBC) count, particular T or B cell phenotypes, specific chromosome abnormalities, or central-nervous-system (CNS) involvement at the time of diagnosis, who fare less well on chemotherapy.15-17 Similarly, patients aged over 16-20 have a less favourable prognosis.18,19-23 Cure rates in high-risk children and adults with ALL were <30% in most series. Several trials of intensive multidrug chemotherapy have shown improved results in the high-risk group, with survival of up to 50% at 3 years. Nevertheless, treatment with currently available chemotherapy fails in a substantial proportion of both children and adults with ALL. Once a patient with ALL relapses while receiving maintenance chemotherapy, the prognosis is extremely poor, with 2-4 year disease-free survival rates below 10% in most series.24-25

Several centres have reported cure rates of 10-20% with bone-marrow transplantation in patients with advanced resistant leukaemia,26-27 resistant or recurrent leukaemia has been the major cause of treatment failure.28 Attempts to reduce the relapse rate with more intensive preconditioning such as high-dose fractionated total-body irradiation (TBI) have been unsuccessful.29 In an effort to reduce the relapse rate, transplants have been carried out at an earlier stage of the disease, such as in second or third remission.30-32 A few transplants have been done in first remission in patients with high-risk forms of ALL.33-35

In the present report we compare the results of bone-marrow transplantation in patients with ALL at various stages of the disease. In particular, we have investigated survival and recurrence data for patients who, at diagnosis, were thought to be at high risk of recurrent leukaemia if treated with chemotherapy alone and/or who were at high risk because of one or more relapses while receiving chemotherapy.

PATIENTS AND METHODS

239 ALL patients who received bone-marrow transplants between Jan 1, 1977, and Dec 31, 1981, were reported to the International Bone Marrow Transplant Registry (IBMTR). Data for 204 of these patients whose donors were HLA-A and HLA-B identical siblings and whose cells were mutually unresponsive in mixed-lymphocyte-culture (MLC) tests were analysed. 35 of the 239 patients failed to meet the study criteria and were excluded from further analysis. Reasons for exclusion were MLC incompatibility (8 patients), fetal donors (7 patients), identical-twin donors (6 patients), parental donors (4 patients), MLC technical failures (4 patients), unrelated donors (3 patients), MLC and HLA incompatibility (1 patient), HLA incompatibility (1 patient), and HL-A technical failure (1 patient). Each of the 37 transplant centres that provided data for this study certified that they reported their consecutive transplant patients.

The status of the leukaemia was determined immediately before transplantation. Chemotherapy and was based on the criteria of Cancer and Leukaemia Group B.36 Patients with 5% or fewer blasts in the bone-marrow and a normal haemogram, physical examination, and performance status were judged to be in complete remission. Patients with 5-25% blasts in the bone-marrow were considered to be in partial remission, and those with more than 25% blasts were considered to be in relapse.
Patients were considered to be at standard risk or high risk at diagnosis on the basis of a prospective assessment at each transplant centre. Reasons for assignment of 66 of the 106 transplants in first or second remission to the high-risk category included one or more of the following: (a) age <1 or > 18 years (n = 44); (b) white blood cells > 50 × 10⁹/l (n = 12); (c) T or B cell surface markers (n = 22); (d) CNS involvement (n = 4), and (e) specific chromosome abnormality (n = 4). Patients without these findings at diagnosis are referred to as standard risk in this report.

Engraftment of transplanted bone marrow was classified by previously reported criteria. 29 Graft-versus-host disease (GVHD) was regarded as mild, moderate, or severe according to the IBMAT criteria. 26 A GVHD score was given, according to severity and duration of dermatitis, liver-function abnormalities, diarrhoea, and other clinical variables. Inasmuch as there are no signs, symptoms, laboratory tests, or histopathological tests generally accepted as pathognomonic of GVHD, this scoring system is arbitrary. For analysis, GVHD was evaluated as a continuous variable on a four-point scale from none to severe.

An abnormal chest X-ray with diffuse interstitial pattern, severe arterial hypoxaemia, or both in the absence of evidence of bacterial infection or congestive heart failure were the criteria for the diagnosis of interstitial pneumonia. In many cases open-lung biopsy or necropsy confirmed the diagnosis.

The closing date for the analysis was Feb 28, 1983. The minimum follow-up time from transplant for surviving patients was 14 months. In univariate analyses, analysis (without the Yates and Bonferroni correction) was used to test for differences between percentages and Student's t test (without correction for multiple contrasts) for differences between groups when a continuous variable was studied. Actuarial survival and recurrence curves were prepared with the life-table method, 44 and differences between curves were tested with the Lee-Desu statistic. 44 Graphical representation of the curves was terminated when fewer than 3 patients were at risk. Multivariate analyses were carried out using the log-linear analysis 45 and the Cox regression models. All probability values cited, with the exception of the beta errors, are from multivariate analyses.

In this type of investigation, in which group sizes are relatively small, it is often useful to compute the beta error. 47 This computation gives the probability of being wrong when one starts that there is no significant difference between two groups. The beta errors in this study were calculated on the assumption that the observed difference between two groups was the true difference.

RESULTS

We analysed the results of bone-marrow transplantation from HLA-identical siblings in 204 patients with ALL transplanted at various points during the course of their disease, including first remission (20), second remission (65), third remission (22), fourth to seventh remission (8), partial remission (21), and relapse (47). From preliminary study the post-transplant survival and recurrence data, it was apparent that the patients could be divided into two major groups—106 patients transplanted in first or second remission and 98 transplanted with more advanced disease (referred to as > second remission). Within each group there were no significant differences in survival or relapse rates or other transplant-related outcomes.

The distribution and frequency of 15 disease-related and transplant-related variables are presented in Table 1; there were no significant differences between the two cohorts of patients. WBC counts > 50 × 10⁹/l were present at the time of diagnosis in 17% of the first and second remission groups and 19% in the > second remission group. 4 patients in the first and second remission group presented with CNS leukaemia, and 10 patients in the > second remission group had CNS involvement previously or at the time of transplant. Chromosomal abnormalities thought to be associated with a poor prognosis by the transplant teams, such as the Philadelphia chromosome and the (t;4;11) translocation, were reported in 11 patients (6 in the first and second remission group and 5 in the > second remission group).

Leukaemia markers were studied in 106 patients: 6 had B-cell markers, 22 had T-cell markers, 27 had the common ALL antigen (CALLA), and 45 had neither B nor T-cell markers but CALLA studies were not done. Thus, 34 of 106 (32%) patients had B or T cell markers and were thought by the various transplant centres to have an unfavourable immune profile; their distribution between the two transplant cohorts was similar. Newer immune analyses, such as cytoplasmic Ig staining or tests with anti-T mononuclear antibodies, 46 were done in relatively few patients; it is therefore likely that a higher proportion of patients had an immune profile associated with an unfavourable prognosis. The distribution of donor/recipient sex-matching, was also comparable in the two groups.

Almost all patients were conditioned for transplantation with cyclophosphamide and TBI. 85 patients received additional antileukaemic drugs including amascrine, 1-aspargine, 1,3-bis[2-chloroethyl]-1-nitrosourea, busulphan, cytarabine, daunorubicin, doxorubicin, methotrexate, piperazinedine, prednisone, teniposide, thioguanine, and vincristine. Single-dose TBI was given to 137 patients (67%), 65 received fractionated TBI (32%), and 2 were irradiated. There were no significant differences in drug or radiation doses or schedules between the two transplant groups.

In summary, when each of 23 disease-related or transplant-related prognostic variables was analysed, there was no significant difference between the 106 first/second-remission patients and the 98 > second-remission patients.

Among the 106 patients transplanted in first or second remission, the actuarial probability of surviving 4 years was 43% (95% confidence interval [CI], 31.5-55%). In contrast, among patients transplanted with more advanced disease, the actuarial probability of 4-year survival was 15% (95% CI, 6.2-24%). The difference was significant (p = 0.01) (figure, A).
Post-transplant relapse data for the two transplant groups are presented in the figure (B). The actuarial probability of relapse among patients transplanted in first or second remission was 32% (95% CI: 20–44%) at 4 years. Patients who were transplanted when their disease was more advanced had a significantly higher (p<0.001) probability of relapse (57%, 95% CI, 53–81%).

Data on the 106 patients transplanted in first or second remission were analyzed in more detail to determine factors related to transplant outcome. We examined two questions: (a) whether high-risk patients at diagnosis had different outcomes when transplanted in first versus second remission, and (b) whether risk factors at diagnosis affected the outcome of patients transplanted in second remission.

66 of the 106 patients in first or second remission were considered to be high risk at diagnosis. These included all 20 first-remission transplants and 46 of 86 second-remission transplants. Age (<1 or >18 years), WBC (≥50×10⁹/L) and/or T or B cell leukemia were the major reasons for designating them high-risk patients (56 of 66), and these features were equally distributed between the two groups. With the exception of interval from diagnosis to transplant (median for first remission 5–5 months, second remission 17–5 months), the two groups were comparable for the variables shown in Table 1. Survival and relapse data for the high-risk patients transplanted in first versus second remission are given in Table 1. Two-year survival was 55±22% for first-remission transplants, compared with 41±15% for transplants in second remission (p=0.38; p<0.83). Relapse rates were 28±24% and 31±19%, respectively.

86 patients were transplanted in second remission—40 with standard-risk and 46 with high-risk features at diagnosis. The two groups were comparable for the variables indicated in Table 1. Survival and relapse data are shown in Table 2. 2-year actuarial survival was 53±17% in 40 patients without high-risk features at diagnosis and 41±15% in patients who were at high risk at diagnosis (not significant; p=0.46, p<0.81). Relapse rates were similar—28±16% and 31±19%, respectively.

Comparison of transplant outcome in patients without high-risk features transplanted in first versus second remission was not possible, because all 20 patients transplanted in first remission were identified at having high-risk features at diagnosis.

In addition to recurrent leukemia, GVHD and interstitial pneumonia (IPN), either alone or together, were other major causes of treatment failure. Mild, moderate, or severe GVHD developed in 104 (59%) of the 189 recipients who survived at least 3 weeks with evidence of engraftment and caused death in 54 (18%). In multivariate analyses, GVHD was significantly (p<0.001) associated with survival; the more severe the GVHD, the lower the survival rate. IPN developed in 61 (30%) of the 204 patients and was fatal in 46 (23%); all cases of IPN appeared within the first week, and the actuarial incidence was 9%. The occurrence of IPN was associated with a significantly lower (p<0.001) probability of survival. Post-transplant infections were often associated with GVHD and/or IPN and developed in 70% of the 204 patients. Infection was a primary or contributory cause of death in 51 patients (25%). There were no significant differences in the incidence or severity of GVHD, IPN, or infection between patients transplanted in first or second remission and those transplanted at a later stage of the disease. Failure to obtain engraftment was not a problem, occurring in only 1 of 190 patients who survived at least 3 weeks.

DISCUSSION

These results show that it is possible to achieve long-term leukemia-free survival in a substantial proportion of individuals with ALL, including those who do not respond to conventional and experimental chemotherapy. The best results were observed in patients transplanted in first or second remission, the 4-year probability of survival being 43% (±12%) and that of relapse 32% (±12%). Even patients...
with advanced disease benefited from transplantation, the probability of leukaemia-free survival being 15% (±5%) 4-7 years after transplant; these results probably are superior to those achieved with alternative therapeutic modalities.\(^{11-15}\) We and others have found that earlier transplantation benefits patients with acute myelogenous leukaemia (AML). Transplantation in first remission was found to be associated with the lowest probability of leukaemia relapse and the highest probability of long-term disease-free survival. The results of the present study show that earlier transplantation in ALL produces the same favourable trend as in AML; patients transplanted in first or second remission had a significantly higher probability of survival and of remaining in remission than did patients transplanted with more advanced disease.

Among patients who were at high risk at diagnosis, those who received a transplant in first remission had a higher survival rate than those transplanted in second remission (55±22% vs 41±15%), but the difference was not significant. However, the possibility of a beta-type error was high, and more patients and longer follow-up will be required to determine if this trend will persist. We found no suggestion of a lower relapse rate between patients in first and second remission (28±24% vs 31±19%).

Several other factors should be considered in the analysis of these data and their implications. First, only a proportion of high-risk patients who relapse during or following treatment with chemotherapy will achieve a second remission;\(^{12-15}\) estimates range from 10 to 70% depending on the clinical circumstances and treatment regimen. Secondly, the survival of ALL patients after relapse is affected to a major extent by whether relapse occurred during or after completion of maintenance chemotherapy.\(^{36,57}\) Thirdly, factors that accurately predict risk of relapse at diagnosis are of less (or no) consequence in patients who have remained in remission for at least 2 years.\(^{44}\) Thus the ultimate prognosis for high-risk patients who relapse will depend, in large measure, on whether they were on or off chemotherapy and the interval from remission to relapse; these factors are clearly interrelated as well. Finally, high-risk patients who achieve a second remission represent a biased population in that they have responded to chemotherapy. Because of the complexity of these and other issues, we urge caution in the interpretation of the aforementioned data on transplant outcome in high-risk ALL. The critical questions of the relative efficacy of transplantation in either first or second remission versus chemotherapy can only be answered in a prospective randomised trial.

We also analysed the results of transplantation in second remission in patients who had standard versus high-risk ALL at the time of initial diagnosis. Again a trend towards higher survival probability but no difference in relapse probability was observed. Results of transplantation in second remission were far more variable regardless of the initial risk assessment. Most of these 85 patients had relapsed while receiving maintenance chemotherapy. Even so, 2-year survival was 47±11% and the relapse rate only 29±12%. These results are at least as good as those reported with other therapeutic modalities in similar patients.\(^{13-15}\)

This study analysed the results of bone-marrow transplantation in patients with ALL at various stages. The results of transplantation in first or second remission were clearly superior to those achieved when the disease was more advanced. We were unable to determine whether transplantation in first remission conferred any survival advantage over transplants in second-remission patients who presented initially with high-risk features. Relapse rates did not appear to be affected. This study did not address the important issue of the relative efficacy of transplantation versus chemotherapy in the various stages of ALL. These questions need to be addressed by performing prospective randomised controlled clinical trials with appropriate stratification; some of these trials are in progress.

Marrow Transplantation for Acute Lymphoblastic Leukemia: Factors Affecting Relapse and Survival

Transplant outcome was analyzed in 690 recipients of bone marrow transplants (BMTs) for acute lymphoblastic leukemia (ALL) in first (n = 299) or second remission (n = 391). Actuarial 5-year leukemia-free survival was 42% ± 9% (95% confidence interval) and 26% ± 6%, respectively; relapse rates were 29% ± 9% and 52% ± 8%, respectively. Five-year leukemia-free survival was 56% ± 18% in children and 39% ± 10% in adults (P < .02) transplanted in first remission. In first-remission adults, non-T-cell phenotypes, bone-marrow donor-recipient mismatch and graft-vs-host disease (GVHD) were associated with decreased leukemia-free survival; inclusion of corticosteroids in the regimen to prevent GVHD was associated with increased leukemia-free survival. Variables associated with decreased leukemia-free survival after second-remission transplants were age ≥16 years and relapse occurring while on therapy. Variables associated with increased probability of relapse were similar for first- and second-remission transplants and included GVHD prophylaxis without methotrexate and absence of GVHD. In first-remission transplants, leukocyte count ≥50 × 10^9/L at diagnosis was also associated with increased relapse; in second remission, relapse while receiving chemotherapy was also associated with increased posttransplant relapse. These data emphasize the importance of both disease- and transplant-related variables in predicting outcome after BMT. They may be used to explain differences between studies, design future trials, and identify persons most likely to benefit from BMT.

C H E M O T H E R A P Y C U R E S a substantial proportion of patients with acute lymphoblastic leukemia (ALL). However, some patients have a high risk of relapse when treated with conventional regimens. These persons can be identified by certain patient- and disease-related variables. Treatment of high-risk patients has evolved over the past decade, and recent studies of intensive chemotherapy indicate improved results. Like high-risk patients, persons who relapse soon after achieving remission have a poor prognosis; few if any achieve long-term leukemia-free survival, although recent improvements in outcome are reported.

Bone marrow transplantation (BMT) has also been used to treat ALL. Results in first remission are encouraging. Transplants performed in second remission for persons who fail chemotherapy result in 5-year leukemia-free survival rates of 10% to 40% depending on the circumstances of relapse.

The relative roles of chemotherapy and BMT in high-risk children and adults with ALL and in persons who relapse after chemotherapy are controversial. Ideally, one would like to select patients for transplant whose predicted outcome with chemotherapy is poor. This approach is based on the assumption that factors which predict poor outcome with chemotherapy do not adversely influence transplant outcome. If, as suggested by several studies, similar disease and treatment characteristics are associated with poor prognosis after chemotherapy and BMT, the outlook for such patients may not be significantly improved by transplant. Deciding which is the better therapeutic option would thus be better addressed by comparing the results of chemotherapy and BMT in patients with similar prognostic features.

Prognostic factors for outcome of patients after BMT for ALL are currently ill-defined. Neither is there any agreement regarding the best transplant regimen. This study was undertaken to define patient and disease characteristics predictive of outcome after transplantation for ALL in first and second remission and to identify transplant-related approaches associated with decreased relapse and increased leukemia-free survival.
MATERIALS AND METHODS

Population

Patients with ALL (1,212) receiving allogeneic BMT between January 1, 1978 and December 31, 1986 were reported to the International Bone Marrow Transplant Registry (IBMTR) by 107 teams worldwide. Data for 690 recipients of HLA-identical sibling transplants were analyzed, including 299 patients transplanted in first complete remission (CR) and 391 patients transplanted in second CR. Excluded from this analysis were 177 patients who received marrow from a donor other than an HLA-identical sibling, 103 patients transplanted in third to eighth remission, 235 patients transplanted in relapse, and five patients whose disease status at the time of transplant was uncertain.

CR was defined as the absence of both medullary and extramedullary leukemia. Relapse includes both medullary and extramedullary sites. Patient, donor, and treatment characteristics are shown in Table 1. Age ranged from 1 to 48 years; 56 patients transplanted in first remission and 218 patients transplanted in second remission were aged <16 years. The median interval from diagnosis to first remission was 6 weeks. Among the 391 patients transplanted in second remission, 289 had their first relapse while receiving chemotherapy. The median duration of follow-up was 21 (range 4 to 93) months. Twenty-seven percent of patients were followed ≥ 3 years.

Children and adults transplanted in first remission differed significantly in race (58% white children v 77% white adults, P < .03), immune phenotype (54% T cell v 25% T cell, P < .001; 11% B cell v 5% B cell, P < .03), median leukocyte count at diagnosis (53 v 14 x 10^9/L, P < .0002), and presence of CNS leukemia at diagnosis (11% v 4%, P < .04) (Table 1). These differences in disease characteristics were presumably due to differences in selection criteria for transplant. Consequently, children and adults in first remission were analyzed separately. No significant differences in disease characteristics were evident between children and adults transplanted in second remission; they were analyzed as a single group.

Treatment regimens were similar for patients transplanted in first and second remission. Six hundred eighty patients (98%) received total body irradiation (TBI, median 10 Gy) in either single (42%) or multiple (58%) fractions. Eighty-five percent also received cyclophosphamide: 70% received cyclophosphamide alone, 9% received cyclophosphamide plus cytarabine, and 6% received cyclophosphamide plus other drugs. Fifteen percent received conditioning regimens that did not include cyclophosphamide: 12% received cytarabine with or without other drugs, and 3% received other drugs. Several methods were used to prevent graft-vs-host disease (GVHD). Most (97%) patients received one of the following: methotrexate with or without corticosteroids, cyclosporine with or without corticosteroids, methotrexate plus cyclosporine, or T-cell deletion of donor marrow with or without additional posttransplant immunosuppressive drugs (Table 1).

Statistical Methods

Actuarial probabilities of relapse and leukemia-free survival were calculated by standard life-table methods. Survival and relapse curves were terminated when fewer than three patients remained at risk (Figs. 1-4).

Identification of risk factors for relapse and survival was not attempted among children transplanted in first remission. They were heterogeneous both for disease characteristics and treatment regimens, and the number of patients was too small to allow adequate adjustment for this heterogeneity in multivariate analysis.

The variables in Table 1 were examined for their association with probability of relapse and leukemia-free survival for adults transplanted in first remission and all patients transplanted in second remission. The Lee-Desu statistic was used for univariate analysis. Variables significant in univariate analysis with P < .1 were examined in multivariate analysis using a proportional-hazards regression model with relapse and treatment failure as endpoint variables. Treatment failure was defined as either relapse or death from other causes.

GVHD was defined as moderate to severe (grade II through IV) acute GVHD and/or any grade of chronic GVHD for this analysis. GVHD was entered as a time-dependent covariate in the regression equation so that patients were scored as not having GVHD until the time of onset of grade II through IV acute or any grade of chronic GVHD.

Variables not significantly associated (P > .05) with probability of relapse and/or treatment failure were excluded from the regression model by a backward elimination procedure. Because of the multiple comparisons made, only P < .01 was considered significant. P between .01 and .05 was considered of borderline significance and should be interpreted with caution. Relative risks of relapse and treatment failure were derived from the proportional-hazards model and represent the risk for patients with unfavorable characteristics as compared with those with favorable characteristics, adjusted for effects of other variables in the model. Continuous variables were dichotomized to calculate relative risk. Results of multivariate analyses were examined for possible influence by differences among centers unaccounted for by recorded information by (a) repeating each analysis on the subgroup of patients transplanted in small centers and the subgroup transplanted in large centers; (b) entering center size (ie, the number of patients transplanted for ALL by a particular center during the study period) as a covariate in the regression equations and; (c) by repeating each analysis after excluding patients from each of the eight largest centers in turn. No substantial difference in the relative risks associated with the prognostic variables could be detected with any of these adjustments. Factors predictive of outcome were valid at both small and large centers. All P values are two-tailed and based on the results of multivariate analysis unless otherwise specified.

RESULTS

Results of transplants in first and second remission are shown in Table 2 and Fig. 1. Children aged <16 years transplanted in first remission had a 5-year probability of relapse of 27% ± 16% (95% confidence interval); their 5-year probability of leukemia-free survival was 56% ± 18%. Adults transplanted in first remission had a similar probability of relapse (30% ± 10%) but a lower probability of leukemia-free survival (39% ± 10%, univariate P < .02). Children and adults transplanted in second remission had a 5-year relapse probability of 52% ± 8%. The probability of leukemia-free survival was significantly lower for patients transplanted in second remission (26% ± 6%) than for children (univariate P < .0003) and adults (univariate P < .02) transplanted in first remission. Causes of treatment failure differed in these groups (Table 2). The most common cause of treatment failure among children transplanted in first remission was relapse. Adults transplanted in first remission had similar rates of relapse but increased mortality owing to transplant-related complications such as GVHD and interstitial pneumonitis. Children and adults transplanted in second remission had higher incidences of both relapse and fatal

Fig 3. Probability of leukemia-free survival after BMT of adults with ALL in first remission according to whether or not steroids were administered in addition to methotrexate or cyclosporine to prevent GVHD.

Prognostic Factors for Adults in First Remission

Relapse. Use of methotrexate, especially when administered with corticosteroids, to prevent GVHD was associated with the lowest probability of relapse in this study (Table 3, Fig 2). Sixty-one adults who received methotrexate alone had a 3-year probability of relapse of 17% ± 14%; none of 34 first-remission adults who received both methotrexate and corticosteroids relapsed. In multivariate analysis, the proba-
(29% ± 20%, n = 27) or not receiving (35% ± 32%, n = 20) additional posttransplant immunosuppression. Only ten patients, too few for critical analysis, received both cyclosporine and methotrexate to prevent GVHD.

Development of acute and/or chronic GVHD was significantly associated with the probability of posttransplant relapse among adults transplanted in first remission. Patients without GVHD had a risk of relapse 3.1 times higher than patients with acute and/or chronic GVHD (P < .0004, group 2, Table 4). This effect was independent of the effect of methotrexate on relapse. Leukocyte level at diagnosis had a borderline association with relapse. Adults with leukocytes > 50 \times 10^9/L had a relative risk of relapse of 2.5 (P < .03) as compared with those in whom leukocytes were \leq 50 \times 10^9/L (group 2, Table 4). No other risk factor investigated, including age, time to achieve first remission, immune phenotype, and CNS leukemia at diagnosis, was significantly associated with the likelihood of relapse.

**Leukemia-free survival.** The highest probability of leukemia-free survival was observed in patients receiving corticosteroids for prophylaxis of GVHD in combination with either methotrexate or cyclosporine (Table 3, Fig. 3). The 3-year probability of leukemia-free survival was 67% ± 16% for 34 adults receiving methotrexate plus corticosteroids and 62% ± 27% for 20 receiving cyclosporine plus corticosteroids; it was 40% ± 13% for 61 patients who received methotrexate alone, 33% ± 16% for 69 who received cyclosporine alone, and 34% ± 20% for 47 who received T-cell-depleted BM. In multivariate analysis, patients receiving methotrexate or cyclosporine without corticosteroids had a significantly higher probability of treatment failure (death or relapse) than those who also received corticosteroids (relative risk 2.8, P < .004, group 1, Table 5). The reasons for treatment failure differed according to the prophylactic regimen used (Table 3). Interstitial pneumonitis was the primary cause of mortality among patients receiving methotrexate, whereas relapse was more common among patients receiving cyclosporine. Addition of corticosteroids to either methotrexate or cyclosporine was associated with a decreased incidence of both relapse and other fatal transplant complications. Patients who developed acute and/or chronic GVHD had a risk of treatment failure 1.9 times as high as those without GVHD (relative risk 1.9, P < .002, group 2, Table 5).

Donor-recipient sex match was significantly associated with leukemia-free survival. Females receiving grafts from male donors had a higher risk of treatment failure (relative risk 2.2, P < .002, group 3, Table 5) than those receiving grafts from females and than males receiving grafts from female or male donors. Female recipients of male transplants were similar to other patients in age, sex, immune phenotype, conditioning regimen received, and method of GVHD prophylaxis used. They did not have a significantly higher incidence of graft failure or GVHD. They did have somewhat higher leukocytes at diagnosis than other patients (median 35 × 10^9/L vs. 12 × 10^9/L, univariate P = .07). The reasons for treatment failure were not different for this group than for other sex-match combinations.

A borderline association was observed between immune phenotype and leukemia-free survival (group 4, Table 5). Patients with non-T-cell phenotypes (common ALL antigen [CALLA] null, or unclassified) had a higher risk of treatment failure than patients with T-cell ALL (relative risk 1.7, P < .02). The number of patients with B-cell ALL was too small for multivariate analysis. No other disease-related or treatment characteristic was significantly associated with leukemia-free survival among adults transplanted in first remission. In particular, the time to achieve CR, composition of the conditioning regimen, and posttransplant antileukemia treatment had no significant association with outcome.

Prognostic Factors for Patients Transplanted in Second Remission

Relapse. The regimen used to prevent GVHD was significantly associated with the probability of relapse among children and adults transplanted in second remission of ALL. Patients who received methotrexate with or without corticosteroids to prevent GVHD had a 3-year probability of relapse of 43% ± 11% (Fig 4). In contrast, the 3-year probability of relapse was 64% ± 15% for patients receiving cyclosporine and 68% ± 26% for patients receiving T-cell-depleted BM. Patients treated with cyclosporine or T-cell-depleted BM had a risk of relapse 3.1 times higher than that of methotrexate-treated patients (P < .0001, group 1, Table 4).

An antileukemia effect associated with GVHD was also observed. Patients without GVHD had a risk of relapse 2.0 times higher than those developing acute and/or chronic GVHD (P < .002, group 2, Table 4). This effect was independent of the effect of methotrexate on relapse.

Patients whose first relapse occurred while receiving chemotherapy had a risk of relapse posttransplant 3.3 times higher (P < .0002, group 4, Table 4) than that of patients whose first relapse occurred later. Information regarding the length of time patients were on or off maintenance chemotherapy was not available for analysis.

Leukemia-free survival. Age at time of transplant correlated with the probability of leukemia-free survival after second remission transplants (group 5, Table 5). Patients aged ≥16 years had a risk of treatment failure 1.6 times higher than that of younger patients (P < .0002). The time of first relapse was marginally associated with risk of treatment failure (group 6, Table 5): patients whose relapse occurred while they were receiving chemotherapy had a risk of treatment failure 1.7 times higher than that of patients whose relapse occurred after they completed chemotherapy (P < .02). No other pretransplant or treatment characteristic was significantly associated with probability of relapse or leukemia-free survival in multivariate analysis of patients transplanted in second remission.

DISCUSSION

Effect of GVHD Prophylaxis

This analysis demonstrates a significantly higher risk of relapse associated with use of cyclosporine and in vitro T-cell depletion of donor BM to prevent GVHD as compared with methotrexate in both first and second remission transplants for ALL. Similar but somewhat higher relapse rates have been reported by other investigators after use of methotrexate after BMT for adult ALL. An increased risk of relapse has been reported with T-cell-depleted transplants in both acute and chronic leukemia. T-Lymphocyte depletion has been postulated to increase leukemia relapse by removing cells responsible for a graft-versus-leukemia effect. This would not explain the relapse rates observed in recipients of non-

†Children and adults.

T-cell-depleted transplants receiving cyclosporine unless cyclosporine inhibits the same graft-v-leukemia cells that are removed by T-cell depletion. Neither is the increase in relapse fully explained by an effect of cyclosporine on leukemia cells since T-cell depletion with and without cyclosporine was associated with similar probabilities of relapse. It is unlikely that methotrexate and steroids cause decreased relapse by increasing the incidence of GVHD and GVHD-associated antileukemia effects because the incidence of GVHD was similar in patients treated with methotrexate or cyclosporine. Furthermore, this effect persisted despite adjustment for the effect of GVHD in multivariate analysis. We believe that the association of methotrexate and corticosteroids with decreased relapse is most consistent with a direct antileukemia effect. Both drugs are active in ALL; they may work in the posttransplant period in a manner similar to maintenance chemotherapy. However, this contrasts with lack of a detectable effect of antileukemia maintenance therapy on outcome in this analysis and in a recent small single-center study. An effect of maintenance chemotherapy may be obscured by the effect of GVHD prophylaxis. Alternatively, differences in timing of therapy may be of crucial importance. Methotrexate and steroid prophylaxis for GVHD are administered immediately posttransplant, whereas maintenance chemotherapy is usually delayed for several weeks or more until stable engraftment occurs.

Methotrexate was associated with a fivefold decrease in relapse risk in first remission transplants and a threefold decrease in second remission transplants. No improvement in leukemia-free survival was observed in methotrexate-treated patients, however, due to increased mortality from interstitial pneumonitis. Corticosteroids appear to have a separate association with relapse (Table 3), reducing the risk of relapse by ~15% to 20% in both methotrexate- and cyclosporine-treated patients. This difference was not statistically significant. However, steroids used in addition to methotrexate or cyclosporine were associated with a 2.8-fold increase in leukemia-free survival in first-remission adult transplants due to modest decreases in both relapse and death from transplant-related complications. A similar effect was not observed in second-remission transplants. These findings suggest the desirability of randomized trials in ALL evaluating early use of corticosteroids for posttransplant maintenance therapy.

Effect of Other Transplant-Related Factors

GVHD. GVHD can have both favorable and unfavorable effects on transplant outcome. It may reduce the risk of leukemia relapse but increase transplant-related mortality. In first remission, the decreased relapse rate in patients with acute and/or chronic GVHD was more than offset by the increased risk of death from other causes. Consequently, patients with GVHD had lower leukemia-free survival (relative risk of treatment failure 1.9). In second remission, a similar decrease in relapse rate occurred but leukemia-free survival was not significantly altered. This may reflect the younger age of second-remission patients since the case fatality rate of GVHD is lower in younger persons.

Conditioning regimen. Leukemia relapse remains a major problem after BMT for ALL. To address this problem, addition of other drugs to cyclophosphamide and TBI and variations in radiation doses and schedules have been tried. Some studies used nodal irradiation or intrathecal chemotherapy to prevent relapse in sanctuary sites. Posttransplant leukemia maintenance therapy has also been administered. Because of the small number of patients available for analysis and the relative homogeneity of regimens used within single institutions, the impact of variation in these therapies can best be examined in multicenter studies. In this analysis of nearly 700 patients, none of the maneuvers decreased relapse rates. However, this study was limited to patients transplanted before 1987. Only small numbers of patients were treated with recently introduced regimens such as hyperfractionated TBI or combinations of high-dose etoposide or cytarabine and TBI, which are reported to affect outcome favorably.

Donor-recipient sex match. An unexplained finding was the high relapse rate and significantly increased risk of treatment failure in females receiving transplants from male donors. A similar observation was made in a recent European Bone Marrow Transplant Group analysis. No confounding prognostic variables could be detected, and there is no obvious explanation for the poor prognosis of such patients. One possibility is that host sensitization against H-Y antigens adversely affects the interaction between host and donor cells responsible for a putative graft-v-leukemia effect. However, the small number of patients available for study suggests that caution should be exercised until the
validity of this observation is confirmed or refuted with a larger sample.

Effect of Disease-Related Factors

The probability of leukemia-free survival with intensive chemotherapy overlaps results reported with transplants in first remission.\textsuperscript{11,12} It is not surprising, therefore, that controversy exists regarding their relative merits. Knowledge of whether prognostic variables for chemotherapy are similar to or different from those for transplantation would be useful in addressing this problem.

In this analysis, two prognostic factors reported to have an adverse effect on chemotherapy outcome\textsuperscript{5,12} were associated with adverse outcome of adults transplanted in first remission: leukocytes at diagnosis $>50 \times 10^3/L$ and non-T-cell phenotypes. Insufficient information was available to permit evaluation of the prognostic significance of null cell as compared with non-T, non-B, CALLA$^+$ ALL. These findings emphasize the need to stratify trials of chemotherapy $\rightarrow$ transplantation for cell type and leukocyte level at diagnosis. The interval between diagnosis and CR was not associated with transplant outcome in this study, in contrast to its importance in adults\textsuperscript{13,14} and children\textsuperscript{11,12} receiving chemotherapy, suggesting that patients requiring prolonged induction therapy might do better with transplantation. This should be confirmed in a randomized trial.

That no disease-related factor identifiable at diagnosis had prognostic value for patients transplanted in second remission suggests that the dominant prognostic feature in this group, the failure of primary therapy, overrides other variables. The situation at the time of first relapse was important: patients relapsing while still receiving chemotherapy had a 3.3-fold increase in risk of posttransplant relapse and a 1.7-fold increase in risk of treatment failure as compared with patients relapsing after discontinuing chemotherapy. The favorable prognosis of patients whose first relapse occurred off chemotherapy is consistent with similar observations in patients receiving chemotherapy,\textsuperscript{12,13} suggesting that prospective trials comparing chemotherapy $\rightarrow$ transplant in second remission should be stratified by this variable to allow valid comparison.

Transplantation of Children in First Remission

The data show that general policy has been to select for transplant only a small proportion of children with ALL in first remission and that these children have features perceived by the attending physicians as predicting a high risk of relapse if treated with chemotherapy.\textsuperscript{7} Thus, of the 56 children reported, most had T-cell ALL, CNS leukemia at presentation, or an initial leukocyte count $>50 \times 10^3/L$ (Table 1). Several had more than one adverse prognostic feature. Despite these poor prognostic features, leukemia-free survival was 56% at 5 years. Whether these results might have been achieved with chemotherapy is unknown; however, most recent studies report equivalent or better results. These data underline the need for prospective trials to compare transplantation in first remission with chemotherapy for children with high-risk ALL.

ACKNOWLEDGMENT

We thank D’Etta Waldock Koser, Sharon K. Gurgul, and Todd M. Siebert for help with data analysis, and Karen A. Witekowska and Pauline C. Sova for manuscript preparation.

Factors Associated with Early Mortality Following Allogeneic Bone Marrow Transplantation for Acute Myelogenous Leukemia: A Report From the International Bone Marrow Transplant Registry

M. M. Bortin, R. P. Gale, and A. A. Rimm for the Advisory Committee of the Registry

Comprehensive data were reported to the International Bone Marrow Transplant Registry (IBMTR) by 28 bone marrow transplant centers regarding 156 patients with acute myelogenous leukemia (AML) who were treated with chemoradiotherapy and allogeneic bone marrow transplantation between 1978 and 1980. All patients reported to the IBMTR were included in the study. Sixty-one patients currently are alive and 95 have died; 68 (72%) of the deaths occurred in the first 6 months, 15 (16%) in the second 6 months, and 12 (13%) from 12 to 30 months posttransplant. The purpose of this study was to evaluate more than 20 pre- and posttransplant variables to determine whether they were associated with mortality within 6 months posttransplant or life-threatening complications during the first 6 months posttransplant. The major complications associated with 6-month mortality were infection, interstitial pneumonitis, and graft-versus-host disease (GVHD). Although recurrent leukemia was the primary cause of death for 63% (17/27) of the late deaths, it accounted for only 13% of the deaths within the first 6 months. Thus, recurrent leukemia was a major problem only for patients who survived more than 6 months posttransplant and will be the subject of a separate report from the IBMTR.

Pretransplant Clinical Findings

All 156 patients were included in the general designation of AML and all were considered to have a poor prognosis. The distribution of AML by subtypes was undifferentiated (12 patients), myelocytic (85 patients), promyeloctic (8 patients), myelomonocytic (35 patients), monocytic (8 patients), and erythroleukemia (8 patients). No significant differences were detected between the various subtypes of leukemia and outcome and, therefore, the data were pooled for statistical analysis. Bone marrow transplantation was performed in first complete remission (85 patients), second to fourth complete remission (26 patients), partial remission (22 patients) and relapse (23 patients). Patients were evenly distributed with respect to sex, and

ranged in age from 1 to 62 years, median 24 years of age; 12% were 40 years of age or older at the time of transplantation. Donors and recipients were compatible at HLA-A, HLA-B, and in mixed leukocyte culture tests in 87% of the transplants. Donor-recipient histocompatibility was uncertain in 4% and incompatibility was present in 8%.

During the week pretransplant, all 156 patients were given high doses of antileukemic and immunosuppressive chemotherapy and, in addition, 154 patients received ≥ 8.0 Gy total body irradiation (TBI). Dose-rates of TBI ranged from 2.0 to 30.0 cGy/min with a median of 6.5. To prevent or modify graft-versus-host disease (GVHD), 100 patients were given methotrexate (MTX) and 51 received cyclosporin-A (CyA). Excluded from the analysis were 5 patients who received both MTX and CyA or neither.

STATISTICAL ANALYSIS

The prognostic factors that were included in the analyses are shown in Table 1. Multivariate techniques were used for data analysis because they provide an estimate of the effect of each prognostic variable on each outcome variable after adjusting for all other variables. The multiple logistic function analysis was used when the outcome variable could be measured on a binary scale and the Cox regression method was used to compare survival curves. The prognostic variables of dose-rate of TBI and drug used to prevent or modify GVHD were confounded and, as a consequence, it is not possible to state whether one or both of these variables were associated with outcome.

RESULTS

The 6-month survival rates for the 156 patients according to disease status at the time of transplantation were: first complete remission, 67% (57/85); second to fourth complete remission, 58% (15/26); partial remission, 45% (10/22); and relapse, 26% (6/23). There was a significant association between status of the disease at the time of transplantation and 6-month survival (p < 0.001). The main causes for treatment failure within the first 6 months posttransplant were infection (especially bacterial, fungal, and viral sepsis, and bacterial pneumonia), interstitial pneumonitis, and GVHD.

Among the 85 patients transplanted in first complete remission, the prognostic factors showing significant associations with 6-month mortality were the occurrence of moderate or severe GVHD and use of high dose-rates of TBI. Interstitial pneumonitis occurred with significantly increased frequency among patients given low doses of bone marrow cells, high-dose rate TBI, and/or MTX for prophylaxis of GVHD. Six-month outcome tended to be worse among older patients, those given many pretransplant transfusions, those who were infected at the time of transplantation, and if donors and recipients were incompatible in mixed leukocyte culture tests.

DISCUSSION

This study disclosed five prognostic factors that had significant (p < 0.01) associations with a favorable 6-month outcome: transplantation in first complete remission in comparison with more advanced disease status; administration of higher versus lower doses of bone marrow cells; occurrence of no or mild versus moderate or severe GVHD; use of lower versus higher dose-rates of TBI; and/or administration of CyA versus MTX as prophylaxis of GVHD. In addition, 6-month outcome tended to be favorable (0.10 <
Among younger in comparison with older patients, patient given few versus many pretransplant transfusions, absence versus presence of infection at the time of transplantation, and donor/recipient compatibility versus incompatibility in reciprocal mixed leukocyte culture tests.

Many of the prognostic factors found in this study that appeared to have an important impact on outcome can be controlled by the referring physician or by the bone marrow transplant team. If one assumes that at least some of these factors will be confirmed as having prognostic importance when tested under carefully controlled conditions, then one would expect improvement in the 6-month survival rates reported here. Further, as much as the mortality rate among patients who survived more than 6 months was relatively low, an increase in the 6-month survival rate may very well lead to an improved overall survival experience.

LIMITATIONS OF THIS REPORT

It is important to emphasize that the data summarized in this article were not based on a prospective randomized trial. Differences in practice, experience, and number of patients reported varied widely among the 28 centers that provided their data to the IBMTR. Thus, factors that appeared to have significant associations with outcome may have been influenced by the differences between centers. On the other hand, the random variability between centers tends to obscure significant differences and, we believe, the findings reported here represent conservative estimates of the associations that will be found when controlled clinical trials are employed.

CONCLUSIONS

Five prognostic factors were disclosed that had significant associations with outcome in the first 6 months following allogeneic bone marrow transplantation for AML. Four additional prognostic factors had suggestive associations with 6-month outcome. We recommend that controlled clinical trials be conducted to evaluate prospectively the influence on outcome of the prognostic factors reported here.
Graft-Versus-Leukemia Reactions After Bone Marrow Transplantation

To determine whether graft-versus-leukemia (GVL) reactions are important in preventing leukemia recurrence after bone marrow transplantation, we studied 2,254 persons receiving HLA-identical sibling bone marrow transplants for acute myelogenous leukemia (AML) in first remission, acute lymphoblastic leukemia (ALL) in first remission, and chronic myelogenous leukemia (CML) in first chronic phase. Four groups were investigated in detail: recipients of non-T-cell depleted allografts without graft-versus-host disease (GVHD), recipients of non-T-cell depleted allografts with GVHD, recipients of T-cell depleted allografts, and recipients of genetically identical twin transplants. Decreased relapse was observed in recipients of non-T-cell depleted allografts with acute (relative risk 0.68, \( P = .031 \)), chronic (relative risk 0.43, \( P = .011 \)), and both acute and chronic GVHD (relative risk 0.23, \( P = .0001 \)) as compared with recipients of non-T-cell depleted allografts without GVHD. These data support an antileukemia effect of GVHD. AML patients who received identical twin transplants had an increased probability of relapse (relative risk 2.58, \( P = .008 \)) compared with allograft recipients without GVHD. These data support an antileukemia effect of allogeneic grafts independent of GVHD. CML patients who received T-cell depleted transplants with or without GVHD had higher probabilities of relapse (relative risks 4.45 and 6.91, respectively, \( P = .0001 \)) than recipients of non-T-cell depleted allografts without GVHD. These data support an antileukemia effect independent of GVHD that is altered by T-cell depletion. These results explain the efficacy of allogeneic bone marrow transplantation in eradicating leukemia, provide evidence for a role of the immune system in controlling human cancers, and suggest future directions to improve leukemia therapy.

555
MATERIALS AND METHODS

Population. Comprehensive data for 5,561 persons receiving bone marrow transplants for ALL, AML, or CML between January 1, 1978 and July 31, 1988, were recorded by 142 teams to the International Bone Marrow Transplant Registry (IBMTR). This study was restricted to the 2,254 patients with ALL in first remission (n = 439), AML in first remission (n = 1,046) or CML in chronic phase (n = 769) transplanted from an identical twin or HLA-identical sibling donor and receiving methotrexate, cyclophosphamide, and/or T-cell depleted bone marrow to prevent GVHD. Of these, 2,912 patients were alive at the time of transplant, 301 recipients of transplants from donors other than HLA-identical siblings, and 60 patients receiving either cyclophosphamide against GVHD (except for identical twins) or regimens other than methotrexate, cyclophosphamide, and/or T-cell depletion to prevent GVHD. Because the purpose of this study was to examine the influence of the graft upon leukemia relapse, 134 patients who failed to engraft or who did not survive long enough (2-21 days) to evaluate engraftment were also excluded from analysis.

Patient, disease, and treatment characteristics for the 2,254 subjects are shown in Table 1. Actuarial probabilities of relapse and leukemia-free survival at 5 years for patients with ALL were 30% ± 7% (95% confidence interval) and 44% ± 7%, respectively; for patients with AML, 23% ± 4% and 52% ± 6%, respectively; and for patients with CML, 23% ± 6% and 46% ± 5%, respectively. In 99% of cases, pretransplant conditioning consisted of total body radiation (median dose 10 Gy; range 5 to 16 Gy) and cyclophosphamide with (22%) or without (78%) other drugs. One hundred forty (6%) persons received total body radiation plus drugs other than cyclophosphamide. One hundred ten (5%) patients received chemotherapy alone, usually busulfan and cyclophosphamide. The distribution of conditioning regimens was similar for recipients of non-T-cell depleted and T-cell depleted transplants. Sixty-six of the 70 identical twin transplant recipients received total body radiation plus cyclophosphamide (n = 58) or other drugs (n = 8); three received busulfan and cyclophosphamide; one received busulfan and melphalan. Adjustment for type of conditioning regimen did not affect calculated risks of relapse or leukemia-free survival. Exclusion of patients not receiving total body radiation and cyclophosphamide also did not affect results. Results are presented with all patients included.

Five hundred ninety-one (27%) of 2,184 allograft recipients received posttransplant methotrexate with or without other drugs, excluding cyclophosphamide, to prevent GVHD; 825 (38%) received cyclophosphamide with or without other drugs, excluding methotrexate; 367 (16%) received cyclophosphamide plus methotrexate. Four hundred one (18%) received bone marrow depleted of T lymphocytes. Methods used for T-cell depletion included antibody with or without complement in 314 (78%) cases and physical techniques in the remaining cases. One hundred forty-two (35%) recipients of T-cell depleted bone marrow received no posttransplant GVHD drug prophylaxis; 215 (54%) received cyclophosphamide, and 44 (11%) received other drugs.

Acute GVHD was classified as absent (grade 0), mild (grade 1), moderate (grade II), moderately-severe (grade III), or severe (grade IV) using published criteria. Maximum overall severity of chronic GVHD was scored as absent, mild, moderate, or severe based on severity of skin and other organ involvement according to clinical judgement of the transplant team. In estimating the effect of GVHD severity in patients with both acute and chronic GVHD, patients with grade I acute GVHD and mild chronic GVHD were classified as having mild GVHD, those with grade II acute and moderate chronic as having moderate GVHD, and those with grade III to IV acute and severe chronic as having severe GVHD. One thousand three hundred forty-five (62%) allograft recipients developed grades I through IV acute GVHD. Seven hundred seven (38%) of 1,854 allograft recipients surviving with engraftment 100 days posttransplant developed chronic GVHD. In 551 (78%) persons, chronic GVHD appeared after acute GVHD. In 156 (22%), chronic GVHD developed without detectable antecedent acute GVHD (de novo chronic GVHD). Incidence and severity of acute and chronic GVHD in recipients of non-T-depleted and T-depleted grafts are shown in Table 2.

Complete remission was defined as absence of leukemia in the

*Among patients who survived with engraftment ≥ 100 days posttransplant.

bone marrow and elsewhere. Leukemia relapse was based on hematologic criteria and/or postmortem studies. In patients with CML, relapse usually was accompanied by reappearance of the Ph1-chromosome. Reappearance of the Ph1-chromosome was not scored as relapse in the absence of hematologic or clinical evidence of leukemia since the biologic importance of such cytogenetic changes is unknown. Furthermore, the frequency with which recurrence of the Ph1-chromosome is recognized varies within and among centers because it depends on the frequency of cytogenetic examinations and the number of metaphases studied.

Statistical methods. Actuarial probabilities of relapse and leukemia-free survival were calculated using standard life table methods. Curves were terminated at 6 years or when fewer than five patients remained at risk.

To detect possible influences of allogeneic transplantation on leukemia relapse in association with and independent of GVHD, patients were categorized into a single reference and five comparison groups for multivariate analyses (Table 3). The reference group included recipients of non-T-cell depleted allografts without acute or chronic GVHD. Results in this reference group were compared with (1) recipients of non-T-cell depleted allografts with acute but not chronic GVHD; (2) recipients of non-T-cell depleted allografts with chronic but not acute GVHD; (3) recipients of non-T-cell depleted allografts with both acute and chronic GVHD; (4) recipients of transplants from genetically identical twin; and (5) recipients of T-cell depleted allografts with or without GVHD. Relative risks of relapse and treatment failure (defined as relapse or death from any cause) for each of the five comparison groups as compared with the reference group were calculated separately using Cox proportional hazards regression for all patients (in which the model was stratified by disease) and for patients with each disease. The risk of relapse for the reference group was assigned 1.00 in all multivariate analyses unless otherwise specified. Relative risks less than 1.00 indicate a risk of relapse less than the reference group and relative risks greater than 1.00 indicate a risk greater than the reference group.

To evaluate the effect of GVHD and posttransplant immunosuppression after T-cell depleted transplants and to compare overall risks of relapse between T-cell depleted and non-T-cell depleted transplants, different reference and comparison groups were used; these are specified in the text.

To avoid confounding of results by other variables associated with relapse and/or treatment failure, all regression equations were adjusted for variables associated (P < .05) with relapse and/or treatment failure in previous IBMTR analyses of patients with early leukemia: use of methotrexate, cyclosporine and/or corticosteroids to prevent GVHD, leukocyte levels at diagnosis, recipient age, organ impairment posttransplant, and donor–recipient sex match.

Analyses of GVHD. To accommodate changes in GVHD with time after transplant, patients were assigned to the three GVHD comparison groups described above and analyzed in a time-dependent fashion in the Cox regression models. All patients were considered to be in the “no GVHD” group at day 0. They were then assigned to the “acute GVHD only” group at the time of onset of acute GVHD, and their subsequent survival and relapse experience was compared with patients surviving a similar length of time without developing GVHD. Patients who later developed chronic GVHD were reclassified from the “acute GVHD only” group to the “both acute and chronic GVHD” group when chronic GVHD was diagnosed. Their subsequent survival and relapse experience was compared with patients surviving a similar length of time without developing GVHD. Patients developing chronic GVHD without prior acute GVHD were assigned to the “no GVHD” group until chronic GVHD developed; they were then assigned to the “chronic GVHD only” group. Their subsequent relapse and survival experience was compared with patients in the “no GVHD” group surviving a similar length of time.

P values are two-tailed and, unless otherwise specified, derived from multivariate analyses. Because a large number of statistical tests were performed, we consider only P values < .01 statistically significant and interpret values between .01 and .05 as indicating trends.

RESULTS

Recipients of non-T-cell depleted allografts not developing GVHD (reference group) had a 3-year probability of

*Reference group.
relapse of 25% ± 6% (95% confidence interval). Actuarial probabilities of relapse for the reference and comparison groups are shown in Fig 1 and Table 3. These values are not adjusted for possible confounding variables or for the time of onset of GVHD. Recipients with acute GVHD only, chronic GVHD only, or both had 3-year probabilities of relapse of 22% ± 5%, 10% ± 7%, and 7% ± 3%, respectively. Recipients of transplants from identical twins had a 3-year probability of relapse of 46% ± 15%. Recipients of T-cell depleted transplants had a 3-year probability of relapse of 41% ± 8%. Table 3 also shows the unadjusted 3-year probabilities of relapse for the reference and five comparison groups for each type of leukemia separately.

Relative risks of relapse derived from multivariate analyses are shown in Table 4. Patients who developed only acute GVHD had a relative risk of relapse of 0.68 (P = .01) compared with patients in the reference group; those with only chronic GVHD had a relative risk of 0.33 (P = .0001); and those with both acute and chronic GVHD had a relative risk of 0.23 (P = .03). The relative risks of relapse for recipients of identical twin and T-cell depleted transplants were 2.09 (P = .005) and 1.76 (P = .002), respectively.

Similarities and differences among the different leukemias were observed in the effect of GVHD. Identical twin transplants, and T-cell depletion on relapse (Tables 3 and 4). GVHD was associated with decreased relapse in all three types of leukemia; the risk was lowest in patients with acute and chronic GVHD. Acute GVHD only was associated with a decreased risk of relapse in ALL (relative risk 0.57, P = .004) but not in AML or CML (relative risks 0.78 and 1.15 respectively, P was not significant). A significant increase in relapse risk with identical twin transplants was observed only in AML (relative risk 2.68, P = .008). The increased risk of relapse associated with T-cell depleted grafts was significant only in CML (relative risk 5.14, P = .0001).

Severity of GVHD and leukemia relapse. To determine whether the antileukemia effect of GVHD was related to its severity, the risk of relapse associated with mild, moderate, and severe acute and chronic GVHD among patients receiving non-T-cell depleted allografts was compared with the risk of relapse in patients who did not develop GVHD. Risk correlated inversely with severity of GVHD (Fig 2). One hundred forty-one patients with mild GVHD had a relative risk of relapse of 0.50 (P = .02) or a twofold decrease in relapse risk as compared with those without GVHD; 72 patients with moderate GVHD had a relative risk of 0.22 (P = .009) or a 4.5-fold decrease in risk; none of 49 patients with severe acute and chronic GVHD relapsed (P = .04).

Effect of GVHD on relapse after T-cell depleted transplants. To determine whether T-cell depletion alters the antileukemia effect of GVHD, we compared the risk of relapse among recipients of T-cell depleted grafts with acute and/or chronic GVHD to the risk among recipients of T-cell depleted grafts without GVHD. Patients with GVHD had a risk of relapse 0.61 (P = .02) times that of patients without GVHD. The number of patients was too small to allow separate analysis of acute only, chronic only, and both acute and chronic GVHD groups.

Two analyses were performed to determine whether the increased risk of relapse associated with T-cell depletion could be accounted for by the decreased incidence and severity of GVHD.

First, the risk of relapse for recipients of T-cell depleted transplants without GVHD and those with acute and/or chronic GVHD was compared with the reference group of recipients of non-T-cell depleted allografts without GVHD (Tables 4). Recipients of T-cell depleted transplants without GVHD had a relative risk of relapse of 2.14 (P = .0001). This effect was significant only in CML (relative risk 6.91, P = .0001). Recipients of T-cell depleted transplants developing acute and/or chronic GVHD (relative risk 1.32, P = .25) had a risk of relapse not significantly higher than the reference group. However, when CML patients were analyzed separately, recipients of T-cell depleted transplants with GVHD had a higher risk of relapse than the reference group (relative risk 4.45, P = .003).

Second, the risk of relapse for T-cell depleted transplants was compared with the risk for non-T-cell depleted transplants using a proportional hazards model that adjusted for the incidence and severity of acute and chronic GVHD. After this adjustment the risk of relapse was 2.13 times higher (P = .0001) for T-cell depleted (n = 401) as compared with non-T-cell depleted (n = 1,783) grafts. No significant effect of posttransplant cyclosporine on relapse after T-cell depleted transplants was detected. Persons with CML receiving T-depleted grafts with and without cyclosporine (relative risks 5.37, P = .0001 and 4.74, P = .003, respectively) had significantly higher risks of relapse than the reference group.

Treatment failure. To determine whether altered risks of relapse affected the probability of leukemia-free survival, the risk of treatment failure (relapse or death from any cause) for patients in each comparison group was compared with the reference group (Table 5). Risk of treatment failure was significantly higher for patients with acute GVHD only (relative risk 1.84, P = .0001), with acute and chronic GVHD (relative risk 1.79, P = .0001), and recipients of T-cell depleted grafts (relative risk 1.59, P = .0003). Risks of treatment failure for patients with chronic GVHD only (relative risk 1.19, P = .45) and recipients of identical twin...
transplants (relative risk 1.07, P = .29) were not significantly different than the reference group. Among patients with acute and chronic GVHD, patients with mild GVHD had a risk of treatment failure 1.9 times lower (relative risk 0.53, P = .02) than the reference group, but those with moderate (relative risk 1.73, P = .04) or severe (relative risk 3.32, P = .0001) GVHD had risks higher than the reference group (Fig 2).

Relative risks are derived from multivariate Cox regression adjusting for leukocyte count at diagnosis, recipient age, organ impairment pretransplant, donor-recipient sex-match, and drug used to prevent GVHD. Abbreviations: RR, relative risk in comparison with reference group; CR, complete remission; CP, chronic phase. *Reference group.

### Discussion

Relapse rates differed for patients receiving non-T-cell depleted, T-cell depleted, and identical twin transplants. Because these groups received comparable pretransplant antileukemia therapy, these differences must arise for other reasons. The data presented suggest an additional antileukemia effect associated with bone marrow transplantation. This effect may have three distinct components: (1) antileukemia activity associated with clinically evident GVHD; (2) antileukemia activity independent of clinically evident GVHD; and (3) antileukemia activity independent of GVHD that is modified by T-cell depletion.

**Antileukemia effect of GVHD.** Prior studies of patients with advanced leukemia indicate a decreased risk of relapse associated with acute and/or chronic GVHD. In our study, relapse risk was also decreased in patients with early leukemia developing GVHD. The magnitude of this antileukemia effect correlated with GVHD severity; the lowest relapse rates were observed in patients with severe GVHD.

Assessing the relative effects of acute and chronic GVHD on transplant outcome is complex. Patients must survive sufficiently long to be at risk for acute GVHD and longer to be at risk for chronic GVHD. Consequently, individuals without GVHD include those dying before GVHD (and possibly leukemia relapse) can develop as well as those who survive without developing GVHD. The group with only acute GVHD includes patients with severe acute GVHD who do not survive sufficiently long to be at risk for chronic GVHD (or relapse), as well as those who survive without developing this complication. Additionally, individuals with acute GVHD are those most likely to develop chronic GVHD.

To accommodate changes in GVHD status over time and to determine which forms of GVHD were associated with an antileukemia effect, we used a statistical model that assigned patients to groups of acute GVHD only, chronic GVHD only.
or both in a time-dependent fashion. Using this model, we found decreased risks of relapse with both acute and chronic GVHD, although their relative importance differed for the three types of leukemia. Chronic GVHD had a stronger antileukemia effect in AML and CML, and acute GVHD had a stronger effect in ALL. Patients with both acute and chronic GVHD had the lowest risk of relapse.

There was an increased risk of nonleukemia deaths in patients with moderate to severe GVHD. Thus, despite its antileukemia effect, the presence of GVHD did not increase the likelihood of long-term disease-free survival, except for patients with mild acute and chronic GVHD.

**Allogeneic antileukemia effect.** The concept that allogeneic cells have an antileukemia effect independent of GVHD is supported by studies in mice, where T cells with GVL but not GVHD activity are identified. We found indirect evidence for such an effect in humans with AML. AML patients receiving allografts who did not develop GVHD had a lower risk of leukemia relapse than recipients of identical twin transplants. It may be that leukemia-associated antigens, not recognized by genetically identical immune cells, are recognized by allogeneic immune cells. Alternatively, the different relapse rate may reflect nonspecific effects of subclinical GVHD directed at minor histocompatibility antigens. We assume that the development of leukemia in twin transplant recipients represents relapse, but this was not formally proven. It is not possible to absolutely exclude increased susceptibility to leukemia or leukemia transformation in the immediate posttransplant period in genetically identical donor cells; however, this approach is supported by the fact that leukemia has not developed in any of the 70 twin donors. This GVL effect was greatest in AML, of borderline significance in CML, and absent in ALL. However, the number of identical twin transplants available for study in ALL and CML was small.

**Antileukemia effect of T cells.** The data in this study support an antileukemia effect of bone marrow transplantation for CML that is significantly altered by T-cell depletion. This effect is independent of the GVHD and GVL effects described above. It is presumably mediated by T cells but could result from some other cells or factors affected by T-cell depletion. T cells might interact with leukemia cells directly or by facilitating engraftment or producing lymphokines that affect growth of leukemia cells.

Part of the decreased antileukemia activity of T-cell depleted transplants is a consequence of decreased GVHD (Table 2). However, the fact that recipients of T-cell depleted transplants had an increased risk of relapse even after adjustment for GVHD suggests an additional antileukemia effect independent of GVHD. Among patients with CML, patients who developed GVHD after T-cell depleted transplants had a substantially higher risk of relapse than patients who received non–T-cell depleted grafts and did not develop GVHD.

In summary, these data provide evidence for antileukemia effects of bone marrow transplantation not explained by high-dose chemotherapy and irradiation. These activities may be mediated through several mechanisms. Advances in characterizing and controlling these effects are needed to improve results of bone marrow transplantation. It may also be possible to use these effects to treat leukemia outside the transplant setting.

Bone Marrow Transplantation for Acute Myelogenous Leukemia

Factors Associated With Early Mortality

Mortimer M. Borin, MD; Robert P. Gale, MD, PhD; Humphrey E. M. Kay, FRCPath; Alfred A. Rimm, PhD
for the Advisory Committee of the International Bone Marrow Transplant Registry

Comprehensive data were reported to the International Bone Marrow Transplant Registry, Milwaukee, regarding 156 patients with acute myelogenous leukemia who were treated with allogeneic bone marrow transplantation between 1978 and 1980. The minimum observation period was 15 months after transplant and most deaths occurred within the first six months. Prognostic factors were evaluated for associations with early mortality or life-threatening complications. Most early deaths were due to infections, interstitial pneumonitis, and graft-versus-host disease (GVHD). Multivariate analyses disclosed five factors with significant associations with early death or a major cause of early death: (1) disease status; (2) dose-rate of irradiation; (3) drug used to prevent GVHD; (4) severity of GVHD; and (5) dose of marrow cells. It is emphasized that several of the important prognostic factors are within the control of the referring physician or the transplant team.

(JAMA 1983;249:1166-1175)

IN THE 1970s, a number of transplant teams demonstrated that a small but significant proportion of patients with end-stage leukemia could be saved from certain death by treatment with high-dose chemotherapy followed by bone marrow transplantation. Analyses of data from these patients (whose leukemia was in relapse and refractory to traditional doses of chemotherapy) disclosed several important factors that were associated with success. The most important findings were that patients who underwent transplants relatively early in the course of the disease and while they were in good clinical condition had significantly higher survival rates than those who underwent transplants later in the disease and while they were in poor clinical condition. Largely on the strength of these observations, several bone marrow transplant teams initiated programs in which bone marrow transplantation was used to treat high-risk, poor-prognosis forms of leukemia when the disease was in complete remission.

Reported herein are the results of analyses of pooled data provided to the International Bone Marrow Transplant Registry (IBMTR), Milwaukee, by 28 transplant teams throughout the world, regarding 172 patients with acute myelogenous leukemia (AML) who were given treatment with high-dose chemoradiotherapy and bone marrow transplantation between Jan 1, 1978, and Dec 31, 1980. One hundred twenty-three patients were given grafts when their disease was in complete remission. Among the 156 patients who were given marrow from allogeic donors, 61 currently are alive one to four years after transplant; 98 have died. Seventy-two percent of these deaths occurred during the first six months after transplant. The major causes of death during this period were infection, interstitial pneumonitis, and graft-versus-host disease (GVHD). Analyses were performed to determine which of more than 20 factors occurring before and after transplant were associated with six-month mortality and with each of the three principal causes of death. The aim of this study was to detect prognostic factors that can be manipulated by referring physicians, bone marrow transplant teams, or both, so as to decrease the risk of early mortality.

1978, and Dec 31, 1980, were included in this study; there were no exclusions. Shown in Table 1 is the distribution of patients on which this report is based. To the best of our knowledge, each team reported its consecutive bone marrow transplant experience; however, one team reported only those patients who were treated when the disease was in complete remission, and another team reported only patients given transplants between February 1978 and August 1978.

Eighty-four of the patients were male and 88 were female. The patients ranged in age from 1 to 62 years, with a median of 32.7 years; 91% were younger than 40 years at the time of transplantation. The majority of patients given transplants while in complete remission were in good clinical condition. For example, only 4% of the patients who underwent allogeneic bone marrow transplantation while in complete remission had infections at the time of transplantation. Among the patients who underwent allogeneic bone marrow transplantation while in partial remission or relapse, infections were present in 15%. In comparison, in an earlier report from the IBMTR,1 infections were present in 41% of patients with end-stage AML at the time of transplantation.

### Classification and Status of Leukemia

Usual clinical, morphological, and laboratory criteria were applied by the reporting transplant teams to establish the diagnosis of leukemia and its type.

Patients with acute undifferentiated, myelogenous, promyelocytic, myelomonocytic, monocytic, and erythroleukemia have been included in the general designation of AML. Although some groups sizes were small, there were no significant differences between the various subtypes of leukemia with respect to the survival data or the other outcome variables; therefore, for analysis the data were pooled. All patients with AML were considered to have a poor prognosis, irrespective of the status of the disease at the time of bone marrow transplantation.

The criteria summarized below were used to describe the status of the disease at the time just before initiation of pretransplant chemoradiotherapy and were based on criteria described by Cancer and Leukemia Group B.

**Complete Remission (CR).**—Five percent or fewer blasts in the bone marrow, no blasts in the peripheral blood, no hepatosplenomegaly, no lymphadenopathy, no mediastinal mass, and no gonadal or CNS involvement.

**Partial Remission (PR).**—A concentration of 5.1% to 25% blasts in the bone marrow, 1% to 5% blasts in the peripheral blood, or both, and modest hepatomegaly, splenomegaly, gonadal, or CNS involvement, with or without bone marrow and blood findings.

**Relapse.**—A concentration of 25.1% blasts or greater in the bone marrow, 5.1% blasts or greater in the peripheral blood, or both; and moderate to marked hepatomegaly or splenomegaly, with or without bone marrow and blood findings.

### Interval From Diagnosis to Bone Marrow Transplantation

The interval from diagnosis to transplant is shown in Table 2 for the 156 patients who received marrow from allogeneic donors. Among the 85 patients who received transplants when their disease was in first complete remission, 25% were given transplants within 3.8 months, 50% within 5.5 months, and 75% within 7.4 months of diagnosis.

### Chemoradiotherapy Before Transplantation

All patients received high-dose chemoradiotherapy in the ten days preceding bone marrow transplantation for leukemia cytoreduction and immunosuppression. Cyclophosphamide was given on two consecutive days to 162 (94.9%) patients at a dose of 2 mg/kg of body weight (mean, 129.0 ± 105.5 SD; range, 33 to 200 mg/kg). Additional chemotherapy including 1,3-bis-(2-chloroethyl)-1-nitrosourea, cytosine arabinoside triacetate, daunorubicin hydrochloride, doxorubicin hydrochloride, methotrexate hydrochloride, piperazinedione, prednisolone, or procarbazine hydrochloride was administered to 20 patients less than ten days before transplant. Total body irradiation (TBI) was given to 169 patients (median, 10.0 Gy; range, 9.8-12.9 Gy). A single dose of TBI was given to 152 patients and 17 patients received two to seven fractionated doses. A wide range of dose-rates of TBI was used (median, 6.6 cGy/min; range, 2.0 to 10.0 cGy/min).

### Donor-Recipient Relationships and Histocompatibility

Among the 172 patients, 156 received marrow from allogeneic donors and 16 from genetically identical twins. Of the allogeneic transplants, 156 donor-recipient sibling pairs were compatible at HL-A, HL-A, and in mixed leucocyte culture (MLC) tests; additional histocompatibility tests were performed in many instances (eg, HL-A-C, HL-A-D, HL-A-DR), and in no case did the results alter the histocompatibility relationship. Seven sibling pairs were HL-A-A and HL-A-A identical, but MLC tests were technical failures or were not performed. Thirty donor-recipient pairs (nine siblings and all four parental donors) were incompatible as determined by MLC tests; additional incompatibilities were present at HL-A-A or HL-A-B, or both, in four of these cases. Seven of the histoincompatible transplants were performed in first complete remission, three in second to fourth complete remission, and three in partial remission. There were no significant differences between the MLC-compatible, MLC-unknown, and MLC-incom-
Engraftment

Engraftment of transplanted bone marrow was classified according to criteria adopted by the Advisory Committee of the IBMTR. Sustained engraftment occurred in 116 (59%) of the 198 patients with leukemia who survived long enough for their conditions to be evaluated, ie, at least 21 days. In comparison, sustained engraftment occurred in only 76% of patients with severe aplastic anemia in a previous IBMTR report.

GVHD

Graft-versus-host disease was classified as none, mild, moderate, or severe according to the degree of cutaneous, gastrointestinal, and hepatic dysfunction. Inasmuch as there are no signs, symptoms, laboratory test results, or histological findings generally accepted as pathognomonic of GVHD, this scoring system is based, in large measure, on the judgment of the transplant team. For analysis, patients were divided into two groups: those scored as having no or mild GVHD, and those scored as having moderate or severe GVHD.

Prophylaxis of GVHD

For the purpose of evaluating the effectiveness of various regimens administered after transplant to prevent or minimize GVHD, the patients with allografts were divided into two groups according to treatment: methotrexate, 100 patients; and cyclosporin A, 51 patients. Five patients, three who received both methotrexate and cyclosporin A and two who received neither, were excluded from multivariate analyses.

STRATEGY FOR DATA ANALYSIS

The main focus of this article is on prognostic factors associated with early mortality among patients with AML who were treated with allogeneic bone marrow transplantation. The closing date for the analysis was March 31, 1982, and the minimum follow-up period was 15 months after transplant. Survival times were calculated from the date of transplant. As of March 31, 1982, ninety-five of the 156 patients with allografts had died and 63 (72%) of the 95 deaths occurred within six months following transplantation. Twenty-seven deaths occurred after six months: recurrent leukemia was responsible for 17 of these deaths. A study of factors associated with late deaths will be addressed in a separate communication from the IBMTR.

More than 20 prognostic variables occurring before and after transplant were evaluated to determine if they were associated with six-month mortality or with the principal causes of early death. Among the prognostic factors studied were age, sex of patient, sex of donor, donor-recipient sex match, disease, disease status, number of remissions, number of transfusions before or after transplant, ABO match, HLA match, MLC match, interval from diagnosis to transplant, year of transplant, presence or absence of infection at the time of transplant, pretransplant chemoradiotherapy regimen, total dose of TBI, dose rate of TBI, dose of marrow cells per kilogram of body weight, severity of GVHD, and drug used to prevent or modify GVHD.

For this study, the 156 patients with allografts were grouped according to status of disease at the time of transplantation: first complete remission, 86 patients; second to fourth complete remission, 25 patients; and partial remission or relapse, 44 patients. Survival data also are presented for the 15 patients who received marrow from genetically identical twin donors.

Statistical Methods

Initially, univariate analyses were used to screen the prognostic variables to determine whether an association existed between each of them and each of the following four outcome variables: development of infection, interstitial pneumonitis, GVHD, or death within six months. Chi square analysis (without the Yates and Bonferroni corrections) was used to test for differences between percentages. Student's t test (without correction for multiple contrasts) was used to test for differences between groups when a continuous variable (such as age or cell dose) was studied. The life-table method was used to prepare actuarial survival curves and the Lee-Deen statistic was used to test for differences between the curves. Graphical representation of the survival curves was terminated when fewer than three patients were at risk. Results from the univariate analyses were used to select factors for inclusion in multivariate analyses.

In multivariate tests, the multiple logistic function analysis was used when the outcome variable could be measured on a binary scale (eg, alive or dead, yes or no), and the Cox regression method was used when the outcome variable had a time dimension. The multivariate approach was used because it provides an estimate of the effect of each prognostic variable on each outcome variable after adjustments are made for all other variables, and because the importance of an association found in a univariate analysis may be altered when the interrelationship of other prognostic variables is taken into account.

The prognostic variables of dose rate of TBI administered before transplant and
drug administered after transplant as prophylaxis against GVHD were confounded ($r=.745, P<.0001$). Patients given a low dose rate of TBI frequently also were treated with cyclosporin A; patients given high dose rate of TBI generally also received methotrexate. In view of the fact that one or both of these prognostic factors appeared to have important associations with several outcome variables, analyses were performed twice: once with dose rate of TBI included and drug excluded, and once with drug included and dose rate of TBI excluded. The results of both analyses are presented.

In this type of report, in which many statistical tests were performed, it is possible that some results will indicate statistical significance when, in fact, the difference between groups occurred by chance. To minimize false-positive associations, we recommend that $P$ values of .01 or less be considered to be statistically significant; $P$ values between .01 and .10 are shown to indicate possible trends and to present a more complete display of the probability levels. All $P$ values are based on the results of multivariate analyses.

**RESULTS**

Presented in Fig 1 are life-table curves showing the probability of survival for 156 AML patients with allografts, grouped according to disease status at the time of transplan-
tation. The steep slope of all curves within the first six months is evident. The overall difference between the curves was significant ($P<.001$). The two-year unadjusted actuarial survival rates (and 95% confidence intervals) according to disease status were: first remission, 48% (36% to 60%); second to fourth remission, 34% (14% to 54%); partial remission, 23% (5% to 41%); and relapse, 22% (5% to 39%).

The proportion of patients who survived at least six months after transplant and the primary causes of death within six months are displayed in Fig 2. Both primary and contributory causes of death for the 58 patients with allografts who died within the first six months are shown in Table 3. Bacterial, fungal, and viral sepsis and bacterial pneumonia were the most common types of infection leading to death. Interstitial pneumonitis and GVHD were the other major causes of death within six months after transplant. In view of these findings, multivariate studies were undertaken to determine whether leads could be found that might help disclose reasons for the early deaths.

**Six-Month Survival**

The results of multiple logistic analyses testing for associations between prognostic factors and six-month survival are shown in Table 4. Patients given transplants in first complete remission who had no or mild GVHD had significantly higher six-month survival rates than those in whom moderate or severe GVHD developed. In general, patients who were treated with low rather than high dose rates of TBI and/or cyclosporin A, rather than methotrexate, also had higher six-month survival rates. It should be noted, because of confounding of dose rate of TBI with drug used to prevent GVHD, that only one of these two prognostic factors may be important.) Six-month survival rates tended to be higher among patients given few, rather than many, transfusions before transplant and among the younger patients.

**Interstitial Pneumonitis**

Interstitial pneumonitis occurred in 24% (37/156) of the patients with allografts and was lethal in 73%

(27/37) of these. No cases of interstitial pneumonitis developed more than six months posttransplant. Multivariate analysis disclosed four factors that were associated with development of interstitial pneumonitis (Table 5). Among patients given transplants in first complete remission, low doses of bone marrow cells and high dose rate of TBI or methotrexate were associated with a high incidence of interstitial pneumonitis. As reported previously by the IBMTR,⁶ because TBI dose rate and drug used to prevent GVHD were confounded, it is not clear whether one or both factors were associated with development of this complication. Also, patients given many, rather than few, pretransplant transfusions tended to have a higher incidence of interstitial pneumonitis.

*Prognostic variables were dichotomized to show maximum differences in outcome. Significance tests were not performed on these groupings.
\(P\) Values are from multiple logistic function analyses and are for patients given transplants while in first complete remission. All continuous variables were analyzed as such, rather than as "best splits."

GVHD was significantly associated with an increased incidence of interstitial pneumonitis in the univariate analysis, the association was not statistically significant when other factors were taken into consideration in the multivariate analysis.

### Infection

Overall 114 (72%) of the 156 patients given allografts had infections of varying degrees of seriousness develop during the first six months after transplant; the infection led to death in 23% (26/114) of the infected patients. Multivariate analysis disclosed that the incidence of infection tended to be higher among patients transplanted in first complete remission when given high dose-rate TBI, methotrexate, or both, and in patients given marrow from MLC-incompatible rather than MLC-compatible donors (Table 6).

GVHD

Of 151 patients given allografts who survived long enough to be at risk, 62 (41%) had moderate or severe GVHD develop. This complication caused or contributed to death within six months in 35% of the 62 patients. Graft–host disease of moderate to severe intensity occurred with somewhat higher frequency among older patients, patients given high dose-rate TBI, patients given lower doses of bone marrow cells, and in patients who had infections at the time of transplantation (Table 7). It should be noted that no significant differ-
ence was found in the severity of GVHD among patients given methotrexate in comparison with those given cyclosporin A as prophylaxis against GVHD (number in whom moderate to severe GVHD developed/number of engrafted patients who survived at least 21 days: methotrexate, 42/94 [45%]; and cyclosporin A, 16/51 [31%]).

Recurrent and Persistent Leukemia

Twelve patients had recurrence of leukemia within six months after transplant. Six of the recurrences (5%) were among the 111 patients given transplants while in complete remission and six (16%) among the 45 patients given transplants while in partial remission or relapse. Overt leukemia persisted despite pretransplant chemoradiotherapy in an additional three patients and they died of leukemia within 36 days. As shown in Table 3, recurrent or persistent leukemia was responsible for only 18% (9/68) of the early deaths in the patients given allografts. In contrast, recurrent leukemia was the most frequent cause of death among patients who survived more than six months. The problem of recurrent leukemia will be the major focus of another report from the IBMTR regarding factors associated with late mortality following marrow transplantation for acute leukemia.

Histiocompatible Transplants

Among the ten patients who received histiocompatible marrow during complete remission, four are alive in complete remission, without maintenance therapy, 18 to 23 months after transplant. None of these patients given transplants while in partial remission are alive following transplantation of histiocompatible marrow (mean survival time, 40 months).

Second Transplants

Nine patients who were given transplants while in complete remission received a second transplant: five for recurrent leukemia, two for partial engraftment or no engraftment, and two for chronic GVHD. Of these nine, three are currently alive and free of leukemia, 16, 19, and 25 months after the second transplant. Two patients who were given transplants initially while in partial remission or relapse subsequently had recurrence of leukemia and received second transplants. One had transient engraftment and died of infection shortly after the second transplant. The second patient suffered a relapse after the second transplant and is receiving chemotherapy more than three years after the first transplant.

Identical Twin Transplants

Of 12 patients with AML who were given transplants while in first complete remission with marrow from syngeneic donors, nine currently are alive and free of leukemia from 15 to 33 months after transplant. Their median survival time exceeds 24 months. Three died of recurrent leukemia at ten to 14 months after transplant. An additional four patients received syngeneic marrow when their disease was in partial remission or relapse; two are alive 29 and 47 months after transplant.

COMMENT

The most important result of this study was that five factors were identified that had a strong relationship with six-month mortality or with one or more of the major causes of early death (Table 3). Use of higher dose rates of TBI was associated with a

*Factors associated with end points of six-month survival, interstitial pneumonia, infection, and/or GVHD having P values of <.01 or less. Dose rate of total irradiation and drug used to prevent GVHD were confounded; only one may prove to be important.
†GVHD indicates graft-vs-host disease; MLC, mixed leukocyte culture.
‡Factors associated with end-points of six-month survival, interstitial pneumonia, infection, and/or GVHD having P values in the range between .01 and .10.
significantly higher probability of death within six months and with an increased risk of interstitial pneumonitis, infection, and life-threatening levels of GVHD. Use of methotrexate rather than cyclosporin A similarly was associated with an unfavorable six-month outcome. Because dose rate of TBI was confounded with drug used to prevent GVHD, it is not possible to state with certainty whether the rate of irradiation, the drug, or both were critical prognostic factors.

As reported previously by the IBMTR, we found that dose rate of TBI, drug used to prevent GVHD, or both, were important prognostic indicators for interstitial pneumonitis. It should be noted, however, that 117 of the 156 patients described here were included in the previous analysis. In contrast to an article by Keane et al, who reported that total absorbed lung dose of irradiation was related to death from idiopathic interstitial pneumonitis, we found no evidence to indicate that total dose of TBI within the range of 8 to 13 Gy was associated with either the incidence of or death from idiopathic or virus-associated interstitial pneumonitis. A direct comparison with the finding of Keane and colleagues could not be made, however, because the IBMTR did not have absorbed lung dose data. Larger group sizes need to be studied to evaluate fully the role of total dose, dose rate, absorbed lung dose, kinetics of repair, and fractionation of irradiation on the pathogenesis of interstitial pneumonitis.

A new finding in the present report was that the dose of bone marrow cells also had a significant association with interstitial pneumonitis. It is possible to speculate that the lower doses of bone marrow cells resulted in delayed restoration of immune competence with increased susceptibility to the disease. Although age was not significantly associated with interstitial pneumonitis in the multivariate analysis, it may have played a role, because younger patients tended to receive higher doses of bone marrow cells per kilogram of body weight, while cell doses were lower in older patients. The mean cell doses per kilogram of body weight by age quartiles were: 1 to 15 years, 3.8; 16 to 24 years, 2.9; 25 to 32 years, 2.7; 33 to 62 years, 2.6, and the two factors were significantly correlated.

In a study of 67 patients with aplastic anemia, leukemia, and lymphoma who received allografts, Ramsey et al found a highly significant association between the recipient's age and occurrence of acute GVHD. Furthermore, they observed no cases of GVHD in approximately 17 patients younger than 12 years. Although the incidence of life-threatening GVHD in the present report tended to be lower in younger patients (Table 7), it still represented a formidable problem. Thus, among those at risk, moderate or severe acute GVHD occurred in 41% of 39 patients aged 16 years or older and in 24% of 17 patients younger than 12 years.

Fewer than 50% of the patients in whom moderate or severe GVHD developed following bone marrow transplantation during the first complete remission survived for six months (Table 4). Shown in Fig 3 is a life-table analysis comparing overall survival of patients in whom moderate or severe GVHD developed with those in whom no or mild GVHD developed. The difference in the survival curves was significant (P<.005) and emphasizes the importance of developing improved methods to prevent, circumvent, or treat GVHD.

The observation that the dose of bone marrow cells per kilogram of body weight tended to be inversely proportional to the severity of GVHD (Table 7) was contrary to observations in other mammalian systems. One possible explanation to account for this difference may have been that recipients who were given lower cell doses had donors from whom marrow was difficult to aspirate, and, as a consequence, more mature T cells were present in the inoculum due to admixed peripheral blood.

Unfavorable outcomes tended to occur in older patients, patients given many pretransplant transfusions, patients who acquired infections at the time of transplantation, and the presence of MLC incompatibility between donor and recipient (Table 8).

As shown in Figs 1 and 2, an additional prognostic factor that showed a significant association with six-month outcome was status of the disease at the time of transplantation: the more advanced the disease, the higher the mortality rate (P<.001).

The strong and suggestive prognostic factors found in this study can be divided into two groups—those that often can be controlled by the referring physician or by the transplant team and those that are difficult or impossible to control. For example, the severity of GVHD and the age of a patient requiring bone marrow
transplantation are difficult factors to control. On the other hand, the status of the disease at transplant, the dose rate of TBI, the drug selected to prevent GVHD, the dose of bone marrow cells administered, and the number of pretransplant transfusions often can be manipulated.

A controlled clinical trial would be the best mechanism to evaluate the importance of the favorable and unfavorable prognostic factors found in the present study (Table 8). Knowledge that associations were found between these factors and six-month outcome should be helpful in planning a prospective study. In those situations when it is difficult to conduct a controlled clinical trial within a reasonable period of time, pooled data from numerous transplant centers (as reported to the IBMTR), can be used to simulate such a trial. For example, presented in Fig 4 is a life-table analysis showing survival among the patients with allografts reported here who were given transplants while in first complete remission. The patients were selected for inclusion on the basis of two prognostic factors from Table 8 that often can be manipulated: number of pretransplant transfusions and dose of bone marrow cells administered. The upper curve represents patients given fewer than 25 transfusions and at least 2.3x10^10 bone marrow cells per kilogram of body weight. The lower curve represents patients given more blood transfusions and fewer bone marrow cells. The magnitude of the difference between these curves (or between curves in life-table analyses evaluating other prognostic factors) should prove helpful in estimating the number of patients needed to be entered into a controlled clinical trial to detect a significant effect of the variables to be studied.

Finally, it should be noted that two-year disease-free survival was achieved in an impressive proportion of patients who had suffered relapses one or more times while receiving chemotherapy, or whose disease could not be brought into complete remission with chemotherapy (Fig 1). This suggests that bone marrow transplantation should be considered for all patients with advanced AML if they are of appropriate age and have an HLA-identical donor available.

LIMITATIONS OF THIS REPORT

We wish to emphasize that the data reported herein were not derived from a controlled clinical trial. Inherent in this type of study, based as it is on data from 28 different centers, is the fact that there were many unrecorded factors and differences in medical practice that may have influenced outcome. To a large extent, differences between centers were due to differences in experience, available support services, and sophistication of the teams. Inasmuch as bone marrow transplantation is still an evolving therapeutic procedure, most teams follow their own unique protocols. Although this contributes to the variability between centers, the differences represent an important strength of the IBMTR. When significant prognostic factors are uncovered, we believe that they are usually conservative estimates, because the random variation between centers tends to obscure significant differences. Thus, factors reported here that showed significant associations often confirmed reports of others or, when previously undescribed associations were found, they likely will be confirmed when more data became available.

Another consideration was that there were distinct differences in the number of cases submitted by the various transplant centers. For example, 11 of the 28 teams submitted only one case each, whereas a single transplant center contributed data for 50 cases, or 29% of the total patients in this study. The next highest contributing center submitted data for 20 patients (12%). The largest center contributed data for most of the patients who were treated with TBI at dose-rates of 5.5 Gy/min or less. With this exception, there were no differences in the results reported here when analyses were performed with or without inclusion of their data.

The Advisory Committee of the IBMTR is concerned that data provided to the IBMTR are reported in a uniform manner. To address this problem, guidelines for uniform reporting of data are distributed periodically to all transplant teams. Nonetheless, problems do exist. For example, what is reported by pathologists at one center as 4% blasts in the marrow (thus fulfilling a criterion for complete remission) could be reported as 6% blasts (and classified as partial remission) at another center. This type of "borderline" classification does not constitute a serious difficulty because multiple criteria are used to reduce the possibility of bias in scoring critical end points, such as status of disease at the time of transplantation or severity of GVHD.

RECOMMENDATIONS OF THE ADVISORY COMMITTEE

In view of the present controversy regarding the relative merits of chemotherapy v bone marrow transplantation for patients with AML in first complete remission, the Advisory Committee of the IBMTR recommends that a prospective and randomized clinical trial be planned to compare these two therapeutic modalities under carefully controlled conditions. Furthermore, it is recommended that the findings reported here be taken into consideration in planning such a study.

The research on which this publication is based was supported by grants from the Jacob and Hilda Blaustein Foundation; Burroughs-Wellcome Fund; Commission of the European Communities; Charles E. Colpeter Foundation; Elizabeth Esher Dochtart Charitable Trusts; Carl and Elizabeth Eberbach Foundation; March of Dimes-Birth Defects Foundation; Ambrose Monell Foundation; Mount Sinai Medical Center (Miami Beach); Samuel Roberts Noble Foundation; Queen Wilhelmina Fund; Sandos Limited; Swim Cancer League; and the Upjohn Company, and was conducted under contracts NOI-AI-00564 and NOI-AI-26903 from the National Institute of Allergy and Infectious Diseases and the National Cancer Institute, US Department of Health and Human Services.

Jill R. Parmer provided help with data analysis and Elaine L. Koba and D'Etta Waldock provided help with preparation of the manuscript.

The bone marrow transplant teams at the following institutions contributed the patient data that was the basis for this report: It is hoped that data provided to the IBMTR by bone marrow transplant teams throughout the world in a spirit of international cooperation will accelerate understanding of the critical factors necessary for successful treatment of patients who might be benefited by bone marrow transplantation.

PATHOGENESIS OF INTERSTITIAL PNEUMONITIS FOLLOWING ALLOGENEIC BONE MARROW TRANSPLANTATION FOR ACUTE LEUKEMIA

Mortimer M. Bortin, M.D.

Statistical Center, International Bone Marrow Transplant Registry, Mount Sinai Medical Center, P. O. Box 342, Milwaukee, WI 53201

ABSTRACT Interstitial pneumonitis (IPn) is one of the major causes of treatment failure following allogeneic bone marrow transplantation. Its cause, prevention and treatment are unknown. Data from individual transplant centers and from the International Bone Marrow Transplant Registry (IBMTR) indicate that one of every four patients with acute leukemia treated with marrow allografts died of IPn. A model was formulated to demonstrate possible pathways for the pathogenesis of the disease.

INTRODUCTION

Interstitial pneumonitis is an extremely grave complication of allogeneic bone marrow transplantation. Data from the IBMTR indicate that 29% (130/450) of patients with acute leukemia developed IPn following

1This work was supported by grants from the Jacob and Hilda Blaustein Foundation, Burroughs-Wellcome Fund, Culpeper Foundation, Lederle Laboratories, Ambrose Monell Foundation, Noble Foundation, Sanofi Ltd., Swiss Cancer League, Upjohn Company, and was performed pursuant to Contracts NO1-AI-02648 and NO1-AI-22669 from the National Institutes of Allergy and Infectious Diseases and the National Cancer Institute, USDHHS and Contract B10/C.520.Us(H) from the Commission of the European Communities.
allogeneic marrow transplantation; the case fatality rate was 69% (90/130) and the mortality rate was 20% (90/450) (manuscript in preparation). In another large series of allografted patients with acute leukemia, Meyers et al. (1) reported an incidence of 47% (153/323), a case fatality rate of 68% (104/153) and a mortality rate of 32% (104/323). The problems are: a.) The cause is not known; b.) No effective preventive measures are known; c.) No effective treatment is known; and d.) At the present time approximately 25% of allografted leukemic patients die of IPn.

In this review, a model is presented to help describe interacting factors believed to be involved in the pathogenesis of IPn. Although the emphasis is on IPn in leukemic patients, at least some of the mechanisms discussed also apply to IPn in marrow allografted patients with primary immunodeficiency disease and severe aplastic anemia, as well as to IPn in general.

PATHWAYS FOR THE PATHOGENESIS OF INTERSTITIAL PNEUMONITIS

To plan effective preventive measures, it is necessary to understand the many complex interacting factors that lead to the development of IPn. A model is presented (Fig. 1) to help sort out these factors. Basic to this model is the concept that there are three major predisposing factors for the development of IPn; a.) an immunosuppressed host; b.) lung damage; and c.) the presence of opportunistic microorganisms (1-13). Any of these three predisposing factors alone can lead to the development of IPn; the three in combination can be likened to a time bomb ready to explode.

Immunovulnerable Host

There is a sequence of pre- and posttransplant events that contribute toward establishment of an immunologically crippled host who, as a consequence, is vulnerable to infection (Fig. 1). For example, acute leukemia at the time of diagnosis often is advanced, debilitating and immunosuppressive. Remission-induction and consolidation chemotherapy given for weeks or months before transplantation has immunosuppressive activity. The pretransplant
Figure 1. Possible pathways for the pathogenesis of interstitial pneumonitis
conditioning regimen has profound immunosuppressive effects. Cyclophosphamide plus total body irradiation (TBI) is the usual basic conditioning regimen, to which other antileukemic drugs having immunosuppressive side effects often are added. Posttransplant immunosuppression with methotrexate, cyclosporin-A, antithymocyte globulin and other immunosuppressive agents, given to prevent, modify or treat graft-vs-host disease (GVHD), adds to and prolongs the immunosuppressed state of the patient. Finally, GVHD, per se, has immunosuppressive effects (14).

Shown in Table 1 is a list of agents that are commonly administered to patients with acute leukemia to induce or maintain remission and/or for immunosuppression in the peritransplant period. Most of these agents have immunosuppressive characteristics; as described below, all have been reported to cause lung damage and to be associated with IPn (15-24).

Thus, as shown in Fig. 1 and Table 1, allografted leukemic patients have multiple and cumulative interacting factors that result in virtual destruction of a major host defense against infection. The fact that opportunistic pathogens often are found in the lungs of patients with IPn suggests that the severe and prolonged injury to the immune apparatus may allow growth of microorganisms, especially in lungs that are damaged (1,11).

<sup>a</sup>Frequent association
Lung Damage

The same sequence of events that leads to immunosuppression also has direct and cumulative effects that injure the lungs (Fig. 1). For example, leukemic infiltrates occasionally appear in the lung and cause localized damage. All the drugs shown in Table 1 have been reported to cause lung damage and to be associated with IPn. Perhaps of greater importance is the observation that several of these drugs were reported to interact with irradiation in such a way as to increase the amount of injury to normal lung tissues (25,26). This observation is of particular relevance to the problem of IPn in allografted leukemic patients. At the present time, most leukemic patients who undergo bone marrow transplantation are treated with cyclophosphamide and/or methotrexate along with TBI; lung damage has been reported to be magnified when either of these drugs was administered in conjunction with lung irradiation (25,26).

Impairment in function and delayed recovery of alveolar macrophages was found in marrow allografted patients (27) and dogs (28) that had been treated with cyclophosphamide, TBI and methotrexate. Inasmuch as pulmonary alveolar macrophages have been shown to contain CMV virus particles during CMV infections, it was suggested that these cells may represent a host defense mechanism against CMV (29). Thus, the combination of increased lung damage and impaired alveolar macrophage function may explain the fact that among patients treated with cyclophosphamide and TBI pretransplant, the incidence of IPn was significantly higher when methotrexate rather than cyclosporin-A was administered posttransplant (4,5).

Although it is well known that irradiation injures the lungs (8,30), the precise role of TBI in the pathogenesis of IPn has not yet been identified clearly. Key questions are the extent to which a.) the dose-rate of TBI, b.) use of fractionated TBI or c.) the total dose to the lung affects the risk of IPn in allografted leukemic patients. Clinical studies at various centers are in progress to try to answer these questions.

Barrett et al. (31) first suggested that the dose-rate of TBI might be an important factor in the pathogenesis of IPn. Subsequently, multivariate analyses of data reported
to the IBMTR disclosed a strong association between dose-rate of TBI and IPn, irrespective of the total dose of irradiation to the lungs (4-6). Thus, the incidence of IPn among patients given TBI at a dose-rate < 6.0 cGy per minute was 6% (4/69), whereas the incidence was 30% (32/107) when the dose-rate was higher (5). This observation has not, as yet, been confirmed in prospective studies.

The use of fractionated rather than single dose TBI was associated with a reduction in the incidence of IPn from 70% to 33% and a reduction in the case fatality rate from 50% to 23% in one study (10). The total dose was 13.2 GY, dose to lungs 9.0 GY (lung shielding), 11 fractions administered over four days, dose per fraction 1.2 GY and dose-rate 10-19 cGy per minute. In contrast, Meyers, et al. (1) found no beneficial effect in a multivariate comparison of allografted leukemic patients treated with cyclophosphamide plus single dose TBI vs cyclophosphamide plus fractionated TBI. Their incidence of IPn with single dose was 51% (84/165) and with fractionated, 37% (30/82). There was no indication in their report, however, whether the radiobiological effect of the single dose and the total of the fractionated doses were comparable. Clift, et al. (32) reported a high incidence (44%) of IPn and/or alveolar pneumonitis when fractionated TBI was used in patients with acute lymphoblastic leukemia in relapse. Six different regimens for 41 patients were evaluated with total doses ranging from 12.0-17.5 GY, six or seven fractions of 1.0-4.0 GY per fraction administered over two to seven days at a dose-rate of 3-8 cGy per minute.

It is possible that the conflicting reports on the effect of fractionated TBI on the incidence of IPn might be due to differences in the dose per fraction in different centers (range 1.0-4.0 GY per fraction). To cause a marked reduction in the risk of IPn, it may prove necessary to reduce the dose of TBI to < 1.0 GY per fraction in order to allow repair of irradiation-induced lung damage.

Another approach to spare the lungs from damage caused by ionizing irradiation has been to restrict lung doses to < 7.5 GY by shielding the lungs with lead during TBI, or by limiting the dose of TBI to < 7.5 GY. Preliminary analysis of data reported to the IBMTR gave no clear indication that this approach was associated with a reduced risk of IPn (manuscript in preparation).
Finally, while the lung is not considered to be a primary target organ of the graft-vs-host reaction, lung damage and decreased pulmonary function have been reported to be associated with both acute and chronic GVHD (33,34).

Thus, as shown in Fig. 1 and Table 1, allografted leukemic patients have multiple and cumulative interacting factors that cause injuries to the pulmonary parenchyma and to alveolar macrophages. The fact that fungal and viral microorganisms often are found in the lungs of patients with IPn also suggests that damaged lungs provide a situs for growth of opportunistic pathogens.

Opportunistic Microorganisms

A partial list of nonbacterial microorganisms reported to be associated with IPn is presented in Table 2. Cytomegalovirus (CMV) was the pathogen found most frequently in the lungs of allografted leukemic patients with IPn (1,3,12,35, and unpublished ISMTR data). Pneumocystis carinii often was associated with IPn in the past (2,11,36), but since the introduction of trimethoprim-sulfamethoxazole prophylaxis, the problem has all but been eliminated from bone marrow transplant recipients (1,12). It should be borne in mind, however, that the finding of opportunistic microorganisms such as CMV, Pneumocystis, etc. in the lungs of patients with IPn does not prove that the organism is the causative agent. Damaged lungs in immunosuppressed patients with IPn may simply provide a suitable ecologic niche for overgrowth of opportunistic pathogens.

If one assumes that CMV is, in fact, important in the pathogenesis of IPn, then the question of its mode of entry is of considerable import and has generated numerous studies. Activation of a latent CMV infection is one possible route (Fig. 1). Neiman, et al. (35) found that 45% of 80 marrow allografted patients had significant antibody titers against CMV pretransplant and were presumed to have had previous exposure to the virus. GVHD, antileukemic and immunosuppressive agents have been shown to be capable of activating latent CMV and other herpes viral infections (37-39). Their cumulative effects (Fig. 1) could readily account for activation of endogenous microorganisms. For these patients without previous viral
or fungal infections, airborne infection and the frequent requirement for transfusion of blood products from multiple donors pre- and posttransplant are other potential sources of these microorganisms (40–42).

Thus, there is no shortage of endogenous or exogenous sources of CMV and other ubiquitous agents as opportunistic pathogens for IPn. The presence of lung damage in an immunovulnerable host strengthens the hypothesis that these microorganisms are, indeed, the etiologic agents and that infection is responsible for many cases of IPn. On the other hand, from approximately 30–50% of IPn cases in allografted leukemic patients are, of necessity, categorized as idiopathic (1,29 and unpublished IBMTR data). Despite the use of careful and thorough microbiological examinations of biopsied lung tissue and, all too often, tissue obtained postmortem, no pathogen could be identified in many cases.

Other Considerations

Mentioned below are some unexplained and intriguing observations that, when clarified, may improve our understanding of the pathogenesis of IPn.

Isografts. In a series of 100 patients that were transplanted with syngeneic marrow for aplastic anemia or hematologic malignancy, Applebaum, et al. (43) found that the incidence of IPn was 17%, but there were no cases of

*Frequent association*
CMV-associated IPn. In contrast, CMV was associated with IPn in 16% (84/520) of similar patients who were given marrow from allogeneic donors (1). The incidence of idiopathic IPn was similar in the isografted and allo-grafted patients. The three main differences were that one group received marrow from identical twins and the other from allogeneic donors; the isografted patients did not receive methotrexate posttransplant, whereas the allo-grafted patients did; and there (presumably) was no host-vs-graft or graft-vs-host reaction in the isografted group. As a consequence of these confounding variables, the authors were unable to identify the mechanism to explain the different risks of CMV-associated IPn in their isografted vs allografted patients (43).

GVHD. Although, as discussed above, GVHD was shown to contribute toward immunosuppression, lung damage and activation of endogenous CMV, multivariate analyses disclosed only borderline associations between the intensity of GVHD and the development of IPn (1,4,5). When taking the isograft findings into account (43), one interpretation of these findings suggests that GVHD plays a relatively minor role in the pathogenesis of idiopathic IPn, but that it may play an important role in activating CMV and, thus, in the pathogenesis of CMV-associated IPn.

Yearly Incidence. Chronologically there has been no significant decrease in the annual incidence of IPn (1) and, as a matter of fact, the incidence may be increasing (unpublished IBMTR data). This is true despite the fact that the risk of Pneumocystis-associated IPn has declined (1,12).

Age. Younger patients were found to have a lower incidence of IPn than older patients (1). The reason for this difference is obscure.

Sex-match. A recent report from the IBMTR regarding 176 allografted leukemic patients disclosed that the sex-match of donor and recipient was significantly associated with the development of IPn (5). In this multivariate study, female patients who received cells from female donors had a 32% incidence of IPn while male patients given female cells had a 44% incidence; the incidence was intermediate when cells from male donors were transplanted into male (17%) or female (18%) recipients. The difference in incidence between female-female donor/recipient pairs and the other sex-match combinations was not due to an increased level of GVHD in the latter groups (5). The
association between sex-match and the risk of IPn has not been confirmed by others and the reason for the significant differences between groups is not known.

Cell Dose. Administration of low doses of bone marrow cells was found to be associated with a high risk of IPn among 85 patients with acute myelogenous leukemia who were transplanted in first complete remission (4). The explanation for this finding also is unknown.

STRATEGIES TO PREVENT INTERSTITIAL PNEUMONITIS

At the present time, use of trimethoprim-sulfamethoxazole prophylaxis has reduced the incidence of Pneumocystis-associated IPn (1,12), but its use has not resulted in a reduction in the overall incidence of IPn. Thus far, there have been no clear indications in reports from individual transplant centers of other measures that are effective at preventing IPn.

Multivariate analyses of IBMTR data identified four factors that were significantly associated with the risk of IPn (4-6). It is hoped that this knowledge will point the way for effective preventive measures against the development of IPn. Identification of these factors was based on retrospective analyses rather than on prospective controlled clinical trials. As yet, none of the associations between these factors and the risk of IPn has been confirmed by individual transplant centers. On the other hand, univariate analyses of an expanded IBMTR database (450 patients with acute leukemia transplanted with marrow from HLA-A, B, and MLC identical allogeneic siblings between January, 1977 and May, 1982) appear to substantiate the earlier IBMTR reports (4-6). It is not possible on the strength of these findings to recommend that individual bone marrow transplant centers change their protocols on the basis of these statistical associations because of the many differences in practice between centers that in some instances could not be identified in the IBMTR analyses. It is recommended, however, that these variables be taken into consideration in planning controlled clinical trials.
Dose-rate of TBI

The incidence of IPn was low when the dose-rate of TBI was low (4-6). The most plausible explanation for this observation is that low dose-rate irradiation allowed repair of normal tissues from the radiation injury. Additional time for repair would occur among patients given low dose-rate TBI because of an increased number of interruptions during irradiation to provide nursing care, turn the patient, etc. than during high dose-rate TBI. In these studies, however, the variables of dose-rate of TBI and the drug used to prevent or modify GVHD were confounded (4-6). It was not possible to determine whether one or both of these prognostic factors was important.

Drug Used to Prevent GVHD

The risk of IPn was low when cyclosporin-A was used as prophylaxis against GVHD, but high when methotrexate was used (4,5). The reason for the difference was unclear. If one assumes that this variable is independent of the dose-rate of TBI and important on its own, then it is possible that the interactions of cyclophosphamide, TBI and methotrexate, in comparison with cyclophosphamide, TBI and cyclosporin-A, resulted in greater cumulative damage to the immune system and the lung and had a greater propensity for activation of endogenous microorganisms. Alternatively, cyclosporin-A may have some as yet unknown salutary effect that allows recovery of an important immune defense, promotes healing of the damaged lung or has an antimicrobial effect.

Sex-match

The IBMTR data suggested that with all other things being equal and given the opportunity, female patients should receive marrow from female rather than male donors (5). The reason for the increased incidence of IPn in male patients who received marrow from male donors and in recipients who received marrow from sex-mismatched donors is unclear.
Bone Marrow Cell-dose

In a multivariate study, patients given relatively low doses of bone marrow cells per kg body wt had an increased incidence of IPn in comparison with patients given higher doses (4). This finding would suggest that for the prevention of IPn, larger rather than smaller doses of bone marrow cells should be given. However, the group sizes were small, the effect of cell-dose on other end-points has not been studied thoroughly, and the reason for the association is not understood. Therefore, with this possible preventive measure, as well as the others mentioned, additional studies are necessary.

SUMMARY

Dividends are beginning to be realized from analyses of data from the burgeoning number of leukemic patients being treated with high-dose chemoradiotherapy and allogeneic bone marrow transplantation. Some of the mysteries regarding the interrelationships between factors present in the peritransplant period and the pathogenesis of IPn are beginning to be unraveled. A model was presented to help clarify some of these interactions (Fig. 1). Three critically important predisposing factors have been recognized: damage to the lungs, immunovulnerability of the host, and the frequent presence of opportunistic pathogens. Discussion was focused on some of the issues that need to be resolved in order to prevent this terrible complication of bone marrow transplantation.

Everyone involved with clinical bone marrow transplantation recognizes the magnitude of the IPn problem. Transplant teams are encouraged to report their data to the IBMTR for pooling and analysis in an effort to help solve the problem. Also, randomized controlled clinical trials urgently are needed to investigate methods to reduce the risk of IPn in prospective studies.

ACKNOWLEDGMENTS

I thank Ms. Jill R. Farmer who helped review the literature and formulate the model. Dr. Alfred A. Rimm and Dr. Robert L. Truitt reviewed the manuscript critically and
made helpful suggestions. Thanks, also, to Ms. Roberta J. 
Hilbert and Ms. Patricia J. Minks for their help in 
preparation of this manuscript.

Interstitial Pneumonitis After Bone Marrow Transplantation
Assessment of Risk Factors

ROY S. WEINER, M.D.; MORTIMER M. BORTIN, M.D.; ROBERT PETER GALE, M.D., Ph.D.; ELIANE GLUCKMAN, M.D.; HUMPHREY E. M. KAY, F.R.C.Path.; HANS-JOCHEM KOLB, M.D.; ARTHUR J. HARTZ, M.D., Ph.D.; and ALFRED A. RIMM, Ph.D. Gainesville, Florida; Milwaukee, Wisconsin; Los Angeles, California; Paris, France; London, England; and Munich, West Germany

Data from 932 patients with leukemia who received bone marrow transplants were analyzed to determine factors associated with an increased risk of developing interstitial pneumonitis. Interstitial pneumonitis developed in 268 patients for a 2-year actuarial incidence of 35 ± 4% (SD) and with a mortality rate of 24%. Six factors were associated with an increased risk: use of methotrexate rather than cyclosporine after transplantation (relative risk, 2.0; p < 0.0002); presence of severe graft-versus-host disease (relative risk, 1.5; p < 0.0003); long interval from diagnosis to transplantation (relative risk, 1.6; p < 0.002); performance ratings before transplantation of less than 100% (relative risk, 2.1; p < 0.0001); and high dose-rates of irradiation in patients given methotrexate after transplantation (relative risk, 3.2; p < 0.03). The risk of developing interstitial pneumonitis ranged from 8% in patients with none of these adverse risk factors to 94% in patients with all six. These findings may help to identify patients at high risk for this complication.

Bone marrow transplantation from an HLA-identical sibling is an important treatment for leukemia (1-7), aplastic anemia (8, 9), severe combined immunodeficiency (10), and other disorders (11-13). Long-term, disease-free survival is now achievable in approximately 50% of these patients. Despite these advances, several transplantation-related complications have limited the further success of this technique. Most prominent among these are graft-versus-host disease (14, 15) and interstitial pneumonitis (16-18).

Interstitial pneumonitis accounts for more than 40% of transplantation-related deaths in most large series. Patients with this complication develop dyspnea, fever, nonproductive cough, and hypoxia. Roentgenograms of the chest typically show bilateral interstitial infiltrates, and ventilatory tests show decreased diffusion capacity. Histologic examination of the lung shows edema, fibrosis, a variable cellular infiltrate, and alveolar exudates (19-21).

The onset of interstitial pneumonitis characteristically occurs within 90 days after bone marrow transplantation. Reported incidence rates are highly variable, ranging between 10% and 84% in several series (16-19, 22, 23). The reason for this variability may be related to different definitions of the disease (19-21), different diagnostic criteria, and, most importantly, the relatively small number of patients studied at most centers.

Cytomegalovirus, Pneumocystis carinii, herpes simplex virus, herpes zoster virus, Aspergillus, Candida, and other infectious agents have been isolated from the lungs of patients with interstitial pneumonitis, either by open lung biopsy or at autopsy. Reports from individual centers suggest that interstitial pneumonitis is associated with cytomegalovirus infection in 30% to 70% of the cases. Pneumocystis infections, once common, are now rare, probably because of the prophylactic use of trimethoprimsulfamethoxazole (16). Other viral, protozoal, and fungal infections occur less frequently; in some instances more than one organism has been isolated. No pathogenic organism is identified in up to 60% of the cases, which are referred to as idiopathic. It is likely that some of these cases represent undiagnosed infections, particularly with cytomegalovirus, because techniques to isolate this virus require greater sophistication than is available at some centers. Other cases may result from drug or radiation toxicity or possibly from immune reactions involving the lung.

There have been several analyses of factors associated with the development of interstitial pneumonitis (17-19, 22-25). Factors reported to be predictive include prior infection of the recipient or donor with cytomegalovirus, lung dose or dose-rate of irradiation, sex-matching of donor and recipient, exposure to chemotherapy before transplantation, dose of bone marrow cells, number of transfusions before transplantation, granulocyte transfusions after transplantation, drug used to prevent or treat graft-versus-host disease, year of transplantation, and so forth.

others. Most reports have been controversial, with different centers reporting disparate results.

Because of these contradictory reports and the importance of accurately predicting the occurrence of interstitial pneumonitis in patients, we analyzed data from 932 patients with leukemia who received HLA-identical bone marrow transplants between 1978 and 1983. We identified six factors that appear to predict independently the development of interstitial pneumonitis.

Patients and Methods

PATIENTS

Comprehensive data were reported to the International Bone Marrow Transplant Registry by 69 transplant centers worldwide for 1183 consecutive patients with leukemia who received bone marrow transplants between 1 January 1978 and 30 June 1983. The minimum follow-up time was 7 months. Data from the 932 patients who received transplants from HLA-A, B-, and mixed-leukocyte-culture-identical sibling donors with no evidence of histoincompatibility at other HLA loci are the basis for this study. Forty-six of these six patients had acute myelogenous leukemia, 339 had acute lymphocytic leukemia, and 187 had chronic myelogenous leukemia. Characteristics of patients before transplantation are presented in Table 1. Univariate analyses showed that neither diagnosis nor disease status was significantly associated with the occurrence of interstitial pneumonitis. As a consequence, subsequent analyses combined all 932 patients.

Most patients (920 of 932) were prepared for transplantation with both immunosuppressive-antileukemic cytotoxic chemotherapy and total body irradiation. After transplantation, patients were given methotrexate, cyclosporine, corticosteroids, antithymocyte globulin, or other agents, alone or in combination, to prevent or treat graft-versus-host disease. In this report, interstitial pneumonitis includes any nonmalignant pneumonia with radiographic or histologic features commonly associated with the disease (19-21). Biopsy or autopsy material was studied from more than 75% of patients.

Statistical Methods

Thirty-three potential prognostic variables were studied (Table 2). The association between each factor and the occurrence of interstitial pneumonitis was tested with chi-square and t tests. Factors found to be significantly associated with interstitial pneumonitis by these univariate tests were included in a multiple logistic equation. From the logistic analysis, we derived the probability of interstitial pneumonitis for a patient with a single risk factor or a specific profile of risk factors. The relative risk associated with a single risk factor or profile was computed as the probability of disease for patients with that risk factor or profile divided by the probability of disease for patients with none of the risk factors.

To determine whether risk factors differed according to the type of disease, we did separate univariate and logistic analyses for patients with interstitial pneumonitis that was idiopathic or associated with cytomegalovirus. Differences between treatment centers that could not be accounted for by recorded information were tested in two ways in logistic analysis after we adjusted for the known risk factors: first, by comparing the group of patients given transplants in smaller centers with an approximately equal-sized group given transplants in larger centers; and second, by comparing rates of interstitial pneumonitis in patients from each of the seven largest centers with rates in the remaining patients. The actuarial incidence of interstitial pneumonitis was computed by standard life table methods (26).

Results

Two hundred sixty-eight patients developed interstitial pneumonitis for an actuarial incidence at 2 years of 35 ± 4% (SD). The median time from transplantation to onset of interstitial pneumonitis was 52 days (range, 2-49); in 71% of the patients the disease occurred within 90 days, and in 91% it occurred within 180 days after transplantation. Interstitial pneumonitis was the primary cause or a contributory cause of death in 224 patients, for a case-fatality rate of 84%.

presence of severe graft-versus-host disease (Figure 1C),
performance ratings (27) before transplantation of less
than 100% (Figure 1D), and increased time from diag-
nosis to transplantation (Figure 1E). Dose-rates of irra-
diation of 6.0 cGy/min or more were associated with
an increased incidence of interstitial pneumonitis in the 672
patients who received methotrexate for prophylaxis
against graft-versus-host disease (Figure 1F). A dose-
response trend was apparent at lower dose-rates, but a pla-
teu was reached at 6.0 cGy/min with no further incre-
ment in the risk of disease with dose-rates up to 108 cGy/
min. This relationship between dose-rate and the occur-
rence of interstitial pneumonitis was not observed in the
208 patients who received cyclosporine.

The relationship between donor-recipient sex-match and
the occurrence of interstitial pneumonitis was similar to
that reported previously in a smaller series of patients (18),
and it approached statistical significance (p < 0.06). The
incidence was lowest among female patients who received
bone marrow from female donors (21%, 38 of 182) and
highest (34%, 77 of 227) in male patients who received
bone marrow from female donors. No other variable in-
vestigated (Table 2) was associated with the risk of inter-
stitial pneumonitis.

MULTIVARIATE ANALYSES

All six factors found to be significantly related to the
occurrence of interstitial pneumonitis in the univariate
analysis (Figure 1) were significant when simultaneously
included in the logistic equation. The transplantation
center was not a significant prognostic factor.

To simplify presentation of the results, we did a second
logistic analysis with dichotomized variables. The relative
risk of interstitial pneumonitis and the associated p val-
ues for the dichotomized variables are presented in Table
3.

When data from patients with idiopathic and cytomeg-
alomavirus-associated interstitial pneumonitis were tested
separately in logistic analyses, the only risk factor that
differed significantly (p < 0.04) was age of the patient.
The relative risk for older patients was 1.8 in those with
idiopathic disease and 3.2 in those with interstitial pneu-
onitis associated with cytomegalovirus. There was no
significant difference between small and large centers in
the incidence of interstitial pneumonitis or in the propor-
tion of patients with idiopathic as compared with cyto-
meagalovirus-associated disease.

Logistic analysis was used to estimate the probability of
developing interstitial pneumonitis for a patient with a
given profile of prognostic factors. The estimated proba-
bility was 8% when none of the adverse risk factors were
present, and this probability significantly increased as
each of the six significant adverse risk factors was added
(Figure 2). When all six adverse risk factors were pres-
ent, the probability of interstitial pneumonitis was 94%,
and the risk of a patient developing the disease was grea-
ter than 11 times higher than that seen in patients who
had none of the adverse risk factors.

The six factors of prognostic importance can be divid-
ed into two categories according to their ability to be

Of the 268 patients who developed interstitial pneu-
onitis, the disease was considered to be idiopathic in
50%; it was associated with cytomegalovirus in 37%,
with Aspergillus or Candida, with P. carinii in 4%, and
with herpes simplex virus, herpes zoster virus, Torulop-
sis, or Actinomycetes in 4%. The case-fatality rate was
78% (105 of 135) for patients with idiopathic disease,
93% (92 of 99) for those with cytomegalovirus, and
80% (28 of 35) for patients with other agents.

UNIVARIATE ANALYSES

To facilitate presentation of the data and for descript-
ive purposes, the results of the univariate analyses are
shown in Figure 1. The incidence of interstitial pneumo-
nitis was increased with increasing age of the patient
(Figure 1A), the use of methotrexate (Figure 1B), the

Controlled by the referring physician or transplantation team. Controllable variables include the drug used to prevent graft-versus-host disease, interval from diagnosis to transplantation, and dose-rate of total body irradiation. Uncontrollable variables include age of the patient, performance rating before transplantation, and severity of graft-versus-host disease. When all three controllable risk factors were unfavorable, the relative risk of interstitial pneumonitis was 4.5. When the three uncontrollable factors were unfavorable, the relative risk was 6.1.

ROLE OF RADIATION THERAPY REGIMEN

In addition to dose-rate (Figure 1F, Table 3), several irradiation variables were tested for possible associations with interstitial pneumonitis. The incidence of interstitial pneumonitis for patients exposed to x-irradiation was similar to that for patients given gamma-irradiation (30%, 169 of 564 compared with 28%, 97 of 352). The rate was somewhat higher (p < 0.08) in patients given lung doses of 12 Gy in five or six fractions (36%, 25 of 70) than in patients given 10 Gy in one fraction (24%, 29 of 121). These doses were selected for comparison because data from animal experiments indicate that 10 Gy in a single dose has a radiobiological effect that is equal to or greater than that of 12 Gy of fractionated irradiation (28, 29). Thus, our data do not indicate that fractionation, at least in the doses and schedules used, provides protection against interstitial pneumonitis. No dose-response relationship was found between the occurrence of interstitial pneumonitis and mean lung doses of irradiation within the range of 5.6 to 12.5 Gy (Figure 3). This relationship was still not significant after we adjusted for dose-rate and number of fractions by using logistic analysis.

Discussion

Our analysis of 932 patients with leukemia who received bone marrow transplants from HLA-identical siblings demonstrates several important risk factors associated with the development of interstitial pneumonitis.

DRUG USED TO PREVENT GRAFT-VERSUS-HOST DISEASE

As in a previous report by the International Bone Marrow Transplant Registry in a smaller study (18), we again found a strong association between the use of methotrexate and an increased risk of interstitial pneumonitis. Both cyclosporine and methotrexate are immunosuppressive and may predispose to infection from endogenous or exogenous organisms. Methotrexate also, however, has been reported to be associated with pulmonary toxicity via several mechanisms: direct toxicity, changes in number and function of pulmonary alveolar macrophages and neutrophils, and allergy (30-32). Particularly relevant are reports describing interactions between methotrexate and radiation and between methotrexate and cyclophosphamide resulting in additive and synergistic pulmonary toxicity (33-35). Moreover, methotrexate usually is administered after transplantation at frequent intervals, and this frequent dosing, rather than cumulative dose, correlates with lung damage (36). Thus far, most data from animal or human studies (37, 38) have suggested no direct toxicity of cyclosporine to the lung.
One recent study supports our finding that methotrexate given after transplantation is associated with an increased risk of interstitial pneumonitis (39). Patients who received methotrexate showed an increased incidence of interstitial pneumonitis (44%, 15 of 34) in comparison with the group that received no treatment to prevent graft-versus-host disease (14%, 3 of 21). This difference was unrelated to the relative incidences of graft-versus-host disease in the two groups.

In contrast to our study, a randomized clinical trial comparing methotrexate and cyclosporine has failed to indicate a significant difference in the incidence of interstitial pneumonitis: 22% (9 of 41) and 25% (9 of 36), respectively (40). The reason for this disparity is unclear. The relatively small number of patients in that trial and resultant large beta-error made the likelihood of detecting a significant difference less than 50%.

**AGE OF PATIENT**

Younger patients had a lower incidence of interstitial pneumonitis compared with older patients, confirming a similar observation made at one center (17). The reason for this difference is unclear but could be related to differences in previous lung damage or to age-related differences in drug metabolism, toxicity, tissue resistance to radiation or drugs, or ability to repair tissue injury. The difference might also reflect the increased likelihood of older patients having had prior exposure to cytomegalovirus (with reactivation after transplantation). This suggestion is supported by the increasing rate of seropositivity to cytomegalovirus with increasing patient age (41). This possibility is supported further by our observation that cytomegalovirus pneumonia occurred in only 6% (27 of 451) of patients less than 21 years of age, whereas the incidence was 15% (72 of 478) in older patients. Although age of the patient was an important risk factor for idiopathic interstitial pneumonitis, the association was significantly stronger among patients with cytomegalovirus-associated disease.

**SEVERITY OF GRAFT-VERSUS-HOST DISEASE**

A strong association was found between the severity of graft-versus-host disease and the incidence of interstitial pneumonitis. Similar (17, 23, 25) and dissimilar (22, 42) results have been reported. Both graft-versus-host disease and its treatment result in profound and prolonged immune suppression after transplantation (14, 15), which may contribute to the increased risk of interstitial pneumonitis. Furthermore, graft-versus-host disease and its treatment can activate latent cytomegalovirus infection in mice (43). Activation of cytomegalovirus can affect the speed and extent of immune reconstitution (44). Patients in our study who developed moderate to severe acute graft-versus-host disease had a relative risk of interstitial pneumonitis associated with cytomegalovirus of 2.5 compared with a relative risk of 1.6 for those with idiopathic interstitial pneumonitis. Similar results were found in a retrospective study of cases not included in this report (19).

**INTERVAL FROM DIAGNOSIS TO TRANSPLANTATION**

The reason for an association between interval from diagnosis to transplantation and the risk of interstitial pneumonitis is uncertain. Patients who receive transplants at a longer interval from diagnosis are exposed to an increased duration and total dose of chemotherapy, which may lead to greater subclinical pulmonary injury and a greater degree of immunoincompetence. The increased incidence of interstitial pneumonitis among patients who received transplants more than 6 months after diagnosis was not due to an increased number of transfusions before transplantation with an associated higher risk of transfusion-transmitted cytomegalovirus infection. Patients who were given transplants within 6 months of diagnosis and those given transplants at longer intervals received similar numbers of transfusions before transplantation (mean, 24.8 ± 25.8 and 21.4 ± 26.2, respectively).
RADIATION THERAPY REGIMEN

Dose-Rate of Irradiation: Radiation to the lung can cause pulmonary damage (45). In this analysis we confirm our previously reported correlation between higher dose-rates and an increased risk of interstitial pneumonitis (18). The correlation was significant, however, only for the 672 patients who received methotrexate after transplantation. This finding is in accord with reports indicating that lung damage is increased when irradiation and methotrexate therapies are combined (33-35). Dose-rates of irradiation did not influence risk of interstitial pneumonitis in patients who received cyclosporine. The relationship between dose-rate of irradiation and occurrence of interstitial pneumonitis is probably complex. Animal studies have suggested that the relationship should be affected by total lung dose and fractionation schedules (28, 29, 46). However, we found that the relationship did not depend on these factors, but rather depended on a combined effect of dose-rate and methotrexate.

Dose of Irradiation: Within the range of 5.6 to 12.8 Gy we found no dose-response effect of pulmonary irradiation. Adjusting for number of fractions and dose-rate did not alter this conclusion. Similarly, Sloane and colleagues (20) have found no dose-response relationship between lung doses of 9.1 to 13.0 Gy and the incidence of interstitial pneumonitis. This finding contrasts with those of Keane and colleagues (43), who reported a direct correlation between the dose of irradiation to the lung and the risk of interstitial pneumonitis. The measurement of the actual dose delivered to the lungs, however, is difficult (46). It is possible that inaccuracies in dose measurement and differences in methods of reporting between centers may have obscured a dose-response relationship. On the other hand, the range of doses used in preparing patients with leukemia for transplantation may have been below or above the level where a dose-response relationship would be detectable clinically.

Fractionated Irradiation: We found no evidence that fractionated irradiation reduced the risk of interstitial pneumonitis. Similar findings have been reported in randomized and nonrandomized trials (47, 48). Other investigators, in small uncontrolled studies, have reported a decreased incidence of interstitial pneumonitis when fractionated irradiation was used (23, 49, 50), but these results must be interpreted cautiously because of the high incidence (58% to 70%) of interstitial pneumonitis in their control patients who were given single-dose irradiation. In two of the studies (23, 49), although the incidence of interstitial pneumonitis was reduced in patients given fractionated irradiation, the rate still exceeded the 29% overall rate in our study. Thus, within the range of doses and schedules tested, fractionated irradiation did not prove useful in decreasing the risk of interstitial pneumonitis.

PERFORMANCE STATUS BEFORE TRANSPLANT

The reason for the reduced risk of interstitial pneumonitis among patients with 100% performance ratings before transplantation compared with patients with ratings of 90% or less is not known. The difference may reflect greater tissue integrity with superior resistance to lung damage by the preparatory regimen for patients who were able to carry on normal activities with no evidence of disease, in comparison with patients whose performance status was even minimally compromised before transplantation. The relationship between performance status and incidence of interstitial pneumonitis was dichotomous. Patients with a 100% rating had an incidence of 24%, compared with 39% in those whose rating was less than 100%. In the group with the poorer ratings, there was no significant trend over the range of 20% to 90% (Figure 1D). It is difficult to assign precise performance scores. A rating of less than 100% may have reflected a clinical impression that although the criteria for a 100% rating were present, the patient was not an ideal candidate for transplantation. Therefore, we believe that conclusions regarding the role of the performance rating before transplantation on the risk of interstitial pneumonitis should be viewed with caution.

RELIABILITY OF DATA

One major concern regarding the results of this study relates to the contribution of transplantation centers of varied size and expertise. In no instance could we detect a "center-effect"; factors predictive of interstitial pneumonitis were valid at small as well as large centers, and data from no single center unduly influenced the study conclusions. A second related concern was the accurate distinction between idiopathic interstitial pneumonitis and that associated with cytomegalovirus and other organisms. Differences in diagnostic expertise undoubtedly exist between centers, but our concern for this issue was lessened because in more than 75% of the cases the diagnosis was established with biopsy or autopsy material. It is therefore unlikely that differences in diagnostic expertise lessened the validity of our conclusions.

Data from this study suggest that multiple factors predict, and probably contribute to, interstitial pneumonitis that occurs after bone marrow transplantation. We emphasize that these analyses were not based on randomized clinical trials. Clinical techniques, experience, and number of patients varied widely among the 69 centers that provided data for this study. Data from any registry have inherent weaknesses associated with inconsistent recording of information and unrecorded factors that confound treatment choices. These problems have been reduced in data reported to the International Bone Marrow Transplant Registry through the use of protocols for uniform reporting of data, through careful and comprehensive recording of patient and treatment information, and through the statistical techniques used. A major advantage of this registry, compared with clinical trials, is that it has a sufficiently large sample size and variability of a number of important prognostic variables that would be difficult or impossible to investigate at a single center. The results of the study reported here can be used to estimate the risk of interstitial pneumonitis for an individual patient and to suggest controlled clinical trials to test specific selection criteria and treatments.

Circulating Coagulation Inhibitors in the Acquired Immunodeficiency Syndrome

ALICE J. COHEN, M.D.; TERRENCE M. PHILIPS, Ph.D.; and CRAIG M. KESSLER, M.D.;
Washington, D.C.

Abnormal coagulation profiles were identified in ten patients with the acquired immunodeficiency syndrome (AIDS) associated with opportunistic infections and malignancies. Partial thromboplastin times were elevated in all patients; three of seven had elevated prothrombin times. All patients had lupus-type anticoagulants characterized by rapid prolongations of the partial thromboplastin time in mixing studies, prolonged dilute thromboplastin inhibition assays, and increased Russell viper venom clotting times. Iby bleeding times were prolonged in three patients with defective platelet aggregation. The lupus anticoagulant was isolated from the sera of healthy heterosexual men and from patients with AIDS with and without the lupus anticoagulant, and in the presence and absence of opportunistic infections. Both polyclonal IgM and IgG from plasma with lupus anticoagulant interfered with clotting studies and platelet aggregation. The inhibitors usually suppressed damped active opportunistic infections and tended to disappear with successful resolution of infection.

The lupus-type circulating anticoagulant was initially detected and characterized in patients with systemic lupus erythematosus (1-3); however, similar inhibitors also have been acquired in association with various other chronic autoimmune diseases, hematologic and nonhematologic malignancies, acute drug hypersensitivity reactions, and in pregnancy (2-6). Occasionally, the lupus anticoagulant may occur as an isolated idiopathic phenomenon (5, 6). The lupus anticoagulants appear to be abnormal acquired IgG or IgM immunoglobulins, or both, which are directed against phospholipid components of the prothrombin activator complex involved in coagulation (7-9) and occasionally against the phospholipid contained in the platelet membrane (10, 11). The resulting inhibition of coagulation and platelet function can be shown in vitro (4, 10, 12), but rarely produces clinical hemorrhagic complications (2, 4, 6) unless the lupus anticoagulant is associated with a qualitative or quantitative platelet defect, or an absolute prothrombin deficiency (2, 4, 6, 8, 10, 11, 13).

Recently, we have seen a circulating anticoagulant in patients with the acquired immunodeficiency syndrome (AIDS). We have shown that these inhibitors of coagulation associated with AIDS may be monoclonal or polyclonal immunoglobulins, that they may produce qualitative platelet defects, and that they appear to arise and subside spontaneously with the onset and successful resolution of opportunistic infections. The in-vitro properties of the agents would allow them to be designated lupus anticoagulants.

HLA Associations With Leukemia

By Mortimer M. Bortin, Joseph D’Amaro, Fritz H. Bach, Alfred A. Rimm, and Jon J. van Rood

Frequencies of 35 HLA A, B, C, and DR antigens were determined in 1,834 leukemic Caucasoids to evaluate possible associations between HLA and leukemia. In comparison with the frequencies of HLA antigens in published controls, the frequency of CW3 was significantly higher in patients with acute lymphoblastic leukemia (relative risk = 2.64, P < 0.0002), acute myelogenous leukemia (relative risk = 1.92, P < 0.0007), and chronic myelogenous leukemia (relative risk = 2.07, P < 0.0002; values adjusted for multiple comparisons). The frequency of CW4 was elevated in patients with acute lymphoblastic leukemia (relative risk = 2.01, P < 0.0003), acute myelogenous leukemia (relative risk = 2.06, P < 0.0002), and chronic myelogenous leukemia (relative risk = 2.14, P < 0.0008). The frequency of AW19 was significantly decreased in patients with acute myelogenous leukemia (relative risk = 0.68, P < 0.01) and chronic myelogenous leukemia (relative risk = 0.59, P < 0.006). None of the other 32 HLA antigens investigated had a statistically significant association with leukemia. The data suggest that CW3 and CW4 may be markers for leukemia susceptibility genes, while AW19 may be a marker for decreased susceptibility to leukemia.

In 1930 Fisher proposed that selective interactions between genes might favor their linkage. Darlington and Mather extended this idea and introduced the term “supergene” for groups of linked genes that are inherited en bloc. Overviews of the HLA supergene were published by Ceppellini, Bach and van Rood, Bodmer, and Bach. The biological importance of supergenes is emphasized by the fact that they are found in all vertebrate species that have been studied. Homology between the major histocompatibility complex (MHC) in different species supports the hypothesis that the MHC has been conserved throughout phylogeny because it confers important biological advantages on the species.

The observation by Lilly et al. that increased or decreased susceptibility of mice to Gross virus-induced leukemia was linked to H-2 and H-2 respectively prompted Amiel in 1967 to search for associations between histocompatibility antigens and pathologic conditions in humans. He reported a significant association for HLA B5 in patients with Hodgkin’s disease. Since then numerous studies investigated HLA associations with disease.

In 1984 we reported the results of analyses investigating HLA associations with leukemia in 1,009 leukemia patients (hereafter referred to as “initial series”). We found a statistically significant increase in the frequency of CW3 and CW4 in patients with acute lymphoblastic leukemia (ALL) and of CW4 in patients with acute myelogenous leukemia (AML). An additional 825 leukemia patients have now been studied (“current series”), and the results from these patients and the combined series are presented here.

PATIENTS AND METHODS

Patients. Detailed information regarding 1,834 North American and European Caucasoid patients treated with chemotherapy and bone marrow transplantation (BMT) for leukemia was reported to the International Bone Marrow Transplant Registry. Transplants were performed between 1969 and 1985 by 96 BMT teams worldwide. The diseases studied were ALL, AML, and chronic myelogenous leukemia (CML; Table 1). Patients’ median age was 21.4 years (range 0.6 to 59 years), and 55% were males. The median interval from diagnosis to transplantation was 9 months (range 0.3 to 144 months). At the time of transplantation 47% of the patients were in first remission or chronic phase, 20% in second remission, and the disease was more advanced in 33%. Chemotherapy failed to induce a first remission in 3% of the patients with acute leukemia.

Antigenic splits were converted to their equivalent broad specificities because many of the splits were not defined in the earlier years of this study. Data for 35 HLA antigens were available for investigation: eight HLA A antigens (1,2,3,9,10,11,w9,28), 15 HLA B antigens (5,7,8,12,13,14,15,16,17,18,21,w22,27,35,46), six HLA C antigens (w1,w2,w3,w4,w5,w6), and six HLA DR antigens (1,2,3,4,5,7). Estimates of the frequency of DRw6 in North American and European Caucasian controls were not thought to be reliable, and this antigen was excluded from analysis. Data were available to analyze the frequency of HLA A in 1,834 patients, B in 1,801 patients, C in 783 patients, and DR in 709 patients.

HLA antigen frequencies for the control series of North American and European Caucasoids were obtained from Tables 6 through 9 in Baer and Daniloff’s population analysis from the Eighth International Histocompatibility Workshop.

Statistical analysis. The extensive polymorphism of HLA not only provides a large number of markers to be tested for possible associations with diseases but also presents problems in interpretation of results. The main problem is that the performance of large numbers of statistical comparisons increases the probability that apparent differences between two groups may have occurred solely by chance. Svejgaard et al. discussed this problem and suggested several methods to help resolve it.

Haldane’s modification10 of Woolf’s method29 was used to assess the significance of the differences in the antigen distributions in the control vs the leukemia populations. Multiplex testing for heterogeneity in a single locus or multiple loci was performed by summing the chi squares provided by the Woolf-Haldane analysis. That value is itself a chi square with degrees of freedom equal to the total number of antigens in the loci or loci.29 Corrected P values were derived by taking into account the 35 antigens that were tested using the method of Edwards.29 Only corrected P values are presented.

Initially HLA antigen frequencies from the 258 North American and the 567 European Caucasoids from the current series were tested independently against their respective controls. Comparisons were then made with the HLA antigen frequencies found in the 628 North American and 381 European Caucasoids from the initial series. This strategy was used because it would be most unlikely that the same association would be observed by chance alone in all four subsets. All four subsets were combined for an overall analysis.

RESULTS

Multiplex testing disclosed no significant heterogeneity in the distribution of HLA A, B, C, and DR antigens between the North American and Eurcjenan patients in the initial or current series. In particular there were no significant differences for the Aw19, Cw3, and Cw4 antigens. The distribution of the Aw19, Cw3, and Cw4 antigens in the North American and European control populations also did not differ significantly.

Of the 35 HLA antigens studied, only Aw19, Cw3, and Cw4 had significant associations with leukemia in general, ie, the combined series ALL, AML, and CML (Table 2). Compared with controls, Aw19 had a lower frequency and decreased relative risk in all four subsets of patients; the pooled data had a frequency of 23% vs 30% for controls with a relative risk of 0.71 and a P value < 0.0006. Both Cw3 and Cw4 had consistently elevated frequencies in all four subsets in comparison with controls, and the relative risks of 2.20 and 2.06 respectively for the pooled data were highly significant (P < 0.00001).

Shown in Table 3 are the relative risks and significance levels for Aw19, Cw3, and Cw4 in the initial, current, and combined series for ALL, AML, and CML. For the Aw19 antigen, note that the relative risk was consistently below 1.0 in each of the North American and European subsets and for each of the diseases studied, but in none of the 12 subsets was statistical significance observed. It was not until the data were pooled, with a resultant increase in the power of the test, that statistically significant lower frequencies for Aw19 were found both for the 665 patients with AML and the 442 patients with CML. In the pooled data from 727 patients with ALL, the frequency of Aw19 was lower than controls, but the level was not statistically significant.

The frequency for Cw3 was consistently elevated for patients with ALL, AML, and CML but was statistically significant in only three of four ALL, in one of four AML, and in one of four CML subsets (Table 3). When the data were pooled, the power of the test increased, and the frequency of Cw3 was significantly increased for each of the diseases. Similarly, the frequency of Cw4 was consistently elevated for all 12 subsets of patients but was statistically significant in only two subsets of AML patients. The combined data indicate that Cw4 has a significantly increased frequency for ALL, AML, and CML.

In the combined series there were 72 patients with ALL or AML in whom complete remission was not attained following induction chemotherapy. They were considered to be refractory to chemotherapy. To determine whether Aw19, Cw3, or Cw4 might be associated with responsiveness to chemotherapy in leukemia patients rather than leukemia per se, the frequencies of these antigens were analyzed in the 1,320 patients with acute leukemia who had responded to chemotherapy and the 72 patients who had not. No statistically significant heterogeneity was found; chi squares were 1.08 for Aw19; 0.03 for Cw3; and 0.01 for Cw4. Among the patients who had not responded to chemotherapy, the frequency of Aw19 was not significantly different from patients who had responded: 31% vs 30% respectively. The frequency of Cw3 of nonresponders, however, was increased; 36% vs 20% for controls (uncorrected P = 0.012), as was the frequency of Cw4; 40% vs 22% for controls (uncorrected P = 0.005).

DISCUSSION

This investigation of 1,834 patients with leukemia disclosed highly significant associations between HLA and the risk of leukemia. In comparison with healthy controls, frequencies of Cw3 and Cw4 were increased (relative risk > 2.0, P < 0.00001), and the frequency of Aw19 was decreased

*Relative risk.  
†Corrected for 35 comparisons.

(relative risk <0.72, P < 0.0006). These findings confirm and extend our previous report investigating HLA association with leukemia.\[16\] Frequencies for the 32 other A, B, C, and DR antigens studied were not significantly different from controls.

Most studies of HLA associations with leukemia have focused on the HLA A, B, or D/DR loci.\[13,14\] The findings have been inconsistent, and no strong associations between these loci and leukemia have been reported (Table 4). In particular, to the best of our knowledge, associations between HLA C and leukemia were not reported prior to or since our initial study.\[16\] De Jongh et al.\[26\] conducted the only study known to us in which HLA C associations with leukemia were investigated. They found no significant difference in HLA C antigen frequency between controls and a group of 44 children with ALL. The discrepancy between their results and ours may have been due to the low power of the test in their study.

The pooled data showed that Aw19 had a significantly lower frequency among leukemia patients in general. In our initial study the lower frequency of Aw19 in leukemia patients was uncertain because it had only borderline significance (corrected P = 0.047) in the North American subset of 628 patients and was not significant in the 381 European patients.\[16\] With the group size increased from 1,009 to 1,834 leukemia patients, it now seems clear that the frequency of Aw19 is indeed decreased in leukemia patients. The frequency of Aw19 was significantly reduced in AML (P < 0.01) and CML (P < 0.005). Although not statistically significant in ALL, it should be noted that the relative risk associated with Aw19 was consistently lower than 1.0 in all four subsets of ALL patients (Table 3). In one study of 60 patients with ALL, a decreased frequency of Aw19 (uncorrected P < 0.05) was reported by Kluoda et al.\[31\] It is possible that when additional patients with ALL become available for study, Aw19 may also prove to be associated with a reduced risk for this disease.

The strong positive association of Cw3 and Cw4 with leukemia supports the possibility that these antigens, or the genes encoding them, are, or are closely linked with, possible susceptibility genes. An increased relative risk of leukemia has been observed in the siblings of leukemia patients,\[4,11\] but the mechanism is not known. Based on the findings reported here, it is possible that the mechanism may be due in part to an increased frequency of Cw3 or Cw4 in siblings of leukemia patients. Studies of HLA C in instances of familial leukemia are encouraged. Another possibility, suggested by other studies, is that Aw19, Cw3, and Cw4 may be markers coding for immune responsiveness to putative leukemia viruses; DeVries et al.\[16\] found a significant association between Cw3 and low in vitro responses to vaccinia virus. Our data show no association between Aw19, Cw3, or Cw4 and responsiveness to chemotherapy in leukemia patients.

The reader is cautioned that our findings may not be representative of all leukemia patients because of several unavoidable biases in the database of the International Bone Marrow Transplant Registry. For example, most teams do not perform BMTs on older patients. As a consequence, almost all patients in this study were less than 50 years of age, and our findings may not apply to older leukemia patients. The 95% remission-induction rate in our cases with acute leukemia is higher than most reports of nontransplanted patients, especially those with AML. All patients reported here survived long enough to undergo BMT. It is likely that some patients for whom BMT was planned died before the plan could be implemented. It is possible that patients with especially virulent forms of leukemia or, as suggested by Rogentine et al., some less hardy patients did not survive long enough to be transplanted and thus were not available to us for study. Other interpretations are possible. Furthermore, HLA data for patients with chronic lymphocytic leukemia were not available to us for analysis, and it is not known whether the findings reported here also apply to these patients or to non-Caucasoids. Studies of HLA associations with morphological, immunologic, and cytogenetic subtypes of leukemia will be undertaken in the future with an expanded database.

The positive and negative associations with leukemia we found with relative risks ranging from 2.64 to 0.59, while highly significant, are weak in comparison with those described in some other studies showing significant associations between HLA and disease.\[15,15\] The extremes, according to Svejgaard et al.,\[14\] are the positive association between B27 and ankylosing spondylitis, with a relative risk of 87.4, and the negative association between DR2 and insulin-dependent diabetes, with a relative risk of 0.2. The analyses presented...

‡This report.

Here clearly show the desirability of a large database in studies investigating HLA associations with disease when there is in fact a relationship but it is not strong. For example, in Table 3, although a trend was present, Aw19 was not significantly associated with AML or CML in any of the subsets. Only when group sizes in the combined series were 665 (AML) and 442 (CML) did statistically significant associations become evident. Similarly, Cw4 was not statistically significant in any of the ALL or CML subsets; using pooled data from the combined series demonstrated highly significant associations with each disease. Another problem with relatively small group sizes is demonstrated by those
REFERENCES

instances when significant associations were found in some subsets but not in others (Table 3). It is clear from the data shown in Table 4 that inadequate group sizes account for many of the conflicting reports in the literature describing the presence or absence of HLA associations with leukemia.

The increased frequency of CW3 and CW4 and decreased frequency of Aw19 in leukemia patients provides strong evidence that the HLA supergene, as H-2 in the mouse, may play a role in increased and decreased susceptibility to leukemia. Although it is far from clear that the mechanism for the association in mouse and man is similar, until now the parallel has been elusive.

It is generally believed that HLA antigens influence the T lymphocyte repertoire. We found that the risk of leukemia is significantly increased in individuals with CW3 or CW4. It seems likely that these people will have a T cell repertoire that is different from individuals who are negative for CW3 and CW4. This simply means that CW3 and CW4 antigens are immune response gene products. It does not answer the question of how these immune response genes confer low responsiveness against a putative leukemia-inducing agent. Our data imply that individuals who have neither CW3 nor CW4 are better able to resist leukemia than those who are positive. This remains purely speculative because there are no available tests to investigate this hypothesis.

The fundamental importance of this study is not that CW3 and CW4 were found to have significant associations with leukemia but rather that HLA C genes, or genes closely linked with HLA C, have hitherto unrecognized properties. Whether HLA C also will be found to be associated with other malignant and nonmalignant diseases remains to be determined.

Temporal relationships between the major complications of bone marrow transplantation for leukemia

M.M. Bortin, O. Ringdén, M.M. Horowitz, C. Rozman, R.S. Weiner & A.A. Rimm

The International Bone Marrow Transplant Registry, Department of Medicine, Division of Hematology/Oncology and the Division of Biostatistics/Clinical Epidemiology, Medical College of Wisconsin, Milwaukee, USA, Departments of Clinical Immunology and Transplantation Surgery, University Hospital, Huddinge, Sweden, Service d’Hematologie, Escuela de Hematologia, Universidad de Barcelona, Spain and Division of Medical Oncology, University of Florida, Gainesville, USA

Summary:

Data from 3113 patients receiving HLA-identical sibling bone marrow transplants for leukemia were analysed to determine the time course of the major causes of treatment failure. The median interval from transplant to onset of acute graft-versus-host disease (GVHD) was 17 days, interstitial pneumonia 63 days, and chronic GVHD 111 days. The median interval from transplant to relapse was 3.3 months for patients transplanted in relapse of acute leukemia or blast phase of chronic myelogenous leukemia (CML), 6.4 months when transplants were performed in second or subsequent remission of acute leukemia or accelerated phase of CML, and 7.8 months for patients transplanted during first remission of acute leukemia or while in the chronic phase of CML. Shorter intervals from transplant to onset of interstitial pneumonitis or chronic GVHD were associated with a significantly lower probability of 2-year survival. The temporal relationships between these complications are displayed graphically and demonstrate the overlapping and competing causes of death following allogeneic bone marrow transplantation.

The first year following allogeneic bone marrow transplantation (BMT) for leukemia is the period of greatest risk for treatment failure (death or relapse). Patients who survive this critical interval have an excellent chance for long-term, leukemia-free survival.

The major causes of failure after allogeneic BMT for leukemia are acute graft-versus-host disease (GVHD),

interstitial pneumonitis (IPn),

chronic GVHD and its associated complications, and relapse. The peak incidence of each of these complications occurs within the first year post-transplant. Interactions among them are complex and have a significant impact on outcome. For example, the risk and lethality of IPn is increased in the presence of GVHD, and the severity of GVHD may favorably or unfavorably affect the risk of leukemia relapse. The severity of GVHD correlates directly with the risk of infection and inversely with the probability of relapse.

Analyses were performed to investigate the sequence of events complicating HLA-identical sibling bone marrow transplants in leukemia. The findings help elucidate pathogenetic mechanisms involved in the major causes of treatment failure following BMT.

Patients and methods

Comprehensive data were reported to the International Bone Marrow Transplant Registry (IBMTR) by 131 transplant centers worldwide for 3113 patients with acute lymphoblastic leukemia (ALL), acute myelogenous leukemia (AML) and chronic myelogenous leukemia (CML). All patients received bone marrow transplants from HLA-identical siblings between 1 January, 1982 and 31 December, 1987. Their distribution by disease and disease status is shown in Table I. Patients transplanted in first remission of ALL or AML or the chronic phase of CML are referred to as having 'early' leukemia; patients in second remission of ALL or AML or the accelerated phase of CML as having 'intermediate' leukemia; and relapse of ALL or AML or blast phase of CML as having 'advanced' leukemia. Minimum follow-up time was 4 months, and the median was 19 months. Median patient age was 26.8 years (range 0.9–59 years) and 1789 (57%) were male. The pretransplant preparative regimen included cyclophosphamide in 2734 (88%) patients and total body radiation in 3011 (97%) patients. Prophylaxis against GVHD included methotrexate in 930 (30%) patients, cyclosporine in 1173 (38%), both methotrexate and cyclosporine in 328 (11%), T cell depletion in 600 (19%) and other methods in 82 (3%).

Events studied were acute GVHD, IPn, chronic GVHD and relapse. The overall incidence and actuarial probability of these complications are shown in Table II. To demonstrate the time when patients are at risk of each complication, intervals from transplant to onset and from transplant to death from the complication are plotted; the shorter intervals until the median are shown as the ascending limb of the curve and the intervals after the median as the descending limb. Standard life-table methods were used to estimate probabilities. The Lee–Desu statistic was used to test for significant differences between curves. The Kruskal–Wallis statistic was used to test for significant differences between medians.

Received 9 December 1988; accepted 3 March 1989
similar irrespective of the tumor burden present at the time of transplantation. The longer interval between transplant and relapse among patients who developed chronic GVHD suggests a possible graft-versus-leukemia effect. This putative adoptive immunotherapeutic effect was not apparent among patients developing acute GVHD.

In conclusion, most deaths occur in the first year following bone marrow transplantation for leukemia. The major causes of treatment failure are acute GVHD, IPH, chronic GVHD and relapse. Each has its own distinctive time-pattern with respect to the interval from transplant to onset and from onset to death. The time patterns overlap resulting in multiple competing causes of treatment failure.

Summary

In 117 patients with chronic myelogeneous leukaemia (CML) treatment with a combination of high-dose chemoradiotherapy plus transplantation of allogeneic bone marrow from HLA-identical, matched lymphocyte-culture-identical siblings resulted in an actuarial probability of 3-year survival of 63±16% (95% confidence interval) for 10 patients transplanted in chronic phase; 14±14% for 8 transplanted in accelerated phase; and 2±15% for 62 transplanted during blast crisis. Irrespective of disease status at the time of transplantation, and in contrast to chemotherapy, a plateau-effect was observed in the survival curves starting 14 to 19 months after transplantation.

INTRODUCTION

The treatment of chronic myelogeneous leukaemia (CML) has progressed little in the past 50 years. Median survival after chemotherapy is 3–4 years; fewer than 20% of patients survive 5 years, and there are no cures. There is no clear evidence that conventional chemotherapy can prolong life or delay the onset of blast crisis. After transition into blast crisis usually only partial and short remissions can be achieved with chemotherapy. Attempts to treat blast crisis with high-dose chemoradiotherapy followed by infusion of autologous stem cells harvested during chronic phase from bone marrow and blood have also given only short remissions. Bone marrow transplantation (BMT) in accelerated phase or blast crisis using healthy syngeneic or HLA-identical sibling donors has been disappointing owing to early infections, interstitial pneumonitis, failure to eradicate the leukaemia, and incomplete engraftment. Although cytotgenic conversion can usually be obtained even in patients allografted in blast crisis, long-term survival with the potential of cure has been reported in fewer than 20% of the patients.

Experience in patients with acute leukaemia clearly showed that the best results of allogeneic BMT were achieved during first or second complete remission. From these results several teams hypothesised that allogeneic BMT would have a better chance of success for patients with CML if the transplant was performed in first chronic phase rather than in later stages of the disease. In studies of patients with acute leukaemia treated with high-dose cyclophosphamide and total-body irradiation (TBI) morbidity and mortality were similar to those achieved with BMT. Most deaths were due to interstitial pneumonitis or graft-versus-host disease (GVHD). Although the observation period was relatively short, leukaemic relapse was less common in patients with CML than in patients with acute leukaemia treated with cyclophosphamide, TBI, and BMT.

The results of BMT in the chronic phase of CML from genetically identical twins are also encouraging. 8 of 12 patients reported in the literature remained in complete cytogenetic and haematological remission 21 to 60 months after transplantation.

PATIENTS AND METHODS

Data for 138 patients with CML transplanted between July 1, 1976, and June 30, 1982, were reported to the International Bone Marrow Transplant Registry (IBMTR) by 36 transplant centers. 117 of these patients received marrow from HLA-A, B, and mixed lymphocyte-culture (MLC)-identical allogeneic siblings with no other evidence of incompatibility. The minimum follow-up time was 13 months. 21 of the 138 patients did not meet the study criteria and were excluded from the analyses. Reasons for exclusions were: identical twin donor (8 patients), MLC technical failure or not done (6 patients), MLC incompatibility (3 patients), 1 patient each with HLA-A incompatibility, HLA-C incompatibility, or parental donor, and 1 patient with juvenile CML whose disease transformed into acute lymphoblastic leukaemia (ALL) before transplantation. The disease status at the time of transplantation for the 117 patients was evaluated just before the start of pretransplant...
Results

All but 7 patients were conditioned for transplantation with busulfan and TBI. 81 patients received additional antimetabolide drugs including L-asparaginase, busulfan, cytarabine, daunorubicin, dexamethasone, cyclophosphamide, methotrexate, thiotepa, and vinristine. Single-dose TBI was given to 61% of the patients; 15% received fractionated TBI, and 3 patients were not irradiated.

From preliminary study of the post-transplant survival curves (fig 1A), it was apparent that the patients could be divided into three major cohorts according to disease status of CML at the time of transplantation: 39 patients transplanted in first chronic phase, 56 patients transplanted in accelerated phase, and 22 patients transplanted in blast crisis. The distribution and frequency of 21 disease-related and transplant-related variables are presented in table 1.

Among the 39 patients transplanted in chronic phase, the actuarial probability of surviving 3 years was 6% (95% confidence interval CI 47-79%), the actuarial probability of 3-year survival for the 56 patients transplanted in accelerated phase was 36% (95% CI, 7-50%), and for the 22 patients transplanted in blast crisis the actuarial 3-year survival was 12% (95% CI, 0-27%). The difference in probability of survival for the three cohorts of patients was significant (p<0.001) after adjusting for other potentially important prognostic factors (fig 1A). The survival curves reached a plateau at 14, 19, and 17 months post-transplant for patients transplanted in chronic, accelerated, and blast phase, respectively.

Post-transplant relapse data for the three transplant groups are presented in fig 1B. The actuarial probability of relapse among patients transplanted in chronic phase was 7% in 59% CI, 0-16%) at 3 years. The probability of relapse for patients transplanted in accelerated phase (41%, 95% CI, 23-60%) and for patients transplanted in blast crisis (41%, 95% CI, 2-80%) was significantly higher (p<0.001) than for patients transplanted in chronic phase after adjusting for the variables shown in table 1.

3 of the 20 patients who relapsed were still alive at 8-7, 11-6, and 13-5 months after relapse. All were transplanted in accelerated phase, 1 is in chronic phase on chemotherapy, 2 received a second transplant, 1 of the latter relapsed again and is in chronic phase on chemotherapy 5 months after the second relapse, and the other is Ph-negative again 4 months after the second transplant.

experience for patients transplanted in accelerated phase was inferior to that of patients transplanted in chronic phase, their probability of survival was higher than for patients transplanted in blast crisis (fig 1A).

The actuarial risk of relapse among patients transplanted in chronic phase of CML was only 7% (fig 1B). Of the 2 patients who relapsed, 1 was Ph-negative and was given 200 mg/kg cyclophosphamide and 16 mg/kg busulphan but no TBI before transplantation. The other was Ph-positive and received 120 mg/kg cyclophosphamide, 1-88 mg/kg daunorubicin, and 10·0 Gy TBI before transplantation. This low relapse rate contrasts with data from the BHTR in which the risk of relapse following allogeneic BMT in first remission for acute myelogenous leukaemia (AML) was 32%10 and for ITLB 28%.17 The risk of relapse or persistent leukaemia in CML of 41% in both accelerated and blast phases (fig 1) also was somewhat lower than that observed in advanced AML (50%)4 and ALL (67%).17 The reason for the lower probability of relapse in CML than in AML and ALL is not known but may be due to differences in the virulence of the diseases or to greater vulnerability of CML malignant cells to high doses of TBI and cyclophosphamide than malignant cells in AML and ALL. Larger series of patients and longer follow-up are necessary to assess the longer term risk of relapse in CML.

Transplant-related mortality due to interstitial pneumonitis, GVHD, and infection remain as formidable problems in all grafted CML patients as in allografted AML and ALL patients. However, to determine the role of BMT in the management of patients with CML, the risks of severe transplant-related complications have to be compared with the risk of disease itself when other modes of therapy are used. With various chemotherapeutic agents, immunotherapy, splenectomy, the linearity of the decline in survival rates was inexorable and a plateau was not achieved.3,5-7,12 In contrast, a plateau effect was observed in the patients treated with BMT. The length of follow-up for the patients treated with BMT is, however, shorter than for the patients treated with conventional or experimental chemotherapy.

Thus, out of the 117 patients who died. Primary causes of death by disease status are shown in table I. Intestinal pneumonitis was the main cause of death, followed by recurrent or persistent leukaemia, infection, and GVHD.

Examination of the survival data for the 21 excluded patients disclosed that 5 of 8 patients (62%) who received marrow from identical twins are still alive 14-46 months post-transplant. 1 patients died of recurrent leukaemia. 1 of 6 patients who received marrow from HLA-identical donors but at whom the MLC tests were technical failures or not done are alive 13-36 months post-transplant. 1 of 3 patients with MLC compatibility and the 1 patient whose CML transformed before transplantation into ALL are alive 15 and 29 months post-transplant, respectively. Thus, 10 of the 11 patients (45%) who were excluded from the analyses are alive 14-46 months after transplantation.

Discussion

The results presented here show that optimum results of allogeneic BMT are achieved when CML patients are transplanted in first chronic phase. Similar tentative conclusions were reached in previously published reports on smaller series of patients.12,13 Although the survival

Summary

7864 infants were examined within 48 h of birth by junior medical staff. 54 with dislocation, 16 with dislocatable hip, and 25 with joint laxity were referred for abduction splinting. 622 of the infants (7.9%) had minor signs (clicking or grating hip). When these 622 infants underwent clinical and radiological examination at 4 months of age, 34 had serious hip pathology (5 dislocation, 5 dislocatable hip, and 24 radiological abnormalities). Of the 716 infants considered normal in the newborn period, 7 were referred for orthopaedic opinion (1 with dislocation and 4 with subluxation) at age 2-9 months by general practitioners and community health physicians. Thus, dislocated or dislocatable hips were 39 times more frequent in infants who had minor signs on examination within 48 h of birth than in infants considered normal. The implication of these findings is that clicking and grating of the hip are important signs which require systematic follow-up, with radiological examination at 4-6 months.

D. SPEER AND OTHERS: REFERRAL IN CONGENITAL DISLOCATION OF THE HIP

Survival With Bone Marrow Transplantation Versus Hydroxyurea or Interferon for Chronic Myelogenous Leukemia

Hydroxyurea, Interferon, and HLA-identical sibling bone marrow transplantation are common therapies for chronic myelogenous leukemia (CML) in chronic phase. Which is best is controversial. The purpose of this study was to compare survival of patients with CML receiving HLA-identical sibling transplant versus hydroxyurea or Interferon. The transplant cohort included 548 recipients of HLA-identical sibling transplant patients, reported to the International Bone Marrow Transplant Registry. The nontransplant cohort included 196 patients receiving hydroxyurea (n = 123) or interferon (n = 75) on a randomized trial of the German CML Study Group. Survivors were compared using proportional hazards regression with fixed and time-dependent variables to adjust for patient differences and changing risks over time. For the first 18 months after diagnosis, mortality was higher in the transplant than the nontransplant cohort (relative risk [RR], 5.85; P < .0001). From 18 to 56 months, mortality was similar (RR, 0.80; P = .38). After 56 months, mortality was lower in the transplant cohort (RR, 0.16; P < .0001). Seven-year survival probabilities (95% confidence interval) were 59% (50% to 66%) with transplant and 32% (22% to 41%) with hydroxyurea or interferon. There was a significant survival advantage for hydroxyurea or Interferon in the first 4 years after diagnosis and for transplants starting 5.6 years after diagnosis. For transplants done within 1 year of diagnosis, the survival advantage for transplantation began earlier. Survival advantage for transplants was greater and occurred earlier in patients with intermediate- and high-risk prognostic features than in those with low-risk features. This study confirms higher early mortality, but a long-term survival advantage for HLA-identical sibling transplant over hydroxyurea or interferon in CML.

© 1998 by The American Society of Hematology.

OPTIMAL THERAPY for chronic myelogenous leukemia (CML) in chronic phase is controversial. Interferon and/or hydroxyurea are common treatments. Although hydroxyurea controls white blood cell and platelet levels, it rarely produces cytogenetic remissions, prolongs survival only modestly, and does not cure.1,2 Interferon also controls white blood cell and platelet levels; however, in contrast to hydroxyurea, it produces cytogenetic remissions in some patients. In some patients, treatment with interferon survive longer than those treated with hydroxyurea or busulfan.3-10 It is too early to know if there are cures with interferon, but the frequency will be low. Treatment-related mortality with hydroxyurea and/or interferon is negligible; median survival is 3 to 7 years. Features at diagnosis associated with shorter survival include older age, male sex, high levels of myeloblasts and platelets, and splenomegaly.11-13

HLA-identical sibling bone marrow transplantation is also used to treat CML in chronic phase, especially in younger patients. Five-year leukemia-free survival is 50% to 60%.14-20 This contrasts with hydroxyurea therapy where there is no leukemia-free survival and with interferon therapy where 5-year leukemia-free survival is rare. However, transplants are associated with 20% to 30% treatment-related mortality. Factors associated with lower leukemia-free survival after chronic phase transplants include older age, prior treatment with busulfan, T-cell depletion of donor bone marrow, and intervals from diagnosis to transplant greater than 1 year.15-23

Because most persons with CML can expect 4 or more years survival with hydroxyurea or interferon, the decision to do a transplant early, with its attendant risk of treatment-related mortality, is difficult. However, delaying transplant increases transplant-related mortality and decreases the likelihood of cure.10,11 We compared survival of 548 patients with CML receiving HLA-identical sibling transplants in chronic phase and reported to the National Bone Marrow Transplant Registry (NBMT) with survival of 196 treated with hydroxyurea or interferon on a randomized trial of the German CML Study Group.

MATERIALS AND METHODS

Transplant cohort. The study included 548 patients with CML in chronic phase, ≥15 and ≤55 years of age, diagnosed between 1983 and 1991, treated with interferon or without hydroxyurea (n = 131) or hydroxyurea alone (n = 417) followed by a non-T-cell depleted HLA-identical sibling bone marrow transplant with posttransplant methotrexate and cytosine arabinoside for graft-versus-host disease prophylaxis. Patients were reported to the NBMT by 116 centers (Table 1). Median interval between diagnosis and transplant was 10.1 (range, 2 to 84) months; 331 (65%) patients were transplanted within 1 year of diagnosis. Median follow-up was 4.3 years.

The NBMT is a voluntary working group of over 300 transplant centers worldwide that contribute data on their allogeneic and identical twin bone marrow transplants to a Statistical Center at the Medical College of Wisconsin.28 Participants are required to report all consecutive transplants. The NBMT database includes 40% to 45% of allogeneic transplant recipients since 1970. Computerized error checks, physician review of submitted data, and on-site audits of participating centers ensure data quality. Transplant outcomes estimated using NBMT data are similar to those reported by large nonparticipating centers for comparable patients.

Nontransplant cohort. The study included 196 patients with CML in chronic phase, ≥15 and ≤55 years of age, diagnosed between 1983 and 1990 and treated with hydroxyurea (n = 121) or interferon (n = 75) on a randomized trial of the German CML Study Group comparing busulfan, hydroxyurea, and interferon for newly diagnosed CML in chronic phase.22 Details of this trial are published; it enrolled about 10% of the CML cases in West Germany over a 7.5-year period. Patients were treated in 60 centers. In the trial, patients of patients treated with busulfan was inferior to those treated with either hydroxyurea or interferon; there was not a statistically significant difference in survivals of patients receiving hydroxyurea or interferon. Patients receiving busulfan were excluded from the current study. Ninety-five patients receiving hydroxyurea or interferon, but older than 55 years at diagnosis, and 14 with greater than 10% circulating blasts at diagnosis were also excluded from analysis. Median follow-up was 6.5 years. Sixty-five patients in the German study received a transplant at a median interval of 20.0 (range, 3.1 to 77.4) months after diagnosis; they were censored at time of transplant.

Statistical methods. Characteristics of the transplant and hydroxyurea/interferon groups were compared using the x2 test for categorical variables and the Wilcoxon two-sample test for continuous variables.

Comparing outcomes in the transplant and nontransplant groups required adjustment for two sources of bias: differences in time to treatment (time to transplant) and differences in baseline characteristics of patients. To address the first source of bias, which results from the fact that patients must survive in chronic phase a sufficient length of time for a transplant to be done, a left-truncated Cox regression model of time to death was used.20 At each time point in this model, the risk set in the nontransplant cohort consists of all patients still under study, while the risk set in the transplant cohort includes only those with a waiting time to transplant less than the current time point and who are still under study.

To adjust for differences in baseline characteristics, we used two approaches. First associations between survival and potential prognostic variables were evaluated in each group separately by Cox proportional hazards regression with a backwards stepwise approach. Variables considered were: age (≥ v <55 years), sex, white blood cell count (<100, 100 to 199, and ≥200 × 10/L), platelets (<150, 150 to 699, and ≥700 × 10/L), blasts (0, 1 to 3, ≥4%), spleen size (0, 1 to 4, 5 to 9, and ≥10 cm below the costal margin), hemoglobin at diagnosis (≥ v 12 g/dL) and year of diagnosis (< and ≥1988). All of these have been reported to affect survival in conventional treated patients in prior studies. Variables significantly associated with survival in either the transplant or nontransplant cohorts were included as covariates in subsequent survival comparisons. When tests for interaction between significant covariates and type of treatment (transplant vs hydroxyurea or interferon) showed significance, covariates were adjusted separately for each treatment. The proportionality assumption of the Cox model was tested by adding a time-dependent covariate for each covariate. The proportionality assumption did not hold for treatment effect, indicating that the relationship between treatment and outcome differed over time.

To determine regions of the treatment period where the relative risk (RR) of mortality between the two treatment groups was constant, a series of Cox models with different cut-off points for time-dependent treatment effects were fit.21 The final model chosen was the one giving the largest partial likelihood. In this model, treatment was considered as a time-dependent covariate with different coefficients for 0 to 18, >18 to 56, and >56 months after diagnosis. Adjusted probabilities of survival were then generated from the final Cox model stratified on treatment and weighted averages of covariate values using the sample proportion as the weight function. Adjusted probabilities represent predicted outcomes for similar groups of patients receiving each treatment. Estimates and 95% point-wise confidence intervals for differences in survival were obtained by computing estimates of survival for each treatment group separately using the sample proportion as the weight function.

The second strategy to adjust for differences in baseline characteristics was to analyze the impact of Sokal score on outcome in the transplant and nontransplant cohorts and stratify comparisons of treatment effects by Sokal risk group. Sokal score is a widely used predictor of survival in conventional treated CML.22-25 Comparisons in each stratum also used left-truncated Cox regression with time-dependent treatment effects as described above. Survival probabilities for each stratum were calculated using the left-truncated Kaplan-Meier method.

RESULTS

Patient characteristics. Table 1 compares characteristics of patients receiving transplants with those of patients receiving hydroxyurea or interferon. There were significant differences between the cohorts in distributions of age, white blood cell counts, spleen size, percent blasts in the blood, and year of diagnosis. Table 2 shows results of analyses evaluating associations between patient characteristics and survival. Age, sex, spleen size, and year of diagnosis were significant predictors. Tests of interaction indicated a differential effect of year of diagnosis in the transplant and nontransplant cohorts.
diagnosis. Using Cox regression, we identified three discrete time periods after diagnosis with relative risks of death for transplant versus nontransplant treatment that differed: ≤18, >18 to 56, and >56 months. In the first 18 months after diagnosis, patients in the transplant cohort had a higher risk of death than those receiving hydroxyurea or interferon (RR, 5.85; \( P < .0001 \)). Between 18 and 56 months, the risk of death was similar for patients in the two cohorts (RR, 0.80; \( P = .38 \)). After 56 months, patients not at risk in the transplant cohort had a lower subsequent risk of death than those still at risk in the nontransplant cohort (RR, 0.16; \( P < .0001 \)). Figure 1 shows adjusted probabilities of survival after diagnosis, calculated from the Cox models and adjusting for time to transplant, age, sex, spleen size, and year of diagnosis. The 7-year probability of survival (95% confidence interval) was 58% (50% to 65%) with transplant and 32% (22% to 41%) with hydroxyurea or interferon. Figure 2 shows differences in survival probabilities between the two cohorts (survival probability with transplant minus survival probability with hydroxyurea or interferon) over time with 95% point-wise confidence intervals for the differences. Differences greater than zero indicate a survival advantage for transplants at that point in the disease course; those less than zero indicate a survival advantage for hydroxyurea or interferon. The 95% confidence intervals that do not include zero indicate significantly different outcomes. There was a statistically significant survival advantage for hydroxyurea or interferon in the first 2.5 years after diagnosis and a significant advantage for transplants after 5.5 years; survivals were similar between 2.5 and 5.5 years.

Transplants within 1 year of diagnosis. We repeated these analyses, restricting the transplant cohort to 331 patients transplanted ≤ 1 year after diagnosis. These patients have earlier risks of transplant-related death, but better long-term transplant outcomes. Again, the RR of death in the transplant and nontransplant cohorts differed over time. In the first 18 months after diagnosis, the transplant cohort had a higher risk of death than the nontransplant cohort (RR, 5.01; \( P < .0001 \)). Between 18 and 56 months after diagnosis, the RR was 0.42 (\( P = .005 \)), and after 56 months, 0.08 (\( P = .0005 \)). Figure 3 shows adjusted probabilities of survival after diagnosis, calculated from the Cox models. The 7-year probability of survival was 67% (56% to 79%) with a transplant within 1 year of diagnosis and 30% (21% to 40%) with hydroxyurea or interferon. Figure 4 shows differences in survival probabilities between the two cohorts (transplant in the first year – hydroxyurea or interferon) over time. There was a significant survival advantage for chemotherapy in the first 1.8 years after diagnosis and a significant advantage for transplant after 4.8 years.

Association between Sokal score and outcome. Sokal scores based on sex, spleen size, hematocrit level, platelet count, and percent of blasts in the blood at diagnosis were assigned to each patient in the two cohorts (Table 1). There were insufficient data to assign a Sokal score to 211 transplant recipients; however, survival of these patients was similar to the 337 transplant recipients assigned a Sokal score (Fig 5A). Patients were classified as low-, intermediate-, and high-risk as published. Survival in the transplant cohort did not differ among the three risk groups (Fig 5A). Transplant patients were not, therefore, stratified by risk group in subsequent comparisons. In the nontransplant cohort, low-risk patients had significantly longer survivals than intermediate- and high-risk patients, who were similar to each other (Fig 5B).

Figure 6A shows probabilities of survival after diagnosis for transplant recipients and low-risk patients receiving hydroxyurea or interferon. The 7-year probability of survival was 58% (52% to 64%) with transplant and 49% (34% to 63%) with hydroxyurea or interferon. Although the curves cross at about 6 years, there was not a statistically significant advantage for transplant until 7.8 years after diagnosis. Figure 6B compares probabilities of survival for patients receiving transplant within 1 year of diagnosis with low-risk patients receiving hydroxyurea or interferon. The 7-year probability of survival was 67% (60% to 73%) with transplant and 49% (34% to 63%) with hydroxyurea or interferon. The curves cross at 5 years, with a

Fig 1. Adjusted probabilities (from Cox regression model) of survival after diagnosis of CML in persons receiving HLA-identical sibling bone marrow transplants or nontransplant therapy with hydroxyurea or interferon.

Statistically significant advantage for transplant after about 6.5 years from diagnosis.

Figure 7a shows probabilities of survival after diagnosis for transplant recipients and intermediate- and high-risk patients receiving hydroxyurea or interferon. The 7-year probability of survival was 58% (52% to 64%) with transplant and 21% (12% to 31%) with hydroxyurea or interferon. The curves cross at 3.5 years, with a statistically significant advantage for transplant after 4.7 years. Figure 7b compares probabilities of survival for patients receiving transplant within 1 year of diagnosis with intermediate- and high-risk patients receiving hydroxyurea or interferon. The 7-year probability of survival was 67% (63% to 73%) with transplant and 21% (12% to 31%) with hydroxyurea or interferon. The curves cross at 2.2 years, with a statistically

Fig 2. Differences (with 95% confidence interval) in adjusted probabilities of survival after diagnosis of CML between patients receiving HLA-identical sibling bone marrow transplants versus hydroxyurea or interferon. Differences were calculated as probability of survival with transplant minus probability of survival with nontransplant treatment. A negative difference indicates a survival disadvantage for transplant; a positive difference indicates an advantage for transplants. A 95% confidence interval that does not include zero indicates a statistically significant difference.
significant advantage for transplants after about 4 years from diagnosis.

DISCUSSION

The best treatment for CML in chronic phase is controversial. HLA-identical sibling bone marrow transplants can cure a substantial proportion of patients with CML, but have high treatment-related mortality. In contrast, hydroxyurea and interferon have little treatment-related mortality and prolong survival, but cure few, if any, patients. This study confirms the initial survival disadvantage of transplants, but also the later advantage; the latter becomes significant between 4 and 8 years after diagnosis, depending on when in chronic phase transplants are performed and disease-related prognostic factors. Importantly, the early survival disadvantage of transplants is increased and the later survival advantage is decreased by delaying
transplants beyond the first year after diagnosis. This results from increased treatment-related mortality and relapse with transplants done later.16,21

The nontransplant cohort in this study included patients receiving hydroxyurea or interferon, treatments with comparable survival in the data set we used.5 This study set differs from other reports in which interferon treatment seemed to have better survival than hydroxyurea in nonrandomized and randomized settings. Differences between the German CML Study and these other studies were recently discussed in detail, including on-study criteria, risk profiles, drug doses, and schedules and frequency of cytogenetic testing.13,26 However, the 62-month median survival of the hydroxyurea and interferon cohort in this study is similar to that reported in other studies of interferon (55 to 72 months) so the comparison between transplant and nontransplant therapy applies to most patients with CML who are <55 years old. Additionally, the late advantage of transplants is seen even when compared with nontransplant therapy.
in low-risk patients in the German trial, who may be more similar to those in other interferon trials. Whether a strategy of early transplant for interferon responders and delayed transplant for interferon responders would improve survival can only be determined in a prospective trial.

The only type of transplant we studied were those from HLA-identical siblings. Because treatment-related mortality after transplants from other related and unrelated donors is substantially higher, our conclusions may not apply to these settings. It is likely that the time point after which alternative donor transplants show better survival over hydroxyurea or interferon is later.

This study confirms a long-term survival advantage for transplants and further indicates that the survival advantage is greatest for persons with intermediate- and high-risk prognostic features at diagnosis and when transplants are performed early. It quantifies the trade-off between early mortality and long-term leukemia-free survival with transplants versus hydroxyurea or interferon for newly diagnosed CML and provides data for counseling patients deciding between therapies.
Fig 7. Adjusted probabilities of survival after diagnosis of CML in intermediate- and high-risk persons receiving hydroxyurea or interferon versus persons receiving an HLA-identical sibling bone marrow transplant (A) at any time after diagnosis or (B) within 1 year of diagnosis.

Data on 405 patients with chronic myelogenous leukemia who received bone marrow transplants in chronic phase were analyzed for factors predictive of outcome. The 4-year actuarial probability of relapse was 13% (95% confidence interval [CI], 12% to 28%) and of survival, 55% (95% CI, 50% to 60%). In multivariate analyses the probability of relapse was higher for recipients of T-cell-depleted bone marrow compared with recipients of non-T-cell-depleted bone marrow (relative risk, 5.4; \( P < 0.0001 \)) and for patients who did not develop chronic graft-versus-host disease with patients who did (relative risk, 3.1; \( P < 0.01 \)). The probability of survival was lower for patients who developed moderate to severe acute graft-versus-host disease than for patients with no or mild acute graft-versus-host disease (relative risk, 2.6; \( P < 0.0002 \)). Duration of disease before transplant was not associated with outcome. Bone marrow transplantation done in the chronic phase of chronic myelogenous leukemia offers some patients prolonged leukemia-free survival. The T-cell-depleted grafts are associated with an increased probability of relapse.

Patients with chronic myelogenous leukemia in chronic phase usually receive treatment to improve their clinical condition, but there is little evidence that it prolongs the chronic phase or that overall survival is increased. Until recently patients with chronic myelogenous leukemia could not be cured. Even when the leukocyte count is reduced to normal, cytogenetic abnormalities such as the Philadelphia chromosome indicate persistent leukemia. The chronic phase evolves into the accelerated or acute (blast) phase in a median of 3 years.

The advanced phases usually are fatal within 3 to 12 months.

Experience with high-dose chemoradiotherapy and bone marrow transplantation, initially with genetically identical twin donors (1) and more recently HLA-identical sibling donors (2-10), shows that long-term leukemia-free survival can be achieved in many patients. Disease status at transplantation is strongly correlated with outcome. Recipients of transplants in chronic phase have a higher probability of survival and lower risk of relapse than recipients of transplants with advanced disease (7-10).

Data from 405 patients with chronic myelogenous leukemia in chronic phase were analyzed to identify factors predicting relapse and survival. All patients received bone marrow transplants from HLA-identical siblings. We address two issues: when transplants should be done in chronic phase and the effect of T-cell depletion on outcome.

The risk for transformation and death in patients with chronic myelogenous leukemia who receive conventional treatment is approximately 10% in each of the first 2 years after diagnosis and 20% to 25% per year thereafter (11). In contrast, transplantation, although currently the only possibility of cure, is associated with substantial early morbidity and mortality. These facts make it difficult for the physician to decide when in chronic phase to recommend transplantation. A recent report (9) suggests that results are best when transplantation is done early in chronic phase. We tested this finding in a large, independent patient population.

One major reason for mortality associated with allogeneic bone marrow transplantation is acute graft-versus-host disease. To reduce the risk for this complication, several centers have depleted donor bone marrow of T cells before infusion. However, this depletion may decrease the postulated antileukemic effect of allogeneic bone marrow transplantation (12, 13). Thus, an increased risk for leukemia relapse might offset the benefit of a decreased risk for graft-versus-host disease. We therefore also evaluated the effect of T-cell depletion on outcome.

01988 American College of Physicians
Patients and Methods

PATIENTS

Data for 455 patients with chronic myelogenous leukemia in first chronic phase, receiving bone marrow transplants between 1 July 1978 and 31 December 1985, were reported to the International Bone Marrow Transplant Registry by 82 transplant teams in 27 countries. Excluded were 36 recipients of bone marrow from donors other than HLA-identical siblings, 12 recipients of bone marrow from genetically identical twins, and 2 patients with juvenile chronic myelogenous leukemia. This study was restricted to 405 recipients of bone marrow from HLA-identical siblings. The closing date was 30 September 1986. The median follow-up time was 25 months (range, 4 months to 6.4 years).

Most patients (98%) were prepared for transplantation with high-dose chemotherapy and total body radiation administered as a single dose (38%) or in several fractions (62%). Seven patients received chemotherapy alone and one patient received radiation therapy alone. Eighty-seven patients from 20 centers received donor bone marrow cells that had been depleted of T-cells in vitro to prevent or modify graft-versus-host disease. The depletion involved incubation of donor marrow with one or more monoclonal antibodies with or without complement in 76 patients. Other methods, such as sheep erythrocyte rosetting with or without lectins and elutriation, were used in 11 patients.

Sixty-three of eighty-seven (72%) recipients of T-cell-depleted grafts also received cyclosporine after transplant to prevent graft-versus-host disease; 2 (2%) received methotrexate; and 22 (25%) received no additional prophylaxis. Of the 318 patients receiving non-T-cell-depleted bone marrow 96 (30%) received methotrexate; 200 (63%), cyclosporine; 16 (5%), both methotrexate and cyclosporine; 1 (0.3%) corticosteroids alone; and 5 (1%) no prophylaxis against graft-versus-host disease. Acute graft-versus-host disease was classified as absent, mild, moderate, moderately severe, or severe using previously published criteria (14). The reproducibility of this approach among centers has been extensively studied (15). Signs and symptoms associated with chronic graft-versus-host disease were classified as absent, mild, moderate, or severe. An overall score for chronic graft-versus-host disease was generated by the transplant team and verified at the Statistical Center of the Registry.

Relapse of leukemia was defined by hematologic criteria and supported by cytogenetic findings, that is, recurrence of the Philadelphia chromosome. However, reappearance of the Philadelphia chromosome alone was not scored as relapse because the biologic importance of such cytogenetic changes is not yet established (9, 10, 16, 17). Furthermore, the frequency with which recurrence of the Philadelphia chromosome is recognized varies because it depends on the frequency of cytogenetic examinations of bone marrow and number of metaphases examined.

Statistical Methods

Thirty variables (Table 1) were studied in univariate analyses for possible association with relapse or survival. Chi-squared analysis was used to test differences between groups in discrete variables and Student t-test was used to test differences in continuous variables. Actuarial curves for relapse and survival were prepared using standard life tables. Curves were truncated when fewer than three patients remained at risk. Curves showing outcome according to whether patients developed acute graft-versus-host disease were derived from life-table analyses of patients who survived at least 1 day after transplant with evidence of engraftment, and were at risk for acute graft-versus-host disease. Curves showing the probability of relapse according to whether patients developed chronic graft-versus-host disease were derived from life-table analyses of patients who survived at least 21 days after transplant with evidence of engraftment, and were at risk for chronic graft-versus-host disease. Only 6 of 123 (5%) patients who developed chronic graft-versus-host disease did so before this time.

Because most transplants using T-cell-depleted marrow were done after 1982, data at 2 or 3 rather than 4 years were used to compute probability of relapse among recipients of such grafts. Variables associated with relapse or survival in univariate analyses with P < 0.10 were studied in multivariate analyses using Cox proportional hazards regression models (18). Acute and chronic graft-versus-host disease were entered into the regression equation as time-dependent covariates; that is, patients were scored as having acute or chronic graft-versus-host disease only after the time of its occurrence. Relative risks for relapse or death associated with particular prognostic factors were derived from the proportional hazards models.

All multivariate analyses were examined and adjusted for possible center effects both by treating transplant center as a covariate in the regression model, and by using a proportional hazards model stratified by center (19). The relative risks and statistical significance of prognostic variables were virtually identical with and without these adjustments. All P values are two-tailed and, unless specified, based on the results of multivariate analyses. Because comparisons of several factors were made, only P < 0.01 was considered significant; P values between 0.01 and 0.05 were considered marginally significant and are presented only to show trends.

Results

Probability of Relapse and Survival

The 4-year probability of relapse in 405 patients was 19% (95% CI, 12% to 28%), the 4-year probability of survival was 55% (95% CI, 50% to 60%), and the 4-year probability of leukemia-free survival was 46% (95% CI, 40% to 52%). Two hundred and nine patients (52%) are in continuous complete remission, and 27 (7%) are in chronic phase after relapse of chronic myelogenous leukemia. One hundred and sixty-nine patients have died, only 5 (1%) of leukemia. Causes of death are shown in Figure 1.

Factors Associated with Relapse

Six variables were associated with the probability of relapse in univariate analyses with P < 0.10 (Table 1). Two factors remained significant in multivariate analyses: the method of graft-versus-host disease prophylaxis and the presence or absence of chronic graft-versus-host disease.

The 3-year probability of relapse for 318 recipients of non-T-cell-depleted bone marrow was 9% (95% CI, 5% to 15%) compared with a probability of 48% (95% CI, 32% to 65%) for 87 recipients of T-cell-depleted marrow (relative risk, 5.4; P < 0.0001). There was no indication of biased selection of patients to receive or not receive T-cell-depleted grafts. At 15 centers, T-cell-depleted grafts were done sequentially, and at 5 centers according to predetermined protocols. Patient and treatment characteristics as well as outcomes after transplant of recipients of T-cell-depleted and non-T-cell-depleted bone marrow are shown in Table 2. Recipients of T-cell-depleted marrow were significantly older than recipients of non-T-cell-depleted marrow, and more likely to receive splenic radiation, fractional rather than single-dose radiation, and radiation at higher dose rates. Patients were also less likely to have had splenectomy, intrathecal chemotherapy, or trimethoprime-sulfamethoxazole before transplantation. Adjustment of multivariate analysis for these differences did not significantly alter the relative risk of relapse associated with T-cell depletion.

* Associated with the probability of relapse at \( P < 0.01 \) level.
† Associated with the probability of relapse at \( P < 0.001 \) level.
‡ Among patients surviving 31 or more days after transplant with evidence of engraftment.
§ Among patients surviving 31 or more days after transplant with evidence of engraftment.

In univariate analysis, T-cell depletion was associated with a decreased incidence of moderate to severe acute graft-versus-host disease (15% in recipients of T-cell-depleted marrow compared with 51% in recipients of non-T-cell-depleted marrow; \( P < 0.0001 \)), of chronic graft-versus-host disease (19% compared with 39%, respectively; \( P < 0.003 \)), and of death from graft-versus-host disease (7% compared with 27%, respectively; \( P < 0.0002 \)). To determine whether the increased risk of relapse associated with T-cell depletion was mediated through its effect on graft-versus-host disease, patients with and without acute and chronic graft-versus-host disease were analyzed separately (Figure 2). An increased risk of relapse was seen in recipients of T-cell-depleted marrow regardless of whether clinically evident acute or chronic graft-versus-host disease developed.

There was no significant difference (\( P = 0.34 \)) in the 2-year probability of relapse among 22 patients who received T-cell-depleted marrow alone (30% [95% CI, 11% to 59%]) compared with the 63 patients who received T-cell-depleted marrow and cyclosporine (48% [95% CI, 29% to 67%]). Duration of follow-up in patients who received T-cell-depleted marrow without cyclosporine was inadequate to allow calculation of relapse probability beyond 2 years. Among recipients of non-T-cell-depleted bone marrow, the probability of

---

Figure 1. Principal causes of death after transplantation in patients with chronic myelogenous leukemia in chronic phase. If leukemia was present at death, it is shown as the cause regardless of underlying or concomitant cause. IPN = interstitial pneumonitis; GVHD = graft-versus-host disease. "Other" includes death from organ failure (7), veno-occlusive disease (7), bone marrow aspiration (3), pulmonary embolism (2), acute encephalopathy (1), suicide (1), intestinal volvulus (1), and drug toxicity (1).

* All analyses are seven variance contrasted variables compared using Student's t-test; compared variables compared using chi-squared test. NS = not significant.

Relapse was not significantly different between patients receiving methotrexate (7% [95% CI, 3% to 17%]) or cyclosporine (10% [95% CI, 6% to 17%]) to prevent graft-versus-host disease.

The absence of chronic graft-versus-host disease was associated with a higher probability of relapse at 4 years (24% [95% CI, 16% to 34%]) compared to patients surviving more than 51 days (after transplant) than the occurrence of chronic graft-versus-host disease (6% [95% CI, 3% to 13%]; relative risk, 3.1; P < 0.01). Development of chronic graft-versus-host disease was associated with a decreased risk of relapse whether or not the patient had received T-cell-depleted bone marrow (Figure 2, right).

A higher 4-year probability of relapse was seen in 340 patients 20 years of age or older (23% [95% CI, 14% to 35%]) compared to younger patients (8% [95% CI, 3% to 21%]), but this finding had only borderline significance (P < 0.03).

We studied whether the interval from diagnosis to transplant influenced the likelihood of relapse. At 4 years after transplant, the probability of relapse was 17% (95% CI, 9% to 29%) in 136 patients receiving a transplanted bone marrow.

---

**Figure 2.** Life-table analyses of actuarial probability of relapse of patients with chronic myelogenous leukemia in chronic phase remaining in remission. The number of patients living and available for analysis at each time point is shown in parentheses. Figure 2, left. Figure shows whether bone marrow was or was not replaced with T cells and whether acute graft-versus-host disease (AGVHD) developed in patients at risk. Figure 2, right. Figure shows whether donor bone marrow was or was not replaced with T cells and whether chronic graft-versus-host disease (C GVHD) developed in patients at risk.
plant within 1 year of diagnosis. 28% (95% CI, 15% to 46%) in 181 patients receiving a transplant 1 to 3 years after diagnosis, and 13% (95% CI, 6% to 26%) in 87 patients receiving a transplant more than 3 years after diagnosis. These differences were not statistically significant.

**FACTORS ASSOCIATED WITH SURVIVAL**

Seven variables associated with survival in univariate analyses with $P < 0.10$ (Table 1) were included in multivariate analyses. Two variables remained significant: severity of acute graft-versus-host disease and age of the patient (Figure 3, left).

Moderate to severe acute graft-versus-host disease was strongly associated with mortality. Of the 395 patients surviving at least 21 days with engraftment, and at risk for acute graft-versus-host disease, the 4-year probability of survival was 74% (95% CI, 68% to 79%) for the 221 patients with no or mild acute graft-versus-host disease and 35% (95% CI, 28% to 43%) for the 174 patients with moderate to severe acute graft-versus-host disease (relative risk, 3.7; $P < 0.0001$).

Patient age was another determinant of survival and was a significant risk factor whether analyzed as a continuous variable, by decade (Table 1), or as a dichotomous variable (Figure 3, left). The 4-year probability of survival for 65 patients less than 20 years of age was 75% (95% CI, 63% to 84%); this was significantly higher than the 52% (95% CI, 46% to 58%) probability for 340 older patients (relative risk, 2.6; $P < 0.0002$). Older patients had higher mortality rates due to acute graft-versus-host disease and interstitial pneumonitis than younger patients. The incidence of interstitial pneumonitis was similar in older and younger patients (27% compared with 22%, respectively); however, the case-fatality rate was significantly higher in older patients (82% compared with 43%; univariate $P < 0.002$). Similarly, the incidence of moderate to severe acute graft-versus-host disease was not significantly different in patients aged 20 years or older or patients less than 20 years (42% compared with 46%, respectively) but the case-fatality rate was higher among older patients (51% compared with 27%; univariate analysis $P < 0.009$). A higher probability of survival also occurred with younger donors; however, donor and recipient ages were highly correlated ($r = 0.79$) and it was impossible to determine whether donor age, recipient age, or both influenced survival.

No other variable studied, including T-cell depletion, was significantly associated with the probability of survival. There was no significant influence of duration of the disease before transplant on survival (Figure 3, right).

**LEUKEMIA-FREE SURVIVAL**

The effects of older patient age, acute and chronic graft-versus-host disease, and T-cell depletion on leukemia-free survival were studied using multivariate analysis. Patients with moderate to severe acute graft-versus-host disease had a risk for treatment failure (death or relapse) 3.2 times higher than patients with no or mild acute graft-versus-host disease ($P < 0.0001$). The probability of leukemia-free survival was decreased in patients aged 30 or older (relative risk, 2.5; $P < 0.0001$). After adjusting for the effects of age and acute graft-versus-host disease, patients with chronic graft-versus-host disease had a slightly lower risk of treatment failure (relative risk, 0.8) but this value was not statistically significant ($P = 0.23$). The T-cell depletion was not significantly
associated with leukemia-free survival in univariate or multivariate analysis (relative risk, 1.3; P = 0.19). Decreased early mortality due to reduced incidence and severity of graft-versus-host disease in recipients of T-cell-depleted marrow was offset by an increased frequency of graft failure and relapse (Table 2).

Discussion

Two factors associated with the risk of relapse are whether or not T cells were depleted from donor bone marrow as prophylaxis against graft-versus-host disease and whether or not chronic graft-versus-host disease occurred. Recipients of T-cell-depleted bone marrow had a higher probability of relapse than recipients of non-T-cell-depleted bone marrow. This finding is consistent with data in animals and humans showing an antileukemic effect associated with allogeneic bone marrow transplantation (12, 13, 20-22). This effect is believed to be due to a graft-versus-leukemia reaction mediated by transplanted T cells.

Data in humans supporting this concept include a high risk for relapse in identical twin transplants for acute myelogenous leukemia in first remission (12, 13), an inverse correlation between acute and chronic graft-versus-host disease and relapse in acute myelogenous leukemia in first remission and in advanced acute leukemias (23-25), and several reports (26-28) suggesting an increased likelihood of relapse in recipients of T-cell-depleted bone marrow compared with recipients of non-T-cell-depleted marrow. These last reports are confirmed in this analysis. It also is possible that T-cell depletion, often associated with delayed hematopoietic engraftment (29), might provide a nonimmunologic survival advantage to damaged leukemic stem cells after chemotherapy and radiation.

A decreased risk for recurrent leukemia associated with chronic graft-versus-host disease has been reported in acute leukemias (12, 13, 26). Why a significant antileukemic effect was seen with chronic but not acute graft-versus-host disease in chronic myelogenous leukemia is not known. It is possible that different subsets of T cells or mechanisms are responsible for acute and chronic graft-versus-host disease. Also, the cells responsible for the graft-versus-leukemia effect are not necessarily identical to cells responsible for graft-versus-host disease (12). Both direct (30) and indirect (31, 32) evidence derived from animal studies suggest that at least some cells responsible for graft-versus-leukemia reactions are distinct from cells causing graft-versus-host disease.

Two factors were significantly associated with survival after transplantation in chronic phase: the severity of acute graft-versus-host disease and age. These factors also adversely affected leukemia-free survival. Patients who developed no or only mild acute graft-versus-host disease had a greater chance of survival than patients with moderate to severe acute graft-versus-host disease. Younger patients had a higher probability of survival than older patients. It is important to emphasize that because both variables are significant in multivariate analysis, the relative risk for treatment failure associated with patients 20 years or older represents the effect of age over and above its association with acute graft-versus-host disease. Younger patients had significantly less mortality from acute graft-versus-host disease and interstitial pneumonitis than older patients in the first few months after transplantation. Although incidences of interstitial pneumonitis and acute graft-versus-host disease were not higher in older patients, case-fatality rates were significantly increased. The reason older patients were less likely to survive interstitial pneumonitis and acute graft-versus-host disease than younger patients is not known but may relate to relative ability to sustain and repair tissue damage.

Despite its impact on the probability of relapse, use of T-cell-depleted marrow did not significantly affect overall probability of survival or leukemia-free survival. In univariate analyses, use of T-cell-depleted marrow decreased the incidence of acute and chronic graft-versus-host disease and, therefore, death from graft-versus-host disease (Table 2). It did not alter the case-fatality rate of moderate to severe acute graft-versus-host disease, or the incidence or case-fatality rate of interstitial pneumonitis (Table 2). Use of T-cell-depleted marrow substantially increased the incidence of graft failure and death from aplasia (Table 2). These opposing effects on outcome offset each other when looking at the overall effect of T-cell depletion on survival and leukemia-free survival. Although the median follow-up of patients who received T-cell-depleted bone marrow was shorter than that for patients who received other methods of graft-versus-host disease prophylaxis, the relapse curves in Figure 2 do not show a plateau that might signify a decrease in the risk for relapse with time in these patients. If the rate of relapse does not decline with continued follow-up, the ultimate effect of T-cell depletion on long-term leukemia-free survival may be negative.

Duration of disease had no influence on relapse or survival, contrary to a previous study (9). In a series of patients who received transplants in the chronic phase of chronic myelogenous leukemia, Thomas and coworkers (9) found that 16 patients who received transplants more than 3 years after diagnosis had a significantly lower probability of survival than 24 patients who received transplants within 1 year of diagnosis. The disparity between these reports is not known. Differences in chemotherapy used before transplantation may play a role but insufficient data regarding type and amount of previous chemotherapy were available for analysis, and such differences did not appear to play a role. It is possible that we failed to detect a difference due to chance alone; however, with a sample size of 405 patients, the probability of missing a real difference of the magnitude reported in the study of Thomas and coworkers (9) is less than 1 in 100.

Two studies (10, 33) also failed to find a relation between disease duration and survival. Furthermore, most patients with chronic myelogenous leukemia referred for transplantation have not been treated by any standard protocol before transplantation. Therefore, it is unlikely that specific patterns of patient referral or the multi-institutional nature of our study account for the absence of a relation between disease duration and survival.
It is important to consider which patients with chronic myelogenous leukemia are candidates for transplantation. Because of the generally accepted adverse influence of increasing age in allogeneic bone marrow transplantation, an upper age limit might seem reasonable. Our data show that the adverse effect of older age is fully manifested by age 20 and does not seem to increase thereafter. No appreciable difference in the probability of survival was seen among patients who received transplants in the third, fourth, and fifth decades of life (Table 1).

Deciding when to recommend bone marrow transplantation for the patient with chronic myelogenous leukemia who has an HLA-identical sibling is difficult. Clearly transplantation is most successful when it is done before the onset of blast crisis, but this step cannot be predicted with certainty once transplantation has occurred. The results of bone marrow transplantation are much poorer. Because transplantation offers the only possibility of cure, the opportunity should not be lost by prolonged delay, especially in younger patients with an HLA-identical sibling.

CHAPTER 4
CYCLOSPORIN-A
THE FIRST LOCAL INNOVATION
Bone marrow transplantation using HLA - identical and MLC non-reactive siblings has become the accepted form of treatment for patients with severe acute aplastic anaemia and immunodeficiency disease. This procedure also gave encouraging early results in leukaemia when transplanted in first complete remission. In a study of 30 patients with acquired bone marrow failure who had been minimally exposed to antigens contained in blood the projected survival at six years was 75%. In selected cases the incidence of graft rejection, previously in the range of 25 to 60%, was reduced. Nevertheless graft-versus-host disease still affects over half of those causing long-term problems in 20% of the survivors.

Attempts to immunologically influence this complication were undertaken by testing a unique undecapeptide molecule derived from mushroom cultures by Jean Borel working at Sandoz in Switzerland. Using the now well standardised rabbit model and establishing a radioimmunoassay benefit was shown that led to confirmatory studies in this particular context. Additional encouragement was derived from use in autoimmune diseases in acute aplasia and on preformed lymphocyte toxic antibodies in cardiac transplantation and nephrology. Turning to the clinical use of this as a single agent in severe acute aplastic anaemia it became clear that, on its own or even in combination with antilymphocyte serum, data were insufficient to recommend use as a single agent. In further studies on haematopoietic stem cell allografting it became clear that, in contrast to very substantial success in solid organ replacement benefit was present but only partial. Thus graft-versus-host disease was reduced in frequency and intensity but not completely abrogated despite pre-treatment of both donor and recipient and when tested in donor pre-treatment alone.

In studies that have continued over the last decade, scattered among centres across the globe, there has been no consensus. Rather documentation accumulated of varying effect for the use of this extraordinary non-cytotoxic immunosuppressive agent but in a somewhat random array of reports. Thus, although still currently employed in our own programs, the unusually low incidence of this unique immunologic disease following on the introduction of the Campath series of monoclonal antibodies, has led to limiting the use of cyclosporin A to the single situation of matched-unrelated volunteer donors and then only for a limited period.
CYCLOSPORIN A RADIOIMMUNOASSAY. A COMPARISON OF SERUM, PLASMA AND WHOLE BLOOD LEVELS
Gail Randall and Peter Jacobs
The University of Cape Town Leukaemia Centre and the Department of Haematology
Groote Schuur Hospital, Observatory, Cape, South Africa

Cyclosporin A is being increasingly employed as an immunosuppressive agent with indications ranging from autoimmune disease to organ transplantation. A number of unresolved issues surround the use of this new agent including the definition of immunosuppressive level in vivo and optimal methods for monitoring adequate drug dosage. In this latter context, the relative merits of high performance liquid chromatography as opposed to radioimmunoassay to attract attention while a number of variables are known to influence the use radioimmunoassay for measuring both the parent substance and its metabolites. The objective of this study was to examine the effect of temperature on separation procedures and to refine the method used for whole blood radioimmunoassay. Separation at 37°C gave plasma or serum concentrations on average 30% higher than when the centrifugation took place at ambient (22°C) temperature. In addition, the distribution of cyclosporin A between whole blood and plasma or serum was significantly different with the former being 2.5 times higher than the latter even when separation took place at 37°C. The recommended method using whole blood was found unsatisfactory because anticoagulated samples frozen and then thawed were difficult to pipette. The method was accordingly modified in one of two ways. The sample was stored at 4°C and then well mixed before use or alternatively the fresh sample was prediluted with buffer and these aliquots then frozen or held at 4°C until required. The measurement using the latter modification gave reproducible values which were not significantly different from those obtained from fresh (4°C) whole blood. However, once whole blood had been frozen and then thawed the values were lower by a factor of 0.83 when compared to either modification. It is concluded that plasma or serum samples are suitable for monitoring cyclosporin A levels but require careful separation at 37°C. Since this is not standard practice the alternative use of whole blood is preferable and in this regard samples should not be frozen and thawed but held at 4°C or alternatively prediluted with buffer after which the disadvantage of freezing no longer applies.

Supported by the University of Cape Town Leukaemia Centre and Staff Research Fund, the National Cancer Association and the Medical Research Council. We thank Sandoz for donation of cyclosporin A and kits used during these studies.
PERSPECTIVES IN IMMUNOSUPPRESSION

Cyclosporin-A Radioimmunoassay: a Modified Method for Whole Blood Determination

Gail Randall and Peter Jacobs
Leukaemia Centre and the Department of Haematology, University of Cape Town and Groote Schuur Hospital, Observatory, Cape Town, South Africa
(Received 1 October 1984; in revised form 11 April 1985; accepted 15 April 1985)

Abstract. Cyclosporin-A levels were determined by radioimmunoassay in plasma or whole blood, using split samples collected from patients receiving this agent as the only form of immunosuppression following allogeneic bone marrow transplantation. In the plasma assay the temperature at which centrifugation took place was critical since the mean levels were approximately 30% higher with separation at 37°C in comparison to 20°C or lower. Furthermore, the level in whole blood samples was 2.4 times higher than that from the matching serum. In addition, anticoagulated blood that had been frozen and then thawed was technically more difficult to pipette and resulted in a recovery of only 83% of the cyclosporin when compared with assay using fresh blood. In contrast, consistent measurements were obtained either when whole blood was stored at 4°C and then well mixed and diluted in buffer immediately prior to use or when such buffered samples were frozen and thawed immediately before analysis. The latter modifications render the whole blood assay a practical and reliable means for monitoring cyclosporin-A concentrations and may avoid excessive and the potentially nephrotoxic levels achieved when plasma levels are held in ranges previously considered therapeutic.

Key words: Whole blood versus serum — Radioimmunoassay — Cyclosporin A

Cyclosporin A (OL 27-400) is a cyclic decapeptide of fungal origin. The purified substance has been demonstrated in vitro to interfere with an early stage of the immune mechanism for antigen recognition, probably at the level of T-lymphocyte helper function. Predictably, such an action is potentially immunosuppressive and studies in experimental animals [1] and man [2] have confirmed this activity in organ transplantation [3], bone marrow grafting [4], and a number of immunologically mediated diseases [5]. The major toxicity of cyclosporin A is on renal function [6], although it has been incriminated in producing liver dysfunction [7].

Since the optimal immunosuppressive level remains debatable, difficulties exist on how best to balance the therapeutic dose against the development of undesirable side effects. Furthermore, cyclosporin A distributes between cellular receptors and lipoprotein in the plasma [8], and elevations in the latter level may therefore reflect drug present over and above that required to saturate tissue-binding sites. Understandably, a number of different approaches to its use have been reported. Initially, plasma or serum levels were used [9], although the recommended ranges varied widely. Since it is difficult to correlate accurately the development of nephrotoxicity with plasma levels, an alternative suggestion was to adjust dosage on the basis of changes in renal function [10]. In part, the large variations in drug concentration are attributable to differences in concentrations of plasma lipoprotein and a failure to standardize conditions such as temperature under which plasma separation takes place [11]. More recently, the whole blood assay has been developed and obviates the variability of this step. The latter technique is also more attractive since whole blood levels appear to fluctuate less in response to oral or intravenous administration (P. Jacobs, unpublished observation) and might be anticipated to correlate more closely with immunosuppressive events occurring on the surface of other cells such as lymphocytes and monocytes.

In view of the technical difficulties encountered in reproducibly measuring cyclosporin A on samples of frozen whole blood, the technique has been further evaluated, and two practical alternative modifications are reported.

Materials and methods

Blood samples. Venous whole blood was anticoagulated with lithium heparin at a ratio of 140 USE units (U)/10 ml blood

- Incubation is for 2 h at ambient temperature, followed by 15 min at 4°C. Separation is by centrifugation after 10 min at 4°C, and thereafter counting of radioactivity in the supernatant.
- TA, total radioactivity in solution; NSB, nonspecific binding equivalent to radioactivity not adsorbed by charcoal in the absence of the antibody; BO, bound 14C tracer at 0 dose of unlabeled cyclosporin A; STD, the standards; and UNK the unknowns.
- The volume can be varied depending upon the anticipated concentration of cyclosporin A in the biological fluids, and volume compensation is effected by adjustment by buffer-B solution. It is imperative that the biological fluid remains the same in all tubes in the assay so that the equivalent adjustments may be made in the standard curve.

(Vacutainer; Becton-Dickinson, Rutherford, New Jersey, USA).

Three separate procedures were followed. First, the well-mixed sample was split and aliquots stored at 4°C and -20°C. Second, a series of dilutions was immediately prepared in buffer at a ratio of 1:50, after which these samples were also stored at 4°C and -20°C. Third, serum or plasma was recovered by centrifugation at 750 g for 15 min (MSE; Super Minor) and stored at -20°C; in one set of experiments, serum or plasma was separated at room temperature (20°C) and, in another experiment, the whole blood sample was equilibrated for 1 h at 37°C, after which the plasma was recovered.

Buffer A. A 0.05-M solution of Tris buffer (Tris [hydroxymethyl] aminomethane hydrochloride) pH 8.5 (Trizma 8.5 Sigma; batch T-5378; St. Louis, MO) was prepared in glass distilled water for each assay.

Buffer B. Tween 20 (Merck; batch 822184; Munchen, FRG) was added to buffer A in a final concentration of 0.03% immediately before each assay.

Control serum. Lyophilized serum (Validate; General Diagnostics, Ireland) was reconstituted with 5 ml glass distilled water for each assay to bring the final protein concentration into the normal range. Alternatively, human AB serum can be used as the control or in the preparation of standard curves.

Control blood. Whole blood was collected from normal volunteers who had not received cyclosporin A, separated, and stored under conditions identical to the test samples. These specimens were used for both control and preparation of standard curves in the whole blood assay.

Tracer solution (cyclosporin RIA kit). A working solution containing 4.5 ng/ml dihydrocyclosporin was prepared by diluting the ethanolic tracer 1:10 with buffer B, supplemented with 10% control serum.

Antiserum (cyclosporin RIA kit). The solution was prepared at least 1 h before use and remained stable at 4°C for four weeks.

Standard dilutions. A total of 1 ml of cyclosporin-A standard containing 40,000 ng/ml was serially diluted, starting at 1 in 20, to give standards containing 2000, 1000, 500, 250, 125, and 62.5 ng/ml. In each case, the plasma or blood used to prepare the standard curves was the same as for the samples being analyzed. Working solutions were prepared from the standards, using buffer B, to give a series of standards containing 4, 2, 1, 0.5, 0.25, and 0.125 ng/0.1 ml.

Sample dilutions. Unless prediluted in buffer and either stored at 4°C or frozen, all specimens of serum, plasma, or whole blood were diluted 1:50 with buffer B for a final concentration of 2 μl of 0.1 ml of buffer.

Charcoal-coated serum. A suspension of 100 ml buffer B containing 0.5 ml of control serum and 1 g of charcoal (Merck; cat. no. 2186, analytical grade; Darmstadt, FRG) was magnetically stirred for 2 h at 4°C immediately before use.

Assay procedure. The standard curve and the unknown samples were run simultaneously in 13 × 85-mm plastic tubes (Medispo, Johannesburg, South Africa), with particular attention to meticulous pipetting technique. All measurements were carried out in duplicate, and reagents were well mixed and allowed to reach ambient temperature before use.

The detailed procedure steps are shown in the assay flow chart (Table 1). Appropriate volumes of buffer, test material, tracer solution, and antiserum were pipetted into the tube, with mixing after each addition, equilibrated at 20°C for 2 h, and then allowed to stabilize in a water bath at 4°C for 15 min. Serum-coated charcoal was added and the tubes agitated on a vortex mixer (Gencos Instruments, cat. no. 34524-200, Breda, The Netherlands). The tubes were then held at 4°C for a further 10 min, after which they were centrifuged at 2000 g for 5 min at 4°C.

A total of 1.0 ml of the clear supernatant was pipetted into counting vials containing 10 ml of scintillation fluid (Instagel, cat. no. 602100; Packard, IL), thoroughly mixed, and radioactivity determined in a liquid scintillation spectrometer (Packard Tri-Carb, model C2423). Results were expressed in either disintegrations per minute or counts per minute, corrected for quenching. The radioactivity of the samples was counted to statistical significance.

Calculation of results. The unknown concentrations are derived from the dose-response standard curves using the unweighted logit-log-linearization method. Since measured radioactivity cannot be related to the amount of unlabeled cyclosporin, the response is expressed as a function of percent relative binding given by the formula:

\[
\% \text{ B/B}_{0} = \frac{\text{dpm of standard or unknown}}{\text{dpm nbs}} - \frac{\text{dpm nbs}}{\text{dpm nbs}} \times 100
\]

Recovery experiments. Analytical grade cyclosporin A in suitable solution added to plasma, serum, and whole blood, whether manipulated at 37°C or 20°C, was quantitatively recovered and showed a pattern indistinguishable from results obtained with the experimental samples, thus excluding interference that might result in underestimating the presence of this material.
Table 2. The effect of separating serum or plasma from red cells at ambient room temperature (20°C) is consistently and significantly lower than when the same procedure is carried out at 37°C.

Statistical methods. Statistical analyses were carried out using the students' paired t-test [12], coefficient of correlation [13], and significance [14], according to standard methods.

Results

Comparison of serum to plasma

There was no statistically significant difference in cyclosporin-A levels between serum and plasma, provided that the conditions of cell separation were identical.

Effect of temperature

Separation at ambient (20°C) temperature compared with 37°C consistently underestimates the amount of cyclosporin A in serum or plasma by 30% (p < 0.005). This difference can be abolished either by immediate cell separation or allowing the sample to remain for 1 h at 37°C before centrifugation at the same temperature and removal of plasma (Table 2).

Comparison of serum or plasma to whole blood

Over the entire therapeutic range, the levels of cyclosporin A in serum or plasma separated at room temperature were consistently lower than those determined by radioimmunoassay on whole blood that had been stored at 4°C or prediluted with buffer; levels for frozen whole blood were intermediate. The ratios were 361:1041:873 ng/ml (Table 3); the precise numbers are derived by correcting the observed readings for dilution necessary to express results in ng/ml.

When whole blood was frozen and thawed, even permitting temperature to reach stability at 20°C (ambient or room temperature) and then mixing on a vortex shaker to obtain uniform dispersion of the sample, the amount of cyclosporin A was under-

Table 3. At any given dosage schedule, cyclosporin-A levels measured by radioimmunoassay are consistently lower in serum than in whole blood. Furthermore, when blood is retained at 4°C or prediluted with buffer the cyclosporin-A levels are significantly higher than when the sample is frozen, thawed, and then reconstituted.

* Separated at ambient room temperature (20°C).
* Stored at 4°C, well mixed, and diluted immediately before assay. Predilution with buffer and storage of these aliquots give essentially the same results.
* Anticoagulated whole blood is frozen, thawed, and well mixed before assay.
estimated in comparison to whole blood that had been stored unfrozen (4°C). In parallel studies, blood immediately diluted with buffer and stored at 4°C, or when such prediluted samples were frozen and then thawed, gave essentially similar results. The difference between whole blood that had been frozen and thawed and samples diluted from whole blood stored at 4°C or prediluted with buffer and then frozen was, respectively, 873 ng/ml and 1041 ng/ml. This difference was significant (p < 0.005) and appears to be related to changes produced in the viscosity of frozen whole blood aggravated by the formation of microaggregates that form under these circumstances.

**Stability of samples**

Whole blood stored at 4°C for up to two weeks gave uniform results. Similarly, blood premixed with buffer and stored at 4°C or frozen gave stable assay values that did not differ from measurements carried out on the original sample.

**Quality control**

Reference samples analyzed serially in duplicate gave intraassay and interassay variations of 15%, with a reliability coefficient of 0.997 and 9.3% with a test to retest reliability coefficient of 0.95, respectively. The corresponding figures for whole blood were 6.8%, with a reliability coefficient of 0.996 and 8.3% with a test to retest reliability coefficient of 0.992. None of these differences was statistically significant.

**Comparison of antiserum**

Comparison of radioimmunoassay for serum, plasma, or whole blood, using antiserum raised in rabbits or sheep, shows the latter to be more sensitive, but ultimate results were identical with both antisera.

**Liquid scintillation counting**

Chemiluminescence is a major variable, particularly in the whole blood assay. Two approaches were used to resolve this difficulty. First, radioactivity in samples could be determined directly as disintegrations per minute or the counts per minute corrected for quenching; under these circumstances, both approaches gave comparable values. Alternatively, the samples could be allowed to stand overnight at 4°C or 0.1 ml of 1 N AR grade hydrochloric acid added (British Drug Houses, London, England) and the samples read immediately. This modification abolished chemiluminescence promptly and reliably.

**Discussion**

Cyclosporin-A administration may be associated with deterioration in renal [6, 15–17] and hepatic [7, 18] function. The former occurs with greater frequency and is aggravated by concurrent use of certain antibiotics and diuretics in a seriously ill patient, so that the widest margin of safety requires regular measurement of both blood levels and biochemical profile.

Serum or plasma separated at 37°C for radioimmunoassay of cyclosporin A gives levels variably above those obtained when centrifugation occurs at room temperature when there is a shift in the balance of equilibrium favoring red cells [19–22].

Whole blood radioimmunoassay is advantageous, particularly when separation procedures are difficult to standardize. We have, furthermore, found these levels more stable than simultaneous measurements on plasma and consistently higher for any given dosage schedule. The extent to which red cell findings can be extrapolated to other cells, such as the lymphocytes more directly involved in the immune process, is presently unknown, but reduced incorporation of tritiated thymidine has been demonstrated in the mixed-lymphocyte reaction when trough levels are maintained between 200 and 400 ng/ml and at a peak 4 h after dosing between 500 and 700 ng/ml. Used in this way, less nephrotoxicity has been encountered but, if peak whole blood levels are persistently greater than 1000 ng/ml, biochemical evidence for renal dysfunction with rising serum creatinine and urea, together with decreased clearance values, can be anticipated.

Three additional points require comment. First, the method described for whole blood radioimmunoassay using frozen and then thawed blood is technically difficult and gives variable underestimation of cyclosporin-A concentration. A useful modification is to store the blood at 4°C and then mix well at room temperature before preparing dilution. Alternatively, it is equally acceptable to pipette the appropriate aliquots of well-mixed blood into buffer immediately after collecting the sample; these are then ready for assay and can be stored at either 4°C or −20°C for batch analysis. Samples handled in either of these two ways gave results that were consistently higher than the frozen whole blood method. Second, where liquid scintillation counting equipment does not have the facility for expressing
results in disintegrations per minute or for quench correction, the addition of hydrochloric acid to the counting medium abolishes chemiluminescence and thereby avoids a delay in obtaining reproducible readings on the samples. Third, distribution between red cells and plasma will be affected by hematocrit (21) so that this variable must be taken into account, as with improvements that may follow successful kidney transplantation. In more general terms there is a correlation between whole blood radioimmunoassay and the concentration of parent substance determined by HPLC (23), but because of cross-reactivity with metabolites the radioimmunoassay may overestimate effective immunosuppressive concentrations by a factor of 4–5 (24).

It is concluded that the monitoring of cyclosporin-A levels in clinical practice, particularly where plasma or serum separation is reliable, may be advantageously carried out using the whole blood radioimmunoassay. A practical modification is the storage of anticoagulated whole blood at 4°C rather than by freezing, when subsequent thawing interferes with pipetting. Alternatively, appropriate predilution can be made with buffer immediately after collection of the whole blood and these aliquots stored at 4°C or frozen at −20°C for batch analysis.

Acknowledgments

We thank Jackie Davies for secretarial assistance, Prof. Bob Miller and Dr. Eva Abisch for technical advice, Mr. S. Isacis for help with statistical analysis, Wendy Faulsen for technical assistance, Miss Lucille Wood and Dr. Rob Martell for help with managing the patients and in preparation of the manuscript, and Dr. H.-R. Sanders, Medical Superintendent of Groote Schuur Hospital, for permission to publish. This study was supported by the University of Cape Town Leukaemia Centre and Staff Research Fund, the Medical Research Council and National Cancer Association. The cyclosporin A and the radioimmunoassay kits were generously donated by Sandoz Products, Switzerland.

SIMULTANEOUS SESSION VII

Chronic GVHD is a late complication of allogeneic marrow transplantation associated with immunosuppression and recurrent infection. To determine the effect of immunosuppressive therapy and prophylactic trimethoprim-sulfamethoxazole (TMP-SMX) on infection acquisition, we reviewed the patients with extensive chronic GVHD transplanted between Jan 1972 and Feb 1982. Since 1977 therapy has included either prednisone alone (Pred, 1.0 mg/kg/day) or in combination with cyclosporine (CS, 1.5 mg/kg/day). Most patients received TMP-SMX (160 mg TMP b.i.d.) during chemotherapy. Since 1980 therapy has been prospectively randomized in a continuing double-blind study of Pred + placebo vs Pred + A2 (Pred +/- A2). Because patients with persistent thrombocytopenia have increased mortality (Blood, 99:673a, 1982), we studied separately those with platelets (plt) > 100,000 at day 100. The following post day 100 infections were analyzed in 198 patients with chronic GVHD (CS aplastic anemia, 147 hematologic malignancy): 1) varicella zoster virus (VZV), 2) non-bacterial interstitial pneumonia (IP), 3) bacterial or fungal pneumonias ("other" pneumonias), 4) bacteremia or meningitis ("other" infections). The table presents the percentage of these infections in the different treatment groups.

The number of infectious episodes determined in patients receiving TMP-SMX and expressed as a ratio: pneumocystis (0/6) / IP, pneumococcal pneumonia (4/17), and pneumococcal bacteremia/meningitis (1/22).

A Log rank analysis of time to first infection showed that recipients of TMP-SMX prophylaxis had fewer non-V2 infections than recipients of Pred +/- A2 (p < 0.001). This difference remains statistically significant when adjusted for the year of transplant and suggests an important role of TMP-SMX prophylaxis in patients with extensive chronic GVHD.

X MARKS THE SPOT: TREATMENT WITH CYCLOSPORIN A IN ALLOGENEIC BONE MARROW TRANSPLANTATION. Jacobs, P., Department of Haematology, Research Centre, University of Cape Town Medical School, Anzio Road, Observatory, 7925, Cape Town, South Africa.

Graft-versus-host disease (GVHD) remains a formidable barrier to the widespread use of allogeneic bone marrow transplantation. This immunologic phenomenon, which may be acute or chronic, occurs despite meticulous matching of donor and recipient at the genetic level. Attempts to prevent or abrogate these syndromes have met with limited success, including the recent introduction of Cyclosporin A (CyA) as an immunosuppressive agent. Although different regimens have been tested in the recipient no attention has been given to pretreatment of the donor with CyA. Since it is theoretically possible that immunocompetent lymphocytes transferred to the recipient may participate in the pathogenesis of GVHD we tested the possibility that administration of this unique fungal metabolite to both donor and recipient might decrease the expression of acute or chronic GVHD. Forty-one patients underwent allografting from HLA-identical and mixed lymphocyte non-reactive siblings. Group I (n=24) were transplanted before CyA was available and severe GVHD occurred in 12 patients (40%) during the acute stage and in 7 (22%) during the chronic stage. Attempts to treat these patients with additional corticosteroids or to use different regimens resulted in severe GVHD in 3 (37.5%) of the patients. In Group II (n=9) the acute stage of GVHD was treated before CyA was available and in 4 (44%) of the patients severe GVHD occurred in 2 (22%). Attempts to treat these patients with additional corticosteroids or to use different regimens resulted in severe GVHD in 3 (37.5%) of the patients. In Group III (n=9) the overall response rate of CyA was 5 (55.5%) of the patients with prompt response to corticosteroids in 3 and complete remission in 2. In Group IV (n=11) the overall response rate of CyA was 7 (63.6%) of the patients with prompt response to corticosteroids in 3 and complete remission in 4. In Group V (n=11) severe GVHD occurred in 2 (18.2%) of the patients with prompt response to corticosteroids in 2. In Group VI (n=11) severe GVHD occurred in 2 (18.2%) of the patients with prompt response to corticosteroids in 2. All studies are carried out with fully informed consent and plasma CyA levels carefully controlled using routine assays. No donor toxicity was encountered although reversible renal dysfunction was present in over 40% of recipients. These preliminary data suggest that a short period of donor pretreatment with CyA may further reduce the incidence and severity of both acute and chronic GVHD compared to our previous study.

I. INTRODUCTION

The well-being of the human race is constantly challenged by the presence of antigens in the environment; some may be foreign or extrinsic, such as bacteria or viruses, while others are intrinsic, being known as autoantigens. Although superficially different, the physiological response in each situation is linked by the functional integrity of the immune system. Historically, credit is due to the stimulating work of early immunobiologists, including Burnet (1), Billingham et al. (2), and Medawar (3), but it is the vast amount of work carried out in the last decade that forms the basis for understanding the physiology and pathology of the immune system (4,5). Under normal circumstances, the immunological response differs between antigen that is foreign, or non-self, and that which belongs, or self. The former elicits the activation of highly specific humoral and cell-mediated mechanisms which interact to remove the antigen, often involving a nonspecific immune process such as production of opsonins and phagocytosis. In contrast, the development of immune tolerance prevents the initiation of a similar process directed against host antigen.

The complex nature of the immune system is gradually being unraveled and disturbances, congenital or acquired, in the humoral or cellular components are being increasingly correlated with distinct clinical syndromes. Thus, failure of immune surveillance to distinguish self from non-self may lead to an autoimmune reaction exemplified by systemic lupus erythematosus. In addition, there is a whole new discipline developing in medicine in which foreign tissue is transferred from one individual to another, and in this process of transplantation, graft acceptance and subsequent function often depend upon the deliberate suppression of the immune response.
In parallel with the better understanding of the structure and function of the immune system and the disturbances that give rise to clinically important disease entities (5), manipulation of immune responsiveness has become the goal of therapy in many patients. Not surprisingly, there has followed the development of a large number of drugs and other agents whose effects vary from stimulation through modulation to immunosuppression. It is the latter that are of particular interest since they are most widely used in the treatment of autoimmune disease and are indispensable in tissue transplantation.

A. Immunosuppressive Drugs: Current Shortcomings

Agents for the suppression of immunologically mediated inflammatory processes are, as a group, nonselective. As a result, undesirable side effects are evident on practically every organ and tissue in the body, notably, the gastrointestinal tract and the hematopoietic system. For this reason, the ever present challenge is for the development of substances with clearly defined sites of action. In theory, these could be directed against the non-specific immune process, interfering with phagocytosis of particulate antigen. Alternatively, the action could be restricted to specific or adaptive immunity influencing macrophages or different lymphocyte subpopulations.

Initially, drugs interfering with immune phenomena included the antihistaminics (6), the anti-inflammatory drugs (7), and the immunosuppressive agents themselves (8). Not only are the actions of these drugs still awaiting accurate characterization, but many have wide-ranging complications, including myelotoxicity (9), and their lack of specificity also predisposes the patient to the serious hazards of opportunistic infection (10) and the risk of malignant disease (11).

In view of these shortcomings, attention has increasingly been directed at improving specificity. The first step in this direction was the development and then the use in clinical practice of antilymphocyte globulin (12). The latter approach suffers from limitation in that there is relative lack of specificity since large numbers of lymphocyte subpopulations may be removed or their function destroyed. Subsequently, antithymocyte globulin (13) was developed in the hope that the target population could be narrowed to T lymphocytes. Further refinement has been the veritable explosion of monoclonal antibodies that followed the introduction of the hybridoma technique (14). While these biological reagents are becoming more abundant, and already whole libraries exist, their availability for therapy is still limited.

It is in this context that the unique and interesting antilymphocyte agent, cyclosporin A, needs to be judged.

B. Cyclosporin A: Historical Perspective

In the general quest to develop greater selectivity for immunosuppressive agents, one option is to identify those with an action predominantly against a specific lymphocyte subpopulation. Cyclosporin A meets this criterion, since the fungal metabolite appears to modify T-helper activity. Of special note is a surprising lack of bone marrow toxicity so that it already has an important role in clinical programs while, at the same time, attracting attention in the study of basic immunological phenomena.

Historically, the synthesis of the cyclosporins began with the isolation of a metabolite from a new strain of Trichoderma, one of the fungi imperfecti. In practice, the large-scale production is achieved by growing the fungi in submerged culture and then extracting the cyclosporin polypeptides from the mycelia since they are not released into the culture medium.
Based on this fermentation procedure, a series of developments took place in the laboratories of Sandoz in Switzerland and, while credit has been given to all those involved (15), Jean Borel stands out as the driving force in getting the product now known as cyclosporin A to clinical trial. It is interesting that the fungal extract has little fungistatic activity in vivo, but it was known that such metabolites of microbial origin may possess cytostatic or other pharmacological activities. Efforts were then made to define its properties, and particular attention was given to elucidating any immune suppressive effects (16,17).

In a long series of systematic studies, this latter property was compared with a variety of immunosuppressive, cytostatic, and other reference drugs, using several different models. These initial observations revealed two important properties of cyclosporin A, in that the immunosuppression was separable from more general cytotoxic side effects and that both humoral and cell-mediated pathways were affected (16,17).

Following purification, characterization by x-ray analysis (18,19), and synthesis, the pure product was further tested. Comparing murine splenic and mastocytoma cells, an interesting phenomenon was demonstrated (20): cyclosporin A, like hydrocortisone and antilymphocyte serum, had a selectivity for lymphoid cells, and this was in sharp contrast to conventional cytostatic drugs which, in this assay system, inhibited both cell types to a similar degree. Furthermore, the effect with the fungal metabolite was achieved without the usually associated myelotoxicity that characterized administration of equipotent doses of immunosuppressive drugs such as azathioprine. Further studies by Borel and his associates (21,22) showed that cyclosporin A was not lymphocytotoxic and had selectivity for the T-helper cells; an effect was also demonstrable on T-effector cells, but this was less evident and depended on the model used. Last, these actions were primarily evident during the induction phase of lymphoid cell proliferation and not during mitosis.

Although initially bedeviled by problems with absorption, the group at Cambridge (23-26) confirmed the claims for an immunosuppressive effect, using an animal heterotopic cardiac allograft model. Subsequently, similar series were reported in patients with mismatched cadaver kidney transplants (27) and following allogeneic bone marrow transplantation (28).

Clearly, then, cyclosporin A is a unique and potentially important new immunosuppressive agent. However, while it enjoys current widespread interest, there remain a number of important questions to be answered. What, for example, is its exact mechanism of action? In which body compartment, serum or red cells, should concentrations be measured? What minimal level in the plasma reflects optimal immunosuppression? Can peak and trough measurements in the serum, whether determined by radiolimunnoassay or high-performance liquid chromatography, be used to monitor the development of short- or long-term toxicity? Is there a particular place for a natural killer cell assay in guiding therapy? What is the ultimate role of cyclosporin A in chronic inflammatory disease and organ transplantation? Should it be used as a single agent or in combination? If the latter, what combination and on what schedule?

Undoubtedly, we are on the threshold of a change in direction for the use of immunosuppressive agents. In this context, cyclosporin A represents an advance in specificity on antilymphocyte globulin comparable with the way in which that material, whatever its inherent limitations are, was a step forward from the use of the cytotoxic drugs where myelotoxicity often limited adequate therapy.

To place in perspective what is currently known about cyclosporin A, we have reviewed the available information and, where relevant, integrated new data from our own experience.
II. CHEMISTRY

A. Origin

Cyclosporin A is a fungal cyclic undecapeptide $C_{62}H_{111}O_{12}$, isolated from *Tolypocladium inflatum Gams*.

B. Structure (Fig. 1)

The compound has several N-methylated amino acids and one novel C$_9$-amino acid. It has a molecular weight of 1202.6 daltons, and its structure is shown in Fig. 1 (18, 19, 29).

C. Properties

The peptide is neutral, rich in hydrophobic amino acids, insoluble in water and a-hexane, but very soluble in all other organic solvents and lipids. Cyclosporin A may be crystallized to a white hydrophobic powder, and this property has given rise to some of the difficulties in its preparation for clinical use.

Originally, animal experiments were carried out, suspending the active principal in 0.5% tragacanth, but more recently a solution in ethanol and Tween has been developed.

---

Figure 1 The chemical structure of cyclosporin A. The molecule is thought to exist partly as an open loop and partly as a $\beta$-pleated sheet. The $\beta$-hydroxy group in the C$_9$-ENE side chain forms a hydrogen bond with the carbonyl oxygen atom of the same amino acid and may account for the immunosuppressive activity of this fungal metabolite. (From Ref. 19.)
Both preparations are well tolerated by experimental animals and when given, using an olive-tipped gastric cannula, dependable administration schedules are easily possible. In clinical trials, a recently formulated drinking solution is well tolerated, particularly in a taste-disguising milk solution to which chocolate, cocoa, or Caotina has been added.

Injectable forms are available, prepared by dissolving cyclosporin A in a mixture containing ethanol and Miglyol, and subcutaneous, intramuscular, and intravenous routes in both experimental animals and patients, in our experience, have been used without any local side effects.

D. Assay Methods

1. High-Performance Liquid Chromatography (HPLC)

The determination of cyclosporin A (OL 27-400) is possible in human plasma and urine, using high-performance chromatographic separation in a reversed phase mode and ultraviolet absorption detection at 210 nm. At this wavelength, the compound has an extinction epsilon of 45,000 with an \( \epsilon_{\text{max}} \) of 66,000 at 195 nm in methanol. The internal standard used is cyclosporin D (33-804), differing only slightly from cyclosporin A in structure and chromatographic properties. The detection limit is 20 ng/ml, and the method has a linear calibration curve in the concentration range of 25-2000 ng/ml. Precision is good, and metabolites do not interfere with determination of the parent compound so that this is a reliable technique with high specificity (30,31).

This method has been further examined and its sensitivity confirmed (32). These workers have emphasized the higher levels obtained with radioimmunoassay when compared with HPLC, which may be attributed to cross reactivity of the antibody with metabolites of the cyclosporin. The generally poor correlation between the level of cyclosporin A in the plasma when determined by the radioimmunoassay and development of toxicity emphasizes a role for HPLC as a means to monitor the parent compound. Similarly, this technique provides the only method for measuring metabolites in the various compartments that include blood cells, biopsy material, and from detailed postmortem studies.

2. Radioimmunoassay (RIA)

Cyclosporin A (OL 27-400) can be determined by radioimmunoassay, using an antiserum raised in rabbits to cyclosporin C (Therovil) hemisuccinate coupled to free amino acid groups of guinea pig immunoglobulin (IgG). The antiserum reacts primarily with cyclosporin A and cross reacts with the metabolites, dihydrocyclosporin A, and dihydrocyclosporin C (33,34).

Based on the continuous use and development of this assay in our laboratory, we have found the standard curve to be reproducible between 0.125 and 4 ng/tube, with linearity from 0.50 to 4 ng/tube, the assay to be sensitive to a lower limit of 62.5 ng/ml, with an interassay variation of less than 5%.

We have not personally evaluated the assay for cross reactivity with metabolites, although this has been reported (33,35). Abish (33) has confirmed the specificity of the assay and tested metabolites designated 1, 8, 17, and 21 for cross reactivity with the antiserum 031180. The highest concentration for these compounds was 40.5, 122, 8, and 64 ng/0.1 ml, respectively. Cross reaction with cyclosporin C and dihydrocyclosporin C is 100%, because cyclosporin C was the hapten used to raise the antibodies.
The detection range with 2-μl samples is 40-2000 ng/ml plasma: but 10 μl of unknown plasma is needed to detect between 10 and 400 ng with any precision.

We consider the radioimmunoassay a dependable method for determining the parent substance and its metabolites in the serum and urine of experimental animals and in patients on clinical trial. It is, however, necessary to appreciate its limitations which are largely the result of cross reaction with metabolites. The question of distribution between the different cellular components in blood and the plasma phase is another theoretical consideration in using RIA.

3. Correlation and Perspective between HPLC and RIA

The correlation between high-performance liquid chromatography and radioimmunoassay in serum (36) has been examined in patients following allogeneic bone marrow transplantation (37), and the results compared by a linear regression analysis. In 50 observations over a 35-day period with the patients on oral administration, the coefficient of correlation was high (r = .933), with the value determined by RIA being 30-70% higher due to cross reacting metabolites.

These data confirm not only the reliability of both methods but establish their linear relationship. Nevertheless, the role of the two methods in monitoring clinical trials requires further attention, particularly since difficulties exist with inability to discriminate between therapeutic administration with optimal immunosuppression and inadequate or excessive treatment (35).

4. Cyclosporin A in Serum and Other Tissues

The distribution and binding to blood components have been reviewed (38), and in vitro studies have shown uptake predominantly by lipoproteins and erythrocytes. The lipoproteins, obtained by ultracentrifugation and fractionation, showed that over 60% of the drug was associated with this compartment independently of drug concentration. Uptake by erythrocytes was rapid and linear, accounting for 50% of the uptake by blood cells. In contrast, leukocytes bound only between 10 and 20%, but the kinetics of this phenomenon were nonlinear and the process was saturable.

Very little data are available at the present time on the distribution of cyclosporin A or its metabolites in different cellular compartments in the body, and a major deficit in our current knowledge is whether there is preferential binding, perhaps to lymphocytes, monocytes, or early hematopoietic precursors in the marrow, that may have profound immunological effects and where pharmacological monitoring by means of plasma levels may be inappropriate.

It may therefore be concluded, with regard to the assay methods currently available, that while radioimmunoassay is suitable for determining plasma levels in experimental animals and clinical studies, a great deal more essential information is required. Of particular importance will be the correlation of immunological effects with levels in the different tissue compartments and clarification on whether these effects and such toxicity as occurs correlate most closely with determination of parent substance or the total spectrum of metabolites determined immunologically by radioimmunoassay.

III. IN VITRO STUDIES

Current interest in the clinical use of cyclosporin A centers on its activity as a potent immunosuppressive agent. The available evidence suggests that these effects are mediated
with little or no bone marrow toxicity. For these reasons it is logical to review first what has been established about the effects that this novel antifungal metabolite exerts on lymphoid cells in vitro. In reviewing what is rapidly becoming a voluminous literature, it is clear that results may, in some studies, have been affected by technical variations. The most notable of these is that since cyclosporin A is an extremely hydrophobic substance, its solubility is critical in standardizing preparation of material for in vitro studies. At the present time, it would seem prudent to follow in minute detail recommendations for its preparation (22). Furthermore, in all studies appropriate solvent control must be included.

A. Nucleic Acid Synthesis

The biological effects of cyclosporin A are its specificity for lymphocytes, a critical dependency on time of administration, and suppression of both humoral and cellular immunity in the laboratory animals (39). The further exploration of these effects (22) was undertaken in vitro in both mouse spleen cells and human peripheral blood lymphocytes. Both the incorporation of tritiated thymidine into DNA and the uptake of radiolabeled uridine into RNA were inhibited by cyclosporin A in doses between 30 and 1000 ng/ml, which are in the range currently achieved in many therapeutic trials. This phenomenon was critically time dependent, requiring addition of cyclosporin A at the same time as the mitogens, concanavalin A or phytohemagglutinin; the later addition of the cyclosporin A to the culture failed to have any inhibitory effect. Furthermore, and of note, was that this phenomenon was reversible, not easily by washing, but by elution over a 24-hr period. This reversibility, occurring without loss of cells in the culture, established a lack of lymphotoxicity (26,40).

These results show a primary effect of this agent directed toward early cellular events in which lymphocytes, in response to mitogenic stimulation, are prevented from undergoing blastogenesis. The cells do not lose their proliferative ability since, following elution of cyclosporin A, this function is again evident. It appears likely that the lymphoid cells are arrested in the G0-phase of the cell cycle and that this is a physiological phenomenon explaining the reversibility of this effect.

B. Effect on Lymphocyte Subpopulations

The mixed lymphocyte reaction (MLR) and cell-mediated lymphocytotoxicity (CML) have been used in the study of porcine, canine, and human lymphocytes.

In the pig studies (26), in vitro assay of T-cell proliferation and mixed lymphocyte reaction demonstrates a dose-dependent inhibition in the presence of cyclosporin A.

In dogs (41), the results from the MLR indicate that cells reactive to histocompatibility antigens persist but are suppressed in the presence of cyclosporin A, whereas recognition of foreign antigen occurred predictably in the absence of cyclosporin A in the culture system under controlled circumstances. Similarly, a suppressive effect could be demonstrated when cultures were carried out in the serum from dogs treated with cyclosporin A, with the effect evident as early as 1 hr after oral administration to the animal. Of note was the persistence of the suppressor effect, in two dogs, for as long as 10-12 days after cyclosporin A administration. CML demonstrated the ability of lymphocytes from cyclosporin-treated dogs to generate cytotoxic effector cells against suitable target cells when the assay was carried out in normal pooled serum, but when the cultures were performed in the serum from cyclosporin-A-treated dogs, this cytotoxicity was suppressed completely. These results suggest that the effects do not occur through either
clonal deletion or a suppressor cell mechanism, but that the action is abrogated or suppressed in the presence of cyclosporin A.

The results of MLR and CML assays carried out on lymphocytes derived from human subjects provide support for the animal data (42,43). Thus, cyclosporin A does not favor generation or induction of suppressor cell lymphocytes; it spares them while inhibiting other subpopulations, resulting in an imbalance in the immune system with consequential profound immunosuppression. This phenomenon may result from the inhibition or killing of T-helper subpopulations. Cyclosporin A interferes with memory cell recognition on a short-term basis, reflected in disturbances in the recognition phase of the mixed lymphocyte reaction. In vitro human lymphocyte responses studied in the MLR showed that the induction of cytotoxic or cytolytic lymphocytes was markedly suppressed by minimal amounts of cyclosporin A, whereas that of alloantigen-activated suppressor cells was much less inhibited, results favoring the induction of suppressor cell mechanisms as opposed to cytolytic effector cells in the primary MLR (44). The latter investigators suggest that a state of specific operational tolerance may be induced in vitro which accords with their earlier in vivo data (45). This is thought to occur without clonal elimination, and this altered immunological state was considered to be induced or maintained by an active suppressor cell which could be identified by its adherence to nylon wool.

C. Molecular Basis of Cyclosporin A Activity

A review of the data reported for the in vitro effects of cyclosporin A in animals and in humans does not support clonal deletion, and while opinion is not uniform on the generation or induction of suppressor cell lymphocytes, the profound immunosuppression that this novel agent has appeared to center on T-helper subpopulations (22,42) and is reflected ultimately in diminished activity of cytolytic or effector lymphocytes.

Studies in mice (22) showed that cyclosporin A effectively inhibited plaque-forming cells when assayed using the Mishell and Dutton technique (46). These results provide evidence of an antithelper cell action for this agent. The selective effect on functional B-cell subsets (47) showed that T-dependent and certain T-independent antigens, the TI-1 mitogens, the TI-2 agents, are exquisitely sensitive. These studies emphasize the value of cyclosporin A in analyzing lymphocyte subpopulations, but it is uncertain whether these observations have clinical relevance. If any extrapolation is possible and B and T cells from humans respond in a similar way to mouse cells, then cyclosporin A should have little impact on established antibody responses and therefore be of limited use for suppression of autoantibody production. Furthermore, cyclosporin A should inhibit some primary antibody responses but leave others unaffected, as might occur with bacterial infection.

The central role played by T lymphocytes raised the theoretical consideration that the various observations could be united through an effect on the interleukins or factors that modulate the activation of lymphocytes. In this regard, it has been shown (48) that concanavalin A-activated suppressor T cells respond to T-cell growth-factor stimulation and exert their suppressor function by absorbing this material, with a consequent decrease in its concentration.

The molecular basis for this action of cyclosporin A on T-cell proliferation is explicable by the interleukins which provide communication between different populations of leukocytes. There are two molecules designated Interleukin 1 and Interleukin 2. The first is a monokine, generated at the time antigen is processed by the Ia+ macrophage and has an effect on the T-helper cell. The latter, simultaneously in all probability, senses
the first signal for antigen presentation from the macrophage. The net result of the presentation of processed antigen to the T-helper cell as well as with the second signal from Interleukin 1, is to permit differentiation of the immature helper T-cell with the subsequent release of Interleukin 2 (Fig. 2) (49). Interleukin 2 facilitates further interaction between the antigen bearing cell and lymphocytes with the proliferation of suppressor and cytotoxic T lymphocytes.

Based on this model, researchers (50,51) have presented evidence that cyclosporin A may interfere with the release of Interleukin 1 from macrophages and the release of Interleukin 2 from activated T-helper cells. A word of caution is necessary since the in vivo or physiological significance of these molecules has not yet been clearly defined, but the hypothesis remains an attractive one and compatible with data previously reported by Borel and his co-workers (20,22). It is also not clear what importance must be attached to reports that cyclosporin A inhibits migration-inhibition factor (52), macrophage-activating factor, and other lymphokines (53).

Cyclosporin A has also been studied in vitro on a number of isolated lymphoid cell populations. In general terms, a direct effect is less clearly demonstrable on the B lymphocytes (20). In vitro, cyclosporin A inhibits immunoglobulin secretion in response to pokeweed mitogen-induced B-cell activation. However, this phenomenon is T-cell dependent (54), and its inhibition may be the result of T-cell inactivation. Similarly, it appears that cyclosporin A specifically deletes or at least inactivates the cytotoxic T-cells normally responsible for the in vitro regression of Epstein-Barr virus lines, so that it may be reasonably speculated that the emergence of lymphoma in patients receiving renal allografts may occur on this basis. There is, however, no evidence that this immunosuppressive agent, in its own right, causes lymphoma.

Figure 2. Putative scheme for the release of Interleukin 1 and Interleukin 2, based on the two-signal concept. (From Ref. 49.)
It has also been shown (55) that cyclosporin A will suppress both T- and B-lymphocyte blastogenesis, and the data have been interpreted by these workers as reflecting immunosuppression due to a direct effect on the blast cell rather than being mediated via a third-party accessory cell. This is an interesting study and provides some support for the controversial “decloning” hypothesis suggested as a possible mode of action for cyclosporin A in vivo (56,57). This evidence would suggest that, at least in humans, cyclosporin A is capable of directly inhibiting certain B-cell activation mechanisms, irrespective of whether these are normally dependent or independent of T-cell activation.

Of interest are the effects that cyclosporin A may have on killer cells, and here the evidence remains debatable. In assays using human lymphocytes in mixed lymphocyte culture, cyclosporin A was shown to efficiently prevent the development of cytotoxic T cells directed against target cells expressing the phenotype of the stimulator cells. This occurred without preventing an increase in the natural killing (NK) activity measured against tumor targets (58). In contrast, cyclosporin A has been shown to inhibit human natural killer activity (59), while another study (60) has shown inhibition of natural killing by cyclosporin A to be rapid, dose dependent, and not requiring the presence of T cells, B cells, or macrophages. These workers interpret the data as direct depression of NK activity with cyclosporin A and could find no evidence that this was mediated through suppressor cells.

These effects occur without marked reduction in lymphoid tissue, notably the spleen, and are in contrast to the effects of other immunosuppressive agents such as cyclophosphamide and azathioprine. The findings are consistent with cyclosporin A producing its effect by interference with stimulation or proliferation of lymphoid cells in the spleen. Similarly, for the thymus (61), data show that the immunosuppressive effects produced by cyclosporin A in vivo are not mediated by the pituitary-adrenal gland system and the results are, therefore, in line with those found in mesenteric lymph nodes and spleen.

What conclusions may be drawn from all this data? The in vitro effects of cyclosporin A are the basis for understanding the observations both in experimental models and in clinical trials. Although results from many studies are not uniform, a number of conclusions are possible. Cyclosporin A acts at a very early stage in the immunologically mediated response to foreign antigens. The available evidence suggests that the major action is on T-lymphocyte-mediated help. The molecular basis is most likely to be by blocking the release of Interleukin 1 from macrophages and thereby preventing the release of Interleukin 2 from T-helper lymphocytes so that generation of cytotoxic T-lymphocytes does not take place. In addition, evidence is accumulating that cyclosporin A has a direct effect both on cytotoxic T and natural killer cells. Its direct action on B cells, if any, awaits clarification.

D. Effects on Nonlymphoid Cells
1. In Vitro Marrow Culture

The most striking observation to be made about in vitro assessment of cyclosporin A on both hematopoiesis and lymphocytopoiesis, using culture techniques, is the paucity of data on which to base any reasonable assessment. Myelopoiesis in humans has been assessed, using an in vitro culture technique (62,63). These studies have limited relevance for the clinical situation since doses between 5 and
10 μg/ml were studied, whereas in therapeutic terms, doses around 1 μg would be much more realistic. Nevertheless, a clearcut reduction in granulocyte-macrophage: colony-forming units in culture (GM:CFUc) was observed, being most obvious at the higher level. In the data reported by Gordon and Singer (63), the T lymphocytes were affected much more than B lymphocytes or hematopoietic precursor cells in the range of 1-5 μg/ml.

Our experience differs from this since the in vivo situation was more closely approximated by using serum from patients containing between 500 and 1000 ng/ml. Control studies were run in parallel using stored serum from the same patients before starting cyclosporin A administration. There was a clearcut uniform suppression of erythroid colony formation, but granulocyte and macrophage growth was normal. These findings, furthermore, correlated with reduced erythropoiesis in the marrow, reflected in low reticulocyte counts and persisting mild anemia while granulopoiesis and megakaryopoiesis were apparently normal. Confirmatory experiments are in progress.

In studies carried out on T-lymphocyte colony formation from peripheral blood and bone marrow (64), it was shown that the effect was most marked on peripheral blood lymphocytes with bone marrow cells being less sensitive, suggesting that this may contribute to the role of this agent in treating graft-versus-host disease in humans.

2. Peripheral Blood Hematology

In mice (39), comparison of cyclosporin A with other immunosuppressive agents showed much less leukopenia, although lymphocytes were approximately 20% below control values. Platelets were not affected. Evaluation of changes in the peripheral blood are difficult to interpret since, for the most part, this immunosuppressive agent is used in patients undergoing allogeneic bone marrow transplantation, of which most are already pancytopenic. However, in a group of patients receiving cyclosporin A as the primary form of treatment for severe acute aplastic anemia, where there was no transplantation option, we have been unable to document any significant changes in peripheral blood hematology.

3. The Phagocytic System

In vitro studies on phagocytic cells (55) failed to show any effect, suggesting that immuno-competent lymphocytes are affected rather than the adherent, radiation-resistant, labelling accessory population.

Similarly, in serial studies on patients following transplantation or those with marrow aplasia receiving cyclosporin A as a primary form of therapy, we have demonstrated no effect on random migration, chemotaxis, phagocytosis, and intracellular killing.

4. Malignant Cells

Tumor cells studied in vitro are of interest. Available results show that the major activity in all the assay systems tested appears directed at T-cell tumors with very little effect on nonlymphoid lines. The common factor appears to be the presence of recognizable T-cell-associated surface antigens, and on this basis cyclosporin A would appear to selectively recognize a series of differentiation antigens on lymphoid cells and their malignant counterparts. It is of further interest that inhibition of permanently growing cell lines requires much higher concentrations than are necessary to produce similar quantitative effects in mitogen-induced T-cell proliferation.
IV. PHARMACOLOGY

A. Human

A single 600-mg oral dose of drinking solution of cyclosporin A, equivalent to approximately 10 mg/kg lean body mass, has a maximal plasma concentration between 242 and 1246 ng/ml when determined by high-performance liquid chromatography. This peak is reached in 3-4 hr after administration and is characterized by a lag time of 0.65 hr, after which oral absorption is fairly rapid with a half-life of about 1 hr. There are two recognizable disposition phases with an α component having a half-life of 1.2 hr and the β clearance curve having a half-life of 27 hr. The maximum concentration is reached in the peripheral compartment after 8 hr; within 12 hr there is roughly eight times more cyclosporin A in this pool than was present in the blood (65).

In a further series of studies reported by the same authors, nine patients undergoing allogeneic bone marrow transplantation had serum levels of cyclosporin A determined after initial intramuscular or continuous intravenous infusion at total doses of 20 mg/kg/day, followed by maintenance at a dose of 12.5 mg/kg/day. These patients showed similar kinetics to the six patients who received a single 600-mg oral dose (65).

In a series of eight studies (66), the clearance of cyclosporin A from plasma was measured, using radioimmunoassay (Fig. 3) and a maximum concentration was found between 2 and 4 hr, with the peak at 2 hr. All patients received oral cyclosporin A as a drinking solution. These studies provide information only for absorption and clearance from the plasma.

The pharmacology is best explained by a two-compartment open model (65) which proposes that cyclosporin A, which is lipophilic, will leave the plasma and distribute itself widely in the tissues of the body, collectively designated as the peripheral compartment. While the validity of this hypothesis awaits confirmation, it has the attraction of emphasizing the need to measure cyclosporin A in tissues other than just the plasma. Our own studies (66) confirm reports that red cell or whole blood levels may be higher than those found in plasma (67). The exact relationship between cyclosporin A levels determined by radioimmunoassay for serum and whole blood hemolysate remains to be established. In this regard, it is theoretically possible that the immunosuppressive level needed may be reflected best by whole blood concentration of cyclosporin A; in contrast, monitoring of plasma concentration may provide a basis for avoiding dose-dependent and reversible renal dysfunction.

The detailed metabolism of cyclosporin A is unknown. However, in pooled plasma collected between 2 and 8 hr after patients had received cyclosporin A in olive oil, 27% of the radioactivity remained present as the parent drug at concentrations of 210 ng/ml. Of importance was the demonstration that 12 separate radioactive components could also be detected, but none was considered to be of major importance. Furthermore, the mean cumulative urinary excretion of radioactivity in a 96-hr period corresponded to 6% of the original dose together with 15 radioactive analogs. These data demonstrate that $^3$H-OL 27-400 is rapidly and extensively metabolized in man to provide a qualitatively similar pattern of metabolites in both plasma and urine.

Further studies on the distribution and binding of $^3$H-OL 27-400 show that over 60% of the drug is associated with lipoproteins and that this distribution occurs independently of drug concentration. The second major blood component that takes up the cyclosporin A are the erythrocytes. At plasma concentrations between 25 and 500 ng/ml, this population will account for approximately 50% of cellular binding and shows a linear
Figure 3  Mean plasma level from eight studies, showing peak at 2 hr. (From Ref. 66.)
distribution with dosage. The leukocyte accumulation varies between 10 and 20% and appears to be a saturable process. The importance of this compartment may be underestimated if only binding capacity is considered, but it may play an important role if there is differential distribution between the various leukocytes. Thus, should the major concentration occur in monocytes and lymphocytes, a greater effect on the immune process becomes a theoretical consideration.

It is this distribution pattern between the lipoproteins in the plasma compartment and the cells, notably the erythrocytes, that raises the important question of the best material for assay to monitor cyclosporin A doses. One approach would be to use radioimmunoassay to detect all immunologically related analogs and to avoid underestimating total body content by measuring levels in whole blood hemolysate.

B. Experimental Animals

Pharmacokinetic studies, including biotransformation, have been carried out in rat, dog, and monkey. In these experiments, tritium-labeled drug was used to examine absorption, distribution, and excretion characteristics, and the data are based on partitioning of total radioactivity.

In rats, absorption was low (12%) when given orally in a solution of Myglyol, with the drug eliminated mainly by the biliary route. Both oral and intravenous administration levels of radioactivity were higher in the tissue of peripheral compartment than in the blood, suggesting tissue affinity for the unchanged drug or its metabolites.

In dogs, oral absorption from a Myglyol solution was again poor, but reached 50% when administered in olive oil, with peak levels between 2 and 3 hr. Biotransformation was extensive, with only trace amounts of parent drug being detectable in the urine.

In rhesus monkeys, absorption characteristics were essentially the same as in dogs, with about 20% of the drug excreted by the kidneys and the biliary route accounting for the majority.

In rabbits, absorption was poor from polyethylene glycol. The presence of a major metabolite and absence of parent drug in the urine were evidence in favor of extensive biotransformation.

In our rabbit studies, we were able to confirm the poor absorption of cyclosporin A when given as the drinking solution. Even on a twice-daily schedule with doses studied systematically between 50 and 300 mg/kg, there was a relatively poor correlation between intake and plasma levels. Using radioimmunoassay, it was seldom possible to achieve consistent concentrations in the plasma in excess of 500 ng/ml. Furthermore, both time- and dose-response curves showed a peak for the rabbit between 1½ and 2 hr (Fig. 4).

The isolation and characterization of the metabolites have been extensively studied (67). The isolation was undertaken on DEAE A25 Sephadex and chromatography on amberlite XAD-2 with the final extraction into diethyl ether. The crude components were purified by liquid chromatography and defined spectrascopically and by amino-acid analysis. The four major metabolites which were designated 1, 8, 17, and 21 contain the intact oligopeptide structure of cyclosporin A, with minor modifications resulting from hydroxylation and N-demethylation reactions. Analysis of all the available information on the metabolism of cyclosporin A indicates that the main biotransformation takes place along a pathway leading to the production of one polar, water-soluble, metabolite designated peak 1, which has not yet been definitively characterized, and a number of associated metabolites extractable with organic solvents such as diethyl ether.
**Figure 4** Rabbit studies showing relationship between peak levels and time at different oral doses of cyclosporin A. The dose approximation in serum levels between the 100 and 150 kg/mg/day curves suggests that an absorption maximum may operate for oral cyclosporin A administration. (From Ref. 66.)

In the light of this information, it should be realized that the pharmacokinetic data which are based on radioactive measurements do not, therefore, differentiate between the parent drug and its major, closely related, derivatives.

In summary, it can be stated, first, that absorption is critically dependent upon the composition of the oral dosage form with Mygylol being a less satisfactory vehicle than when 3H-OL-27 is dissolved in olive oil. In the former situation, absorption ranges between 2 and 12%, but this may approach 50% in olive oil. It appears that the absorption in humans, when cyclosporin A is given in olive oil, approximates that in dogs. It is of note that the time to achieve peak concentration is also shorter with olive oil, being in the range 2-4 hr, but as long as 24 hr with Mygylol.

Second, the blood levels, which may usefully be compared using the β phase, are seen to have a half-life between 27 hr for humans and approximately 50 hr for monkey, with dog being intermediate. This latter point is of particular interest, since it raises important considerations for scheduling a therapeutic dosage of cyclosporin A.

Third, excretion, when studied after a single dose of cyclosporin A, is influenced by route, formulation, and dose. A fairly consistent pattern is demonstrable between all the animal species studied and humans, with approximately 10% appearing in the urine (range 1.1-23.2%) within the first 96 hr and the remainder demonstrable in feces (range 43.1-90.6%) in the same time period. It therefore appears that renal excretion is only a minor pathway of elimination in all the species tested and is lowest when it is administered in the form of either Mygylol or polyethylene glycol (PEG 200). The major route is via the bile, as indicated by the recovery of radioactivity in the feces. In dog and monkey, excretion is incomplete following an intravenous administration, whereas 80-90% of the radiolabel can be recovered in all species after oral administration. This inconsistency again focuses attention on the differential distribution that cyclosporin A may achieve between compartments and emphasizes the need for further studies on biotransformation.
Fourth, such biotransformation data as are available are most complete for rabbit, dog, and humans, where similar metabolite patterns have been demonstrated in plasma and urine.

Finally, protein binding, particularly in the therapeutic concentration range, shows partition between lipoprotein and red cells, but it is clear that data for the different metabolites are as yet incomplete. This latter consideration may have important bearing on not only assay methods but choice of compartment and cyclosporin level selected to monitor therapy.

C. Dosage and Drug Monitoring

Based on the pharmacokinetic data, no uniform recommendation can be made about cyclosporin A administration in humans. Three generalizations are possible. First, sufficient drug must be given for an adequate period of time to allow equilibration between plasma lipoprotein and other compartments before patients are transferred to maintenance programs. Second, the monitoring of plasma levels by high-pressure liquid chromatography provides different information from that derived by radioimmunoassay. The former measures parent substance only, whereas the latter would include immunologically identifiable analogs, some of which share immunosuppressive properties, albeit less than the parent substance. In this regard, it is not yet known which assay method is preferable, particularly since the relative toxicity of the parent substance and metabolites has not been defined. Thus, the relationship between the administered material and its metabolites with immunological reactivity and toxicity require clarification. Third, the relative value of plasma as opposed to red cell leukocyte concentration has not been fully explored. Initial data using radioimmunoassay show a discrepancy between plasma and red cell levels.

In our studies (66), the red cell levels are consistently higher, so that tissue binding may be underestimated by measurements of plasma level alone. Thus far, we have not been able to clearly define a constant relationship, at any one moment, between levels obtained by radioimmunoassay of serum or red cell hemolysate in patients receiving therapeutic doses of cyclosporin A.

In this state of uncertainty, a sound principle would appear to be the administration of sufficient cyclosporin A to achieve a predetermined plasma level by radioimmunoassay. This dose would then be decreased in the presence of toxic effects or increased with the development of escape phenomena such as rejection or emergence of graft-versus-host disease. Our current practice is to correlate serum levels with those in the peripheral tissue compartment, as reflected in red cell cyclosporin A concentration determined by the same assay.

Four additional points require emphasis. First, in the field of organ transplantation, it has not been established what considerations other than dosage and plasma levels need to be incorporated into the design of immunosuppressive schedules. For example, bearing in mind the time taken to achieve plasma levels following oral administration and the absence of data defining the rate at which tissue compartments are saturated, the period before transplantation in which the recipient should be treated is unknown. Furthermore, at least in the case of allogeneic bone marrow transplantation, the question of pretreating the donor cannot be ignored.

Second, the question of cyclosporin A and drug interaction is still confused. When combined with glucocorticosteroids in vitro, there is experimental evidence to support combination therapy. However, despite studies in a variety of animal species and using
differing experimental models to examine this problem in the allografting of kidney, heart, lung, and bone marrow, there is no uniformity of opinion. Thus, at the present time, the role of cyclosporin A as a single agent or in combination with other drugs or radiotherapy to achieve safe but optimal immunosuppression awaits clarification.

The situation in humans (27) has raised questions about adding prednisolone and a cyclophosphamide derivative to cyclosporin A therapy in patients thought to be rejecting their kidneys. Here, too, the relative merits of this agent alone or in combination continue to be actively debated.

Third, consideration needs to be given to the immunosuppressive properties of cyclosporin A in predisposing patients to severe bacterial and viral infections and, undoubt-
edly, the risk would be increased when combined with other immunosuppressive agents. Similarly, the theoretical possibility exists that cyclosporin A, either singly or in combination with other effective agents, may predispose patients to the emergence of second tumors. Concern, for example, about emergence of lymphomas has already been expressed (68); but the specific situation in the patient with chronic renal disease may be different (69), and there is need for caution to avoid prematurely incriminating this drug in the pathogenesis of second malignancies.

Last, the nephrotoxicity associated with cyclosporin A emphasizes the risk of interaction with other drugs potentially likely to impair renal function. These include the aminoglycoside antibiotics which may be present in plasma concentrations not normally considered dangerous. A similar argument applies to some of the diuretics, and these assume importance in many of the clinical situations where cyclosporin A is given to severely ill patients whose renal function is compromised in consequence of their underlying disease.

Drug interaction with cyclosporin A is clearly important: It is incumbent upon physicians using this agent to be fully informed of the theoretical hazards. On the one hand, there is the need to constantly monitor the patients for the adequacy of cyclosporin levels present in plasma or tissue compartment. On the other hand, one should pay attention to additional complications that may arise in consequence of drug interaction, especially the early biochemical changes of deteriorating renal function.

V. TOXICOLOGY

In experimental models and clinical studies, a number of side effects have been reported. The majority are dose related, being reversible with reduction in cyclosporin A dosage.

A. Experimental Studies

Acute toxicity has been examined in mouse, rat, and rabbit, following oral and intravenous injections. Wide differences were found among species, with 14 day LD50 being, re-
spectively, 107, 254, and greater than 10 mg/kg/day for intravenous route and approxi-
mately 2500, 1500, and greater than 1000 for oral administration. Dyspnea, tachypnea, cramplike movements, stupor, pilo-erection, and death occurred within 3 hr after intravenous injection and up to 9 days with oral administration, diarrhea was a prominent sign with enteral administration.

Chronic studies in rats at oral doses of 14 mg/kg/day showed reduced circulating lymphocytes and a generalized atrophy of lymphoid tissue. At higher doses of 45 and 90 mg/kg/day, death resulted from hepatic and renal toxicity, but in animals surviving after discontinuation of cyclosporin A administration, biochemical tests of hepatic and renal
function returned to normal. There was associated cloudy swelling of renal tubular epithelium and single cell necrosis in the liver. It is noteworthy that the red cell series was reduced.

In dogs, low doses of 5 and 15 mg/kg/day were tolerated without toxicity, but diarrhea and conjunctival hyperemia were encountered at 45 mg/kg/day, food intake was irregularly reduced, and weight decreased. The hematology was altered by an increased erythrocyte sedimentation rate, anemia, and decrease in white cell and platelet counts.

In rabbits, three extensive toxicity studies (66) using New Zealand White males with a starting weight of 3 kg have been completed. The animals were individually housed in stainless steel cages in a temperature-controlled vivarium. Water and complete rabbit diet (Epol, Johannesburg) were allowed freely.

The animals in the first study received a single daily oral administration of cyclosporin A (OL 27-400, Sandoz) in a volume of 3 ml, with a loading dose of 25 mg/kg/day in the first week and 12.5 mg/kg/day in the ensuing 12 weeks. At the end of this period, dosage escalation was undertaken with half the animals being maintained at 25 mg/kg/day and the other half at 50 mg/kg/day for 8 weeks; in a further 8-week period, doses were doubled to 50 and 100 mg/kg/day in the two groups, respectively. In all the animals, blood count, chemistry, and radioimmunoassay for cyclosporin A were undertaken weekly. During this study, all the animals gained weight consistently to an average of 4 kg by day 62. Regular monitoring of plasma cyclosporin A levels showed a peak absorption at 1½ hr following oral dosage and maintenance of plasma levels between 100 and 400 ng/ml that had returned to baseline by 6 hr (Fig. 4). No toxic effects were demonstrable on hematopoiesis, but transient elevations in hepatic enzymes were documented at dosage levels above 50 mg/kg/day. The only consistent abnormality was an increase in plasma creatinine, which promptly reversed on discontinuing therapy.

In a second toxicity study, cyclosporin A was given at doses of 50 and 100 mg/kg/day for 17 weeks. There was a consistent fall in hemoglobin, down to a mean of 10 g/dl, and some minor reduction in platelet count that was not statistically significant. Detailed examination of autopsy material showed generalized bone marrow hyperplasia, focal areas of hepatic necrosis, and cloudy swelling with acute tubular necrosis in the kidneys of some animals.

In the third study, higher doses of 75 mg/kg were given twice a day in a deliberate attempt to define any acute toxic effects that may develop within 6 weeks. In a subsequent 6-week period, doses were doubled, in a stepwise manner, to 300 mg/kg/day on a split schedule. In these animals, the pattern of toxicity was essentially the same as that found at the lower doses. At these higher doses, the absorption peak is delayed and elimination is slower (Fig. 4).

The rabbit studies may be summarized by stating that oral administration of cyclosporin A results in demonstrable serum levels when measured by radioimmunoassay, and even at high dosage, minimal clinical toxicity is found over prolonged periods of study. The only two constant hematologic observations were mild to moderate reduction in hemoglobin level in the presence of a normocellular bone marrow with an intact maturation sequence and variable reduction in blood lymphocyte count. At all dosage levels, reversible biochemical changes of renal dysfunction occurred, reflected by elevations in serum creatinine level, although blood urea usually remained normal. Histological examination of the kidneys showed cloudy swelling and, in occasional animals, acute tubular necrosis. Lymph nodes and spleen had general reduction of lymphoid tissue following prolonged periods of administration, and this was associated with an increased rate of infection late in the course of those animals receiving high doses of cyclosporin A.
Cyclosporin A

Studies on carcinogenesis in a variety of animals have failed to demonstrate embryotoxicity or teratogenicity in nontoxic doses. Similarly, mutagenicity using *Salmonella typhimurium* as an indicator organism was unsuccessful. Tumors did not develop in any of our rabbits.

B. Clinical Trials

1. Patient Tolerance

Both the presently available drinking solution (Sandoz, Basel) and the intravenous preparation are tolerated without any gastrointestinal tract discomfort. With experience now in excess of 3 years, we can endorse the recommendation that the cyclosporin A be given in milk containing a taste-disguising additive such as cocoa, chocolate, or Caotina.

2. Nephrotoxicity

The major side effect of cyclosporin A administration is nephrotoxicity, but many of the studies in humans are difficult to interpret because the drug has been used following kidney grafting or after major surgery for pancreatic or hepatic transplantation (70). A similar problem arises when it is administered either to facilitate engraftment or to control graft-versus-host disease in patients receiving allogeneic bone marrow grafts (28).

In patients undergoing renal grafting, data reporting the effect of long-term cyclosporin A on renal function (71) at a dosage level of 5.9 mg/kg body weight (range 4.0-8.6) were compared with a posttransplantation regimen containing corticosteroids and azathioprine. This study included three renal biopsies which showed nonspecific changes of interstitial nephritis which may reflect low-grade graft rejection or cyclosporin A toxicity. It is noteworthy that plasma cyclosporin A levels are not reported, although the authors indicate that this is desirable. Similarly, cyclosporin A is reported as a feasible immunosuppressive agent in patients with oliguric acute tubular necrosis (72), and this group has initiated a randomized prospective study comparing prednisone with cyclosporin A with prednisone, azathioprine, and antilymphocyte globulin for recipients of either cadaver or live related renal grafts.

Reports on the effects of cyclosporin A in the liver and kidney transplants from America (73) confirm nephrotoxicity between 13 and 22 days of therapy in patients receiving 16.3 ± 2.9 (SEM) mg/kg/day of cyclosporin A, but that kidney function returned to normal with dosage reduction to 9.2 ± 2.3 (SEM) mg/kg/day. Of note was the fact that 4 of 66 patients were switched from cyclosporin A to azathioprine after 4-8 months because of persisting unsatisfactory renal function; in 3 of them graft function improved. The experience of this group is that cyclosporin A is nephrotoxic but that this is easily reversed even after many months of treatment. This study is again limited by the fact that plasma cyclosporin A levels were not used in the decision-making process.

It would appear that the nephrotoxicity is due to a tubular effect (74); although other renal biopsy studies have shown no significant glomerular or tubular lesions (75), and this author has commented on possible protective effects of a mannitol-induced diuresis. Apart from mild and transient elevations of blood urea, nitrogen, and creatinine, glomerular thromboses and severe tubular damage have been reported (76) to correlate with both the clinical course and laboratory findings of severe renal failure in three recipients of allogeneic marrow grafts who were given prophylactic cyclosporin A. These workers emphasized that rising creatinine concentration, accompanied by thrombocytopenia, microangiopathic anemia, and hypertension, suggests cyclosporin A nephrotoxicity.
and that kidney biopsy at the onset of renal failure may help elucidate the early principal lesions, since autopsy data probably represent a combination of effects.

Our studies (66) would suggest that cyclosporin A is toxic to renal tubules in a dose-dependent and reversible manner. In a series of patients receiving cyclosporin A as primary immunosuppressive therapy for severe acute aplastic anemia, without prior allogeneic bone marrow transplantation, a predictable increase in biochemical parameters of renal function correlates with increasing administration of the drug. Creatinine is affected more than the urea level, although both bear a linear relationship to peak and trough cyclosporin A levels measured by radioimmunoassay in serum samples (66). Based on these studies, we endorse the observations of the Swiss group (77) that any increase in serum creatinine levels, particularly while still within the normal range, should be treated by oral administration of loop-acting diuretics. Our practice is to commence 40 mg of furosemide in the morning and, if the biochemical changes have not stabilized or started to reverse within 24 hr, to add a second dose in the evening. Further increase in creatinine level on this regimen is managed by 25% reduction in cyclosporin A dosage while monitoring plasma levels. Used in this way, we have found nephrotoxicity related to cyclosporin A an easily controllable problem. Red cell RIA is now recommended as preferable to plasma assay.

These observations have been extended to patients following allogeneic bone marrow transplantation and, to date, such meticulous control of dosage with regular biochemical monitoring has resulted in equal ease of control of cyclosporin A toxic effects.

Two points require additional comment. The administration of cyclosporin A with other potentially nephrotoxic drugs, notably, the aminoglycoside antibiotics, results in deteriorating renal function despite antibiotic levels being monitored and remaining in the supposedly nontoxic range (78). Our own practice has therefore been to avoid any agent with the potential for interfering with renal function. Currently, antibiotics of choice are third-generation cephalosporins, and their use has virtually abolished our previous experience of renal failure related to drug administration.

Second, with regard to histological changes, those evident on light microscopy (76) are supplemented by ultrastructural changes (79) which suggest that cyclosporin A, or its metabolites, may interfere with mitochondrial metabolism.

3. Hepatoxicity

Biochemical evidence of liver dysfunction, in which the hyperbilirubinemia may progress to jaundice, has been reported in association with cyclosporin A administration (80,81). It is, however, necessary to bear in mind that in many of these patients, notably those following allogeneic bone marrow transplantation, other factors such as graft-versus-host disease (GVHD), septicemia, and drugs known to be hepatotoxic may, independently of cyclosporin A administration, produce similar changes. The way in which cyclosporin A compounds the problem remains unresolved. It has been suggested (80) that hyperbilirubinemia is a toxic consequence of cyclosporin A therapy rather than the cause, and it has been postulated (78) that because cyclosporin A is excreted in the bile there may be competition with the pathway used for bilirubin clearance. If this is correct, then any factor inhibiting the excretory pathway of the latter may impair excretion of cyclosporin A, leading to increased plasma levels.

Our experiences with patients undergoing allogeneic bone marrow transplantation and with those receiving cyclosporin A as a primary form of treatment for severe acute aplastic anemia, where no bone marrow transplantation option exists, show a clear
temporal relationship between rising cyclosporin A levels and the development of hyperbilirubinemia, as reported by others (81). It appears that cyclosporin A-induced hyperbilirubinemia occurs with trough levels that are consistently above 400 ng/ml; accordingly, there is a need to monitor plasma levels three times a week. We have found that reduction of cyclosporin A levels will lead to a decrease in bilirubin level, provided this is not raised for some other reason, of which we have found sepsis to be the most common.

To further define the possible mechanism, an isolated rat liver model has been used (82). In this in vitro study, a variety of biochemical techniques have consistently failed to demonstrate cyclosporin A in association with ligandin or the Y-transport protein in hepatic cytosol. This evidence would suggest that competition between bilirubin and cyclosporin A for hepatic proteins is not the mechanism by which their efflux is regulated. The finding of cyclosporin A in association with the 15,000-dalton fraction is compatible with hepatic excretion via the minor or Z-protein-mediated pathway. However, a number of other enzymes, peptides, and low molecular weight proteins found in the same area have made it impossible to definitively incriminate cyclosporin A competitive binding even in this quantitatively less important route for bilirubin excretion.

It therefore appears that hepatotoxicity, and particularly hyperbilirubinemia, is a consequence of a rising plasma cyclosporin A level which, in our experience, invariably follows biochemical evidence for impaired renal function. The mechanism by which cyclosporin A exerts its hepatotoxicity is presently unknown, but direct competition with the bilirubin transport system along the ligandin pathway in the liver seems unlikely.

4. Hypertension

In patients receiving cyclosporin A, systemic hypertension and convulsions have been reported (83) and, while the pathogenesis is not clear, the available data suggest that impaired renal function causes fluid retention which promotes these events. The complications seem directly related to cyclosporin A blood levels, with younger patients being more susceptible to the toxic effects of this drug.

5. Infection

In the immunosuppressed patient following cyclosporin A administration, herpes simplex, herpes zoster, and cytomegalovirus infections have been reported (70). In the Cape Town clinical experience, the incidence of viral or bacterial infections in patients receiving cyclosporin A for aplastic anemia, who have not undergone allogeneic bone marrow transplantation, is no different from the control population. Furthermore, this finding holds true for patients undergoing allogeneic bone marrow transplantation whether they received methotrexate immunosuppression or only cyclosporin A.

6. Immunosuppression and Neoplasms

Breast lumps have been reported in two patients (84). The question of malignant disease in patients receiving cyclosporin A is complicated by the immunosuppressive effects that may be associated with end-stage renal disease and cell-mediated immunity in these patients (85). Nevertheless, concern about lymphoma developing in patients on cyclosporin A started with the report of the Cambridge group (70). Subsequently, this risk has been reemphasized (54,68,86) and, since there is a sound immunological basis for considering this possibility, caution is necessary (69).
7. Other Toxicities

We have not encountered gastrointestinal tract intolerance, pancytopenia, lymphocytopenia, or gingival hypertrophy. Hirsutism has been seen in 1 of 50 patients, and extrapyramidal signs of neurotoxicity elicited by careful examination in 5 of 50 patients, but this was short-lived in 4 and required drug dosage reduction in only 1.

VI. EXPERIMENTAL MODELS

A. Kidney Allografts

A number of experimental animal systems have established, in broad terms, the effectiveness of cyclosporin A administration in maintaining graft function and survival despite histoincompatibility. Apart from species differences, other important variables are dosage, scheduling, and mechanisms by which tolerance is induced.

In rats (87-89), cyclosporin A conferred a clear dose-related advantage to survival of kidneys transplanted from DA to Lewis strains, despite the existence of a strong histocompatibility barrier. Histological studies showed the presence of mononuclear cell infiltration, although function remained excellent. This evidence would suggest that the lymphocytotoxin or humoral antibody-mediated response, leading to acute rejection, was suppressed, whereas the cell-mediated cytotoxicity, reflected in the mononuclear cell infiltration, was little altered.

A second consideration is the presently unexplained way in which this immunosuppressive advantage is lost at high dose. Thus, although plasma levels are not quoted, when cyclosporin A was administered intravenously at 5 mg/kg/day for 14 days (90) or orally (91), levels high enough to impair renal or hepatic function lead to a paradoxical loss of immunosuppression, but it is not clear whether this represents an effect on the donor kidney or an alteration in the host immune response. These observations were extended by studying renal allograft survival in which the recipients had been previously sensitized by skin grafting for up to 5 weeks prior to kidney transplantation (88). The studies showed the drug to be relatively ineffective in suppressing rejection of a renal allograft in a previously sensitized recipient. Of particular importance is the scheduling of the immunosuppressive agent in relation to the transplantation procedure. Thus, neither pretreatment alone nor commencement after a delay of 4 days following transplantation appears effective in suppression of rejection (89,92).

In rabbits, confirmatory data have been reported. At 25 mg/kg/day by mouth, 18- or 28-day courses prolong survival of renal allografts (56,93), while untreated animals died from renal failure associated with acute rejection. In an autografted group from the same study, the survival was not statistically different from those receiving cyclosporin A. Of note was the fact that 6-mercaptopurine was less effective than cyclosporin A in maintaining graft survival. In addition, the latter agent had the unusual property of its immunosuppressive effect persisting in the rabbits after therapy had been discontinued, and this was equivalent whether given by the intramuscular or oral route.

To define the specificity of this tolerance (94-96) experiments using both skin grafts and second kidney transplants from the original or third-party donors were carried out. The accumulated results of the studies were not uniform. One group (94) interpreted the data as reflecting donor but not tissue specificity while another (96) considered the tolerance to be nonspecific. It was pointed out (97) that the discrepancies may in part be explained by the delayed appearance of donor-specific tolerance which is known to occur in the rat (57,98) and in part by the different assay methods used.
In the rabbit, mononuclear cell infiltrates were found in kidney biopsies; but their interpretation remains controversial, and Green (99) raised the possibility that cyclosporin A may have attenuated mainly the humoral antibody response or alternatively could have inhibited migration of lymphocytes. Furthermore, the author questioned whether the cells were T helper in nature or whether the phenomenon was a concentration effect because there were insufficient lymphocytes to mount an aggressive attack and destroy the organs. The latter would be a manifestation of the quantum theory (100) so that the kidneys simply underwent slow attrition over a period of many months.

In dogs (101), early studies demonstrated the immunosuppressive properties of cyclosporin A and showed these were superior to azathioprine but were less spectacular than in rats and rabbits, despite which, some animals survived for long periods after cessation of all therapy (99). In subsequent systematic studies (102), the effects were confirmed, and rejection was completely suppressed with a clear dose-response relationship (103). Of note was the fact that rejection occurred approximately 2 weeks after withdrawal of the cyclosporin A, and this response differed from that observed in the rat. Another point of distinction between species was the observation that cyclosporin A combined with prednisolone did not result in the adverse effects in dogs that had been noted in rabbits (104) and, furthermore, conversion of the immunosuppressive regimen from cyclosporin A to conventional drugs such as azathioprine or prednisone was possible (105,106).

Perhaps surprisingly, reversal of acute rejection could also result from cyclosporin A administration 4 days after allografting (107) which differs from the analogous experiment in rats and rabbits (99).

B. Allogeneic Bone Marrow Transplantation and Graft-Versus-Host Disease

In mice, Borel et al. (17) demonstrated a capacity for cyclosporin A to allow reconstitution of hematopoietic and lymphoid tissues by incompatible spleen cells and to delay the emergence of lethal graft-versus-host-disease.

In rats (45), cyclosporin A provides adequate immunosuppression both for graft acceptance and prevention of subsequent graft-versus-host disease. The animals develop a chimerism with normal immune response and repopulation of T-cell areas in lymphoid organs. The establishment of a chimeric state with specific tolerance to donor and recipient but not to third-party grafts may reflect the generation of a suppressive cell population (108,109).

In the rabbit, conflicting results have been obtained. Histoincompatible skin grafts were possible in a model where red Burgundy donor and outbred New Zealand White recipient animals were used but, at doses of 15 mg/kg subcutaneously, while engraftment occurred, graft-versus-host disease could not be prevented. The experience in Cape Town (110) is different. Using incompatible NZW and R strain animals, there is a statistically significant difference in animals receiving 10 mg/kg/day of cyclosporin A by intramuscular injection for 28 days after transplantation. Thus, at 40 days only 10% of allograft control animals were alive, whereas 44% of those receiving cyclosporin A survived. This difference was even more obvious at 100 days when none of the control animals survived but a third of those that were treated were still alive and well, with normally functioning donor grafts. Furthermore, the histologically recognizable features of graft-versus-host disease were present in all the control animals and in only 25% of those receiving cyclosporin A. It appears that in this animal model, species differences may be critical in trying to understand the differences between results obtained by the Swiss and the South African
groups since, in most other respects, the experimental animal models were remarkably similar.

In dogs (41, 111-113) cyclosporin A increased the incidence of graft failure, although with engraftment median survival is prolonged and the onset of graft-versus-host disease is delayed, despite the failure to induce stable tolerance.

C. Skin Allografting

In mice (29), cyclosporin A was comparable with antilymphocyte serum for graft retention although in subsequent studies (114,115) the immunosuppressive action was demonstrable only as long as cyclosporin A was biologically active and rejection took place between 10 and 14 days after discontinuing the treatment. A similar dose-dependent prolongation of skin graft survival has been reported by other workers (116).

In rats (117), essentially the same phenomenon occurs but may be modified in animals receiving a heart graft. From this, it was suggested that when a large mass of foreign tissue is tolerated, this may be sufficient to block rejection of skin graft, whereas the smaller volume involved in transfer of skin only is incapable of exerting this effect (99).

D. Cardiac Allografts

In rats, heterotopic cardiac transplantation (118) established the potency of cyclosporin A with even short courses, preventing rejection for prolonged periods of time. Subsequently (23), attention was focused on this phenomenon, but these studies are difficult to interpret because information about plasma cyclosporin A concentration, or that found in other cellular compartments, is not available.

In rats, xenografting (119) from outbred Syrian hamsters to the renal vessels of Lewis rats results in modest prolongation of the donor heart while on an oral course of cyclosporin A of 35 mg/kg/day.

In nonhuman primate heterotopic grafting (120), it was established that cyclosporin A is superior to azathioprine and corticosteroid immunosuppression, but that prolonged treatment with this antifungal agent singly or in combination with other drugs may be necessary to maintain function.

In pigs, orthotopic grafting (24) is of particular interest since survival of control animals mismatched at the major locus was 6 days, whereas those animals to which cyclosporin A was administered at a dose of 24 mg/kg/day by intramuscular injection followed by oral maintenance had mean survival times of 265 days. The animals were healthy, without biochemical evidence of hepatic, renal, or hematologic abnormality, and established not only the effectiveness of immune suppression for cyclosporin A in this model but the fact that survival was possible for prolonged periods of time without additional treatment.

Nonhuman primate orthotopic cardiac allografting, which has important parallels for clinical practice, has been extensively studied (120-123). These experiments show that function is prolonged even in association with mononuclear cell infiltration and myocyte injury. As in the heterotopic grafting, cyclosporin A exerts a powerful immunosuppressive effect which is superior to other currently available agents; however, prolonged administration is necessary, and it may well be required in combination with other agents for optimal preservation of function.
E. Pancreatic Allografting

In rats, with segmental and pancreatic islet transplants (124-126) it has been demonstrated that cyclosporin A has a relatively modest effect, although another study (127) has been more successful in inducing long-term survival in the diabetic animals. An attempt to define reasons for both the differences found in these studies and also between results obtained with pancreas and other tissues has been made by exploring a possible role for the macrophage. Indefinite graft survival followed injection of 50 mg/100 g body weight of silica (128), suggesting that this cell system may play a special role in transplantation of this organ.

In dogs, allografting of the pancreas has been undertaken using vascularized segmental grafts, and prolonged survival is possible at high doses of cyclosporin A (129). While neither prednisolone nor azathioprine prolonged survival of animals compared with untreated grafted controls, cyclosporin A at a dose of 25 mg/kg/day orally extended the period of normoglycemia from a mean of 9 to 85 days, and of individual survival from a mean of 13 to a maximum of 129 with a mean of 72 days.

F. Lung Allografting

In dogs (130), it has been shown that survival of this organ for over 5 months was possible with cyclosporin A administered in oral doses of 17 mg/kg/day for 35 days, after which the drug was gradually reduced and given concurrently with low-dose azathioprine (2 mg/kg/day for 14 days). It was remarkable that rejection occurring while on this regimen was later in onset and more easily reversed by high-dose corticosteroids than that developing on standard immunosuppression.

Nonhuman primates (123) have a long survival following lung transplantation with cyclosporin A therapy and, apart from mild lymphocytic infiltration, rejection injury is minimal. This is particularly attractive because bacterial infection is reduced and healing mechanisms appear better preserved. It is currently necessary to define dosage and schedule, to establish whether simultaneous administration of other drugs including corticosteroids may confer additional advantages and, since malignant lymphoma may occur in the primates under these circumstances, to investigate the mechanism of tumor induction.

G. Corneal Allografting

In the rabbit (131,132), skin grafts were placed from the same donor 14 days later to ensure rejection of the cornea. In control animals, the corneal grafts were rejected promptly in contrast to a 50% survival when animals received cyclosporin A at a dosage level of 25 mg/kg by intramuscular route for 28 days from the time of the operation. With a shorter period of administration (14 days), the survival period was intermediate between control and 28-day administrations. Skin graft survival was also prolonged but invariably shorter than the cornea.

Topical application of cyclosporin A was not effective in preventing graft rejection, and it is speculated that this may be due to the scheduling of cyclosporin A and the provocative antigen. It also remains uncertain whether the physical and biological stability of the immunosuppressive agent is altered in the aqueous medium on the surface of the eye.
H. Skeletal Muscle

Cyclosporin A has been demonstrated to permit persistence of an allograft in A and CVA mice, whereas in the nontolerant hosts the allografts were rejected between the tenth and the twelfth day (133).

I. Nerve and Schwann Cells

It has been demonstrated (134) that both minor and major antigens evoke an immune response that prevents functional regeneration in nerve allografts. Nerve fibers, however, regenerate in immunosuppressed hosts. In an extension of these studies (135), it was demonstrated that cyclosporin A can prevent the rejection of nerve allografts with host axon regeneration through long nerve segments.

J. In Vivo Cell-Mediated Immune Reactions

The delayed hypersensitivity skin reaction to oxazolone in mice (20) defined by the suppressive index induced in the skin reaction was examined for both primary and secondary response. It emerged that when cyclosporin A, cyclophosphamide, and azathioprine were compared, the most favorable ratio between toxic and pharmacological effects was found with cyclosporin A.

In guinea pigs, the delayed skin reaction to tubercul in (21) showed a clear advantage for cyclosporin A over large doses of phenylbutazone and azathioprine. The data also supported differences in action between cyclosporin A and the anti-inflammatory agent, phenylbutazone, with the former inhibiting effector cells at clinically well-tolerated doses, whereas phenylbutazone produced severe side effects; azathioprine, although impairing the hypersensitivity reaction, was associated with deaths in some of the animals.

Cell-mediated cytolysis in mice (16) was characterized by clear dose-dependent inhibition of allogeneic target cell lysis by specifically sensitized lymphoid cells. In this assay system, cyclosporin A was compared with procarbazine, cyclophosphamide, the epipodophyllotoxin VP 16-213, and antilymphocyte serum. The results showed a general cytostatic action of procarbazine, cyclophosphamide, and the epipodophyllotoxin whereas cyclosporin A, in common with antilymphocyte serum, appeared primarily to affect lymphocytes at the stage of sensitization.

K. Immune Experimental Models

1. Experimental Allergic Encephalomyelitis (EAE)

In rats, primary sensitization with an emulsion containing spinal cord and killed dried Mycobacterium smegma caused the development of paralysis in control animals (39), and some 8-10 days later in those treated with cyclosporin A at the time of sensitization (39,136). A greater effect was obtained with oral doses of cyclosporin A between 50 and 100 mg/kg than was seen when azathioprine was given as a reference drug. It appears that in this particular test model, cyclosporin A inhibits sensitization and suppresses the effector phase but is not curative, since withdrawal of treatment is followed by development of symptoms after a lag period of 1-2 weeks.

In guinea pigs (137), cyclosporin A was highly effective in suppressing EAE at doses of 35 mg/kg, given on either a prophylactic or a therapeutic schedule. Of note was an unexplained sex difference in the response to drug, with the greater effect being evident in females. Predictably, prophylaxis was the more effective and such therapeutic benefit
as occurred may reflect prevention of T-lymphocyte recruitment to perpetuate the inflammatory reaction.

In the rhesus monkey (138), paralysis killed control animals between day 22 and day 42. In the test group which received 50 mg/kg of cyclosporin A every alternate day, the disease was suppressed, and one animal relapsed but responded to intramuscular injections of the same dose. A similar finding was present in a second animal, while two others developed no neurological signs. Secondary challenge 204 days after beginning the experiment did not alter progression of the established disease. Of note is the finding that two of these animals never developed the disease while on cyclosporin A, despite sensitization. The ability to mount a secondary response is seen as evidence that priming must have taken place, leading to the formation of memory cells.

The information obtained in these studies on experimental allergic encephalomyelitis is of relevance for similar demyelinating diseases in man, such as multiple sclerosis and postinfectious encephalomyelitis.

2. Freund Adjuvant Arthritis

In rats (21), when comparing the effects of cyclosporin A, phenylbutazone, and azathioprine on the prevention and treatment of arthritis, the most striking benefits were found when 30 mg/kg/day of cyclosporin A was given orally on a prophylactic schedule with some limited inhibition also occurring once the arthritis had become clinically manifest. On the preventive schedules, cyclosporin A appeared better than both phenylbutazone and azathioprine, but the expression of the ED₅₀ on a milligram per kilogram basis may not be the most valid basis for comparison. Once arthritis was established, the drugs were given from days 14 to 20 inclusive, and here, azathioprine was not effective, while there was little to choose from between phenylbutazone and cyclosporin A. It was pointed out (21) that the peptide is inactive in the acute inflammatory process, and is without effect in carrageenan paw edema and other such models.

3. Experimental Autoimmune Uveitis

In rats (139), cyclosporin A was effective when given concomitantly with the retinal S-antigen at 10 mg/kg, and caused partial prevention of uveitis down to 5 mg/kg/day. Even when the daily injections were started 7 days after immunization, treatment was effective, but here a higher dose of 40 mg/kg/day was needed to suppress the inflammatory process in the eye.

4. Lupus Erythematosus

In New Zealand mice, the classic model for the study of this autoimmune entity, proteinuria and mortality were the end points of a study (136) comparing the use of cyclosporin A with cyclophosphamide, and showed that at 20 mg/kg/day, cyclosporin A had no effect on proteinuria. This physical sign was, however, markedly suppressed when doses were increased to 60 mg/kg/day, and the result was the same as could be achieved with cyclophosphamide at 60 mg/kg/day given in a 10-day course. Mortality increased gradually through the 18 months of the study, with the first deaths occurring at 8 months and reaching 50% at 12 months. Cyclosporin A was less effective than cyclophosphamide in protecting animals from the autoimmune disease in this model, and therefore the interpretation and extrapolation of relatively incomplete data in humans would be inappropriate. Further detailed characterization is necessary, including patterns of response in other
Experimental animals. While potentially of value, the preliminary data suggest the need for caution in using cyclosporin A in patients with systemic lupus erythematosus.

5. Experimental Infections

Neither bacterial infections in mice nor fungal infestations in mice or guinea pigs appear to be adversely affected by cyclosporin A administration. Viral infections in mice and guinea pigs are marginally altered by cyclosporin A, but currently the evidence is insufficient to incriminate this substance in aggravating this risk.

An antimalarial effect has been reported for cyclosporin A in the mouse (140) in which cyclosporin A started concurrently with the inoculation of the *Plasmodium berghei* or *chabaudi* were less effective than treatment started when parasitemia was already established. The available evidence suggests that the antimalarial action results from direct toxic effect to the parasites.

In the mouse (141), cyclosporin A has been reported to exert an effect on *Schistosoma mansoni* by significantly reducing the number of mature and immature male, and to a greater extent female, worms.

VII. CLINICAL TRIALS

A. Renal Transplantation

The initial study with cyclosporin A in man (27) was in seven patients on dialysis with renal failure who were given kidneys from mismatched cadaver donors and immunosuppressed with intramuscular cyclosporin A for 3 postoperative days and then maintained on oral administration. While establishing clearly the value of cyclosporin A in clinical renal transplantation and the fact that this occurred without marrow toxicity, two other important points emerged. First, while there was no histological evidence for severe rejection, a number of patients had poorer function immediately after transplantation than had been anticipated, necessitating the addition of the other immunosuppressive agents, prednisolone and cytisine, on the basis that low-grade rejection was occurring. In these patients, nephrotoxicity, reflected in raised serum creatinine and urea levels, improved when cyclosporin A dosage was reduced or the drug was withdrawn.

The Cambridge experience was then extended (70), confirming the value of cyclosporin A in the immunosuppression of cadaveric organ grafts and drawing attention to the higher incidence of infection, often lethal, when cyclosporin A was combined with prednisolone or alkylating agents. The occurrence of lymphoreticular malignancy was noted in these patients (142). In addition, when this drug was used in patients who were well hydrated (143), 1-year graft survival was 86%; 11 of 32 patients retained good function for between 3 months and 2 years, never having received steroids; and 13 others required these agents for the treatment of rejection only. The nephrotoxicity associated with cyclosporin A can be anticipated from regular monitoring of plasma or whole blood levels with appropriate dosage adjustment if necessary.

In a controlled trial (97), cyclosporin A was compared with the established azathioprine, low-dose prednisolone regimen in diuresing patients who have received HLA-DR incompatible kidneys. With 35 patients studied, graft survival was comparable and, furthermore, this improved on conversion to azathioprine and prednisolone. The presence of cellular infiltrate in biopsy specimens has led these workers to consider steroids
necessary in conjunction with cyclosporin A with the intention of avoiding longstanding renal damage from rejection.

At least two other clinical experiences can now be analyzed, since sufficient numbers of patients are available for study. In the United States (144,145), cyclosporin A has been combined with prednisolone, and again there have been graft survivals of approximately 80% at 1 year. These investigators consider it important to use corticosteroids in conjunction with cyclosporin A rather than the latter agent on its own.

On balance, there is little doubt that the experience in experimental animals applies also to allografting in humans. There is a consensus that cyclosporin A is effective, but the major unresolved issue is whether this should be used as a single drug or whether long-term benefit will accrue from combination with other agents, such as prednisolone, and perhaps in combination with azathioprine. To a lesser extent, but nevertheless of major importance, are the side effects. These include gum hypertrophy, hirsutism, tremor, and hepatotoxicity with the problems of infection and the possibility of lymphoma in the immunocompromised host still to be defined.

B. Bone Marrow Transplantation

In the initial study (28), cyclosporin A was given to five patients with acute leukemia for the treatment of graft-versus-host disease, with poor results. In an extended study (146), cyclosporin A was used in combination with allogeneic sibling bone marrow transplantation to treat 23 patients, and 15 are reported to be in good health; 1 has developed florid graft-versus-host disease.

In Cape Town, the initial experience in a small number of patients treated with cyclosporin A alone for immunosuppression following allogeneic bone marrow transplantation showed no difference in the incidence of acute or the later development of chronic graft-versus-host disease. The one remarkable observation, however, was that where patients on cyclosporin A did develop acute graft-versus-host disease, this could be rapidly controlled with high-dose prednisolone, whereas we have previously been unsuccessful in managing fulminating GVHD with any currently available immunosuppressive agent.

On the basis of our experience, two considerations have arisen. The first of these is that time- and dose-response curves show a lag period of some 7 days before adequate trough levels are found in the plasma after oral administration of 25 mg/kg/day, suggesting that some time is necessary to saturate peripheral compartments. Under these circumstances, the rationale for giving cyclosporin A together with the donor marrow graft is suspect, and recipients therefore receive cyclosporin A long enough before the antigen to stabilize serum trough levels between 200 and 350 ng/ml and peak levels between 500 and 750 ng/ml.

A second and equally important consideration is whether the donor should be pretreated with cyclosporin A. On the basis that graft-versus-host disease, particularly the acute variant, may reflect transfer of immunologically competent lymphocytes to the recipient, we have followed this policy in the last six patients. All donors take cyclosporin A only after having been fully apprised of the risks and after having given informed consent. To date, no donor toxicity has been encountered, and it is remarkable that the last six consecutive transplant patients have been devoid of graft-versus-host disease. These initial observations require confirmation.

Experience with one patient was initially perplexing in that she developed GVHD on the regimen of donor and patient pretreatment with cyclosporin A where we would
not have anticipated this. Plasma levels showed immeasurable quantities of cyclosporin A, and the patient was insistent that she was taking the drug. However, on admission to hospital, measurement of the dose-response curve showed a prompt oral absorption. Unfortunately, grade 1 cutaneous GVHD had emerged in a butterfly distribution on her face, and while this has not extended, it has also not resolved with continued cyclosporin A and prednisolone treatment. This finding is in keeping with our experience that reversal of established GVHD is less satisfactory than prophylaxis with cyclosporin A.

Two points are of particular interest. The first of these is the question of nephrotoxicity which we find to occur universally in our patients. We completely endorse the Swiss experience (147) that meticulous regular monitoring of plasma urea, creatinine, and clearance levels is mandatory. Any rise in the creatinine level, even while in the normal range, is managed by low-dose loop-acting diuretic and, under these circumstances, control is rapidly achieved providing peak and trough plasma levels are in the arbitrarily defined therapeutic range. Rarely is it necessary to reduce the cyclosporin A dosage in patients because of deteriorating renal function when early management to promote diuresis has been started. In one patient, failure to appreciate the gravity of a rising creatinine level required drug withdrawal and, on continuing diuresis, renal function returned to normal within 14 days. Creatinine clearance, corrected for surface area and renal biopsy, was normal, and the patient subsequently tolerated further cyclosporin A therapy without undue sensitivity to the drug.

We consider the concomitant use of nephrotoxic agents, notably aminoglycoside antibiotics, particularly hazardous. It has therefore been our policy to replace these with third-generation cephalosporins which are considerably less damaging to the kidney, and we are convinced that the drug interaction, leading to impaired renal function on the basis of cyclosporin A administration, has sharply decreased.

The second point is the development of hepatotoxicity, and we have yet to see our first patient where this has occurred ahead of renal failure. When biochemical disturbances in liver function arise, the release of hepatic enzymes into the plasma usually occurs and, in our opinion, reflects GVHD. Hyperbilirubinemia occurs in occasional patients where cyclosporin A administration is improperly controlled or where adequate management of deteriorating renal function has not taken place. Two patients managed with less frequent clinic visits than we consider optimum, because of domestic circumstances, have had transient periods of jaundice. In both, renal function has sharply deteriorated, cyclosporin A levels were high, and in both, drug discontinuation, forced diuresis, and correction of plasma levels of cyclosporin A resulted in bilirubin returning to normal within 21 days. These patients remain on cyclosporin A without the development of GVHD and without further complications, but require close clinical supervision.

On the basis of our pilot study, we believe that pretreatment of donor with cyclosporin A to a standardized plasma or preferably whole blood level can be achieved with minimal side effects and may beneficially influence incidence and severity of acute GVHD. To define this schedule further it is presently being randomly and prospectively compared to a control group in which donors are not pretreated; the recipients in both arms of the trial start CSA 14 days before autograft and continue for at least 180 days.

C. Liver Transplantation

Clinical experience (70,143,144) has been encouraging and doses of 10 mg/kg have not been associated with major hepatotoxicity. However, rejection remains a problem, and it has been concluded (144) that cyclosporin A must be combined with prednisone.
D. Pancreas Transplantation

To date, clinical experience has been limited (70), but the attraction of an immunosuppressive agent which would make it unnecessary to use corticosteroids with their profound effects on carbohydrate metabolism cannot be denied. The published data are insufficient to be able to see the procedure of vascularized segmental pancreatic allografting in any role other than developmental, but the preliminary experience with cyclosporin A (99) in immunosuppressive therapy is encouraging.

E. Nontransplantation Experience

1. Rheumatoid Arthritis

In this condition (148), data are insufficient for any critical evaluation. However, it is interesting that gastrointestinal tract intolerance with reversible nephrotoxicity occurs and that some degree of hepatotoxicity is reported. It is difficult, however, to establish the time sequence between toxic effects on the kidney and on the liver in this study.

2. Severe Acute Aplastic Anemia

In Cape Town, a prospective randomized clinical evaluation has been carried out in patients who meet the internationally defined criteria for severe acute aplastic anemia, but who lack a donor option, to compare cyclosporin A with cyclosporin A in combination with antilymphocyte globulin. The patients were evaluated immunologically with cell membrane surface marker studies and for in vitro erythroid colony growth in the presence of the immunosuppressive agent. By such parameters, no response to cyclosporin A has been obtained. Of particular note has been the opportunity to study, over a mean period of 2 years (range 6 months to 3 years), cyclosporin A toxicity in these patients whose course is not complicated by the severe morbidity of allogeneic bone marrow transplantation.

Quite clearly, nephrotoxicity occurs on a reversible basis. Early recognition of a rising plasma creatinine, while peak and trough plasma cyclosporin A levels are still in an established therapeutic range, can often avert progression by the addition of small doses of loop-acting diuretics. In two patients who followed this course and then underwent renal biopsy, only nonspecific changes were found. Hyperbilirubinemia was encountered in three patients where very high cyclosporin A levels were present in the plasma and where renal function was severely compromised. In each of these, renal function returned to normal within 28 days following the start of diuretics and adjustment of cyclosporin A plasma levels, and bilirubin level returned to normal more slowly but did not remain elevated in any.

In the second phase of the same clinical trial, patients failing to improve on cyclosporin A, with or without antilymphocyte serum, are receiving a 6-month trial of additional anabolic androgen and corticosteroid therapy. None of these patients has improved, despite the longer period of treatment, and no additional toxicity has been noted. Perhaps surprisingly, hepatotoxicity associated with anabolic androgen administration has not been a problem.

In the second phase of the same clinical trial, patients failing to improve on cyclosporin A, with or without antilymphocyte serum, are receiving a 6-month trial of additional anabolic androgen and corticosteroid therapy. None of these patients has improved, despite the longer period of treatment, and no additional toxicity has been noted. Perhaps surprisingly, hepatotoxicity associated with anabolic androgen administration has not

3. Psoriasis

In psoriasis (149), there has been dramatic reduction reported in skin lesions, but these recur on discontinuing therapy.
4. Primary Biliary Cirrhosis

In primary biliary cirrhosis, a significant decrease in the ratio of helper to suppressor T cells has been reported (150); these changes are not seen in other forms of cholestatic liver disease but bear a close similarity to those described in chronic GVHD. In this study, the proportion of suppressor T lymphocytes and liver function improved in six patients, confirming the immunoregulatory action of cyclosporin A, but prolonged studies were precluded by nephrotoxicity.

VIII. COMMENTS

The scientific publications on the pharmacology, immunology, experimental studies in animals, and clinical trials of cyclosporin A increase daily. Despite all this work, a considerable time will need to elapse before the role that cyclosporin A comes to occupy among the immunosuppressive agents is defined. Nevertheless, the availability of this unique fungal metabolite represents an advance in current immunosuppressive therapy. In order to realize the potential that this agent has, both in basic immunology and in clinical practice, effort will be needed to resolve a number of important issues.

First, the specific action of cyclosporin A remains controversial. The bulk of evidence favors interference with a particular molecular event involving interleukin 1 early in antigen recognition. This phenomenon finds its expression as impairment of those immunological responses that depend upon T-lymphocyte help for their optimum activity. Not surprisingly, both humoral and cell-mediated mechanisms have been reported as being defective in the presence of this agent. Of fundamental scientific interest is the need to disentangle the effect on lymphocyte subpopulations and their interactions with other cells of which the monocyte-macrophage system is of special interest.

Second, there is the question of pharmacology. While preliminary observations are available for experimental animals and for humans, it is still not known how best to monitor cyclosporin A therapy. Should plasma or whole blood measurements be used to anticipate the development of toxicity? What is the best method to recognize the maximal immunosuppressive effect that can be achieved? Superficially, these two considerations would appear to be related. However, there is currently no secure basis for the belief that a given plasma or whole blood level will directly correlate with optimum immune suppression of immune integrity. Thus, the current practice of determining plasma levels only provides evidence that the drug is being taken. Most investigators have established broad guidelines to integrate these observations with careful consideration of biochemical changes in renal and hepatic function to anticipate the development of toxic but reversible side effects. It remains to reach agreement on the relative merits of radioimmunoassay as opposed to high-performance liquid chromatography, the compartment to be sampled, and the therapeutic index for cyclosporin A.

Third, much of the toxicology requires confirmation. Although reversible nephrotoxicity is recognized, the correlation of functional with morphological changes, particularly at the ultrastructural level, is in its infancy. Serial studies in experimental animals and clinical studies are needed to define late sequelae and test proposals for drug scheduling where other nephrotoxic agents are unavoidable. A similar degree of uncertainty characterizes liver damage. It is not clear how changes in bilirubin level or enzymes are brought about. In marrow transplantation, there is the added problem of graft-versus-host disease disturbing hepatic biochemical function and how these two are to be separated with certainty. The temporal sequences relating disturbances in renal and hepatic function are
not clear and, until the mechanisms are established, decisions made for patient management must remain largely anecdotal.

Fourth, the many experimental models used and the enormous variation in evaluating cyclosporin A have added to the confusion. Despite meticulous examination of the original experimental reports, painstaking reanalysis of data, graphs, and tables, and attempts to match results from different studies, many insoluble questions remain unanswered. For example, the formulation of the drug has changed during the course of these investigations so that route, schedule, and presentation are not uniform. Few, if any, of the studies have reported measurements of plasma levels, and no data are available on tissue concentrations. Despite these shortcomings, there is now a large block of information which supports an unequivocal immunosuppressive activity for cyclosporin A. Future studies will benefit from the availability of standardized assay techniques, and the experimental model remains a major source of information in urgently answering some of the questions. These would include, for example, the type of infection or the emergence of tumors that may occur in individuals immunosuppressed with cyclosporin A. Another question would be the schedule for allogeneic bone marrow transplantation and our suggestion that donor and recipient pretreatment may be the critical issue in abrogating graft-versus-host disease rather than restricting the agent to the recipient. The answer to these and other questions will in large part be derived from properly designed and meticulously executed studies, but attention must now be given to the inclusion of immunological and pharmacological monitoring in data reporting.

Fifth, the clinical trials are in many areas confirming encouraging results obtained from animal studies. Experience is limited, and many of the same reservations apply to humans as to experimental animals. Undoubtedly, clinical trials with cyclosporin A are now a reality, but results are not uniform. Again, interpretation is bedeviled by changes that have occurred with improvements in drug formulation, often the failure to correlate results with standardized plasma levels, and paucity of data on concurrent monitoring of changes in humoral and cell-mediated immunity. There would be little excuse for persistence with trials that failed to take into account such fundamental requirements. On this basis, a period of consolidation lies ahead. An issue that requires urgent attention is the value of cyclosporin A as a single agent or its role in combination with other immunosuppressive drugs, ranging from antithymocyte globulin through adrenocorticosteroids to cytotoxic agents. Sufficient time has now elapsed to pool experience to answer the question about emergence of infections or neoplasia. Of particular relevance at the clinical level is an urgent need to define a correlation between survival of the transplanted organ with some measurement that will reflect optimal immunosuppression and simultaneously predict for the risk of developing complications.

Clearly, much remains to be learned about cyclosporin A. It can, be concluded, however, that this simple substance is a most powerful immunosuppressive agent and is deserving of all the attention it has received to date. Furthermore, cyclosporin A is unique in exerting its effects without the profound suppression of the bone marrow that has, in the past, characterized drugs given to produce immunosuppression.

Finally, there exists the possibility that it may influence a very specific molecular event occurring early in the immunological response to foreign antigen. If this is confirmed, then cyclosporin A has considerable potential as a more selective immunosuppressive agent and may well be a real advance representing the first step in a new generation of agents for clinically effective immunosuppressive therapy.

Summary

In adult patients with severe acute aplastic anaemia, primary therapy with CyA alone (n = 6) was compared in a prospective randomised trial to an equivalent amount of this immunosuppressive agent in combination with antilymphocyte serum (n = 6). At minimum follow-up of 36 months no response could be attributed to either regimen. Thus, the use of CyA, either on its own or in combination with antilymphocyte serum, cannot be recommended for this indication.

Introduction

Allogeneic bone marrow transplantation is the preferred treatment for patients under the age of 45 with severe acute aplastic anaemia having a suitable donor [3]. Without this option, supportive care [16] is essential, but anabolic androgens do not significantly alter the course of the disease [3]. The demonstration that antilymphocyte serum or antithymocyte globulin [6, 11] produced variable response rates suggested that in some individuals an immunologic mechanism may be active in pathogenesis. To further explore this possibility the immunosuppressive agent, CyA [14], was randomly given to consecutive patients with severe acute aplastic anaemia, either alone or in combination with antilymphocyte serum.

Materials and methods

Twelve patients with severe acute aplastic anaemia [2] were randomised to receive either CyA alone (n = 6) or the same schedule of this agent with concurrent infusion of antilymphocyte serum (n = 6). The trial was approved by the Ethics Committee of the University of Cape Town and Groote Schuur Hospital, and informed consent obtained from each patient. CyA was given at a loading dose of 25 mg/kg/day in two divided doses for one week, followed thereafter by a daily split schedule, with dosage adjustment using radioimmunoassay (Ciclosporin RIA Kit, Sandoz, Switzerland) [12] to maintain peak levels 4 hours after the dose between 300 and 500 ng/ml and trough levels between 200 and 400 ng/ml. Antilymphocyte serum (Merieux, France) was administered by intravenous infusions over half an hour, at a dose of 15 mg/kg on each of 4 consecutive days. The CyA was continued for a minimum period of 3 months unless undesirable side effects necessitated withdrawal.

Patients who failed to respond after 3 months continued receiving CyA and, in addition, were given oral prednisone (0.5 mg/kg/day) in combination with oral oxymethalone (2 mg/kg/day), the latter being increased to the maximum tolerated dosage. All patients received standard supportive care in the form of red cell and platelet transfusion; appropriate antibiotics were given for infections.

Hematologic response was defined as a rise in platelet count above $50 \times 10^9/\text{l}$, absolute granulocytes above $1 \times 10^9/\text{l}$, and no red cell transfusion requirement [8].

Results

The median age of the patients was 27 years (range 12–49); there were 8 males...
and 4 females. In none was there any ascertainable cause for the aplastic anaemia. The period from diagnosis to commencement of CyA varied from 1 month to 2 years. Three patients were lost to follow-up; one at 2 months and two at 18 months. One patient subsequently received bone marrow from an HLA identical and MLC non-reactive sibling, having initially elected to enter the trial of immunosuppressive therapy. Patients have been followed for a minimum of 36 months.

There was no sustained response in either group.

Two patients responded to therapy during the second phase of the study whilst receiving additional prednisone and oxy-metholone. In one patient the remission was sustained until he was lost to follow-up after 18 months. A second patient achieved a transient response only and died after 18 months of treatment, at which time she was again aplastic.

All patients are accounted for, having either died or been lost to follow-up; median survival was 8 months (3-36 months).

Some degree of toxicity occurred. With CyA administration, an elevation of serum creatinine and diminishing clearance was recorded in 6 of the 12 patients but was reversed following dosage adjustment in all but one, in whom the drug was discontinued. Tremor developed in 2, hirsutism in 1, hypertension in 1, and transient elevation of the serum bilirubin level in 3 patients. The antilymphocyte globulin resulted in serum sickness in one individual, and generalised convulsions occurred in a second patient.

**Discussion**

Severe acute aplastic anaemia may occur as a result of irreversible damage to the haematopoietic stem cell [1] although an indistinguishable syndrome can arise on an immunologic basis [15]. Most established cases do not respond to standard forms of immunosuppressive therapy, including adrenocorticosteroids and additional cyclophosphamide administration [7], but there have been reports of significant improvement following antilymphocyte serum and antilymphocyte globulin [6, 11]. The decision to undertake this trial, evaluating CyA in previously untreated patients with severe acute aplastic anaemia, remains largely empirical. Available evidence for the action of this agent suggests that maximum efficiency would be anticipated at the time when antigen exposure first occurs [9] and this may account for the apparent lack of response in our patients.

The combination with antilymphocyte serum, anticipated to be additive to the functional lesions produced by CyA in abrogating a potentially cellular mechanism in the aplastic patients, was equally unsuccessful. The results of treatment with both antilymphocyte serum and antilymphocyte globulin are variable and may reflect differences in dosage, duration of therapy, quality, and type of protein used [5, 15]. Because of the small number of patients in our series, it is not possible to draw any conclusions about the effect of either this particular product or the schedule used for its administration. However, the dosage was lower than had been reported in some trials, where a more favourable outcome was achieved [4]. Alternatively, the failure to obtain any response may be due to concurrent administration of CyA which modified the protein or its action, thereby rendering it ineffective. The subsequent administration of adrenocorticosteroids and anabolic androgens was included to ensure that any patients with hypoplasia rather than aplasia would not be compromised [13]. This approach would appear to be justified in view of the two patients where a response was documented.

CyA is acknowledged to have a range of toxic effects [10] and patients receiving this agent require scrupulous clinical and biochemical monitoring.

It is concluded from this data that CyA either as a single immunosuppressive agent or when used in combination with antilymphocyte serum has no place in treating patients with severe acute aplastic anaemia. The two responses in the present series are attributable to the subsequent administration of adrenocorticosteroids and anabolic androgens. It can, however, not be discounted that in one of these individuals the antilymphocyte serum may have had a minor or contributing role in the response.

Cyclosporin A in the treatment of severe acute aplastic anaemia

PETER JACOBS, LUCILLE WOOD AND ROBERT W. MARTELL University of Cape Town Leukaemia Centre and Department of Haematology, Groote Schuur Hospital, Observatory, Cape, South Africa

Received 19 September 1984; accepted for publication 21 January 1985

SUMMARY. Twelve consecutive adults with severe acute aplastic anaemia, not having a bone marrow transplantation option, were prospectively randomized to receive either cyclosporin A alone or an equivalent amount of this immunosuppressive agent in combination with antilymphocyte serum. The minimum follow-up is 36 months, with half the patients developing nephrotoxicity, which was easily reversible in all but one. No response could be attributed to either regimen. Cyclosporin A does not appear to have a place as primary form of treatment for adults with severe acute aplastic anaemia, either on its own or in combination with antilymphocyte serum.

Bone marrow transplantation is the preferred form of treatment for patients under the age of 40 with severe aplastic anaemia where a suitable donor is available (Storb et al. 1980, 1982; Bortin et al. 1981; Gluckman et al. 1981). In the absence of this option alternative approaches have included supportive care using transfusion of red cells and platelets, with antibiotic administration for infectious episodes (Young, 1981). Anabolic androgens have been prospectively evaluated and shown not to significantly alter the course of the disease (Camitta et al. 1979). Recently, varying response rates have followed the administration of antilymphocyte serum (ALS) or antithymocyte globulin (ATG) (Champlin et al. 1983; Fairhead et al. 1983; Miller et al. 1983; Camitta et al. 1983) to patients with aplastic anaemia, thus supporting the concept that some individuals may have an immunologic mechanism operating. T-lymphocytes are known to play a central role in both immune regulation and the pathogenesis of autoimmune disease and have been shown to produce haematopoietic stimulatory factors (Bacigalupo et al. 1981; Burstein et al. 1982) so that imbalance between helper and suppressor subsets may find expression in marrow aplasia. Such a situation may be reversed by administration of immunosuppressive agents such as cyclosporin A (Stryckmans et al. 1984).

To evaluate a role for cyclosporin A in the treatment of severe aplastic anaemia
consecutive adults, only one of whom had a transplant option, were randomized to receive this agent on its own or in conjunction with antilymphocyte serum.

MATERIALS AND METHODS

Twelve patients who fulfilled the criteria for diagnosis of idiopathic severe aplastic anaemia (Camitta et al. 1976) were randomized to receive either cyclosporin A alone (n=6) or the same schedule of this drug with concurrent infusion of antilymphocyte serum (n=6). The trial was approved by the Ethics Committee of the University of Cape Town and Groote Schuur Hospital, and required informed consent.

Cyclosporin A was given orally at a loading dose of 12.5 mg/kg/d for 1 week, followed thereafter by 6.25 mg/kg/d in two divided doses. Serum levels were monitored weekly by radioimmunoassay (Ciclosporin RIA Kit: Sandoz, Basle, Switzerland) (Randall & Jacobs, 1984). Dosage was subsequently adjusted so that peak levels measured 4 h after the previous dose were maintained between 500 and 500 ng/ml and trough levels between 200 and 400 ng/ml. Antilymphocyte serum (Merleux, Lyon, France) was administered by intravenous infusions over half an hour at a dose of 15 mg/kg on each of four consecutive days (Jansen et al. 1982). The cyclosporin A was continued for a minimum period of 3 months unless undesirable side effects necessitated withdrawal.

Patients who failed to respond after 3 months continued receiving cyclosporin A and, in addition, were given prednisone, at a dose of 0.5 mg/kg/d, and oxymetholone, starting at a dose of 2 mg/kg/d orally and increasing this to a maximally tolerated dose. All patients received standard supportive care in the form of red cell and platelet transfusions; appropriate antibiotics were given for infections.

Haematological response was defined as a rise in platelet count to greater than 50 x 10^9/l, absolute granulocytes above 1 x 10^9/l, and no red cell transfusion requirement.

RESULTS (Table I)

The age of the patients ranged from 12 to 49 years, with a median of 27; there were eight males and four females. In none was there an ascertainable cause for the aplastic anaemia. Three patients were lost to follow-up; one at 2 months (No. 5) and two at 18 months (Nos. 3 and 11) of continuous observation. One patient (No. 12) subsequently received marrow from an HLA identical and MLC non-reactive sibling, having elected to enter the trial of immunosuppressive therapy initially. The period from diagnosis to commencement of cyclosporin A varied from 1 month to 2 years, with all patients meeting the criteria for severe aplastic anaemia on entry to the study. With the previously mentioned exceptions, patients have been followed for a minimum of 36 months.

Two patients responded to therapy during the second phase of the study, following addition of adrenocorticosteroids and anabolic androgens. In one patient (No. 11) the remission was sustained until he was lost to follow-up after 18 months. A second patient (No.

4) achieved a transient response only and died after 18 months of treatment, at which time she was again aplastic.

All patients have died or been lost to follow-up and survival in those where analysis is possible ranged from 3 to 36 months, with a median of 8 months; there was no significant difference in the two groups.

Some degree of toxicity occurred. With cyclosporin A administration, deteriorating renal function was demonstrable on biochemical testing in six of the 12 patients, reflected in an elevated serum creatinine and diminishing clearance. In only one of these individuals, however, was it necessary to discontinue the cyclosporin A before the renal toxicity was reversed. Tremor developed in two, hirsutism in one, and hypertension in one. Hepatotoxicity with rising bilirubin level occurred in three patients. The antilymphocyte globulin resulted in serum sickness in one individual, and in a second, generalized convulsions occurred.
Severe acute aplastic anaemia may occur as a consequence of a severely defective haematopoietic stem cell (Boggs & Boggs, 1976), but an indistinguishable clinical and haematological syndrome can arise on an immunologic basis (Thomas & Storb, 1984). Although most cases of severe acute aplastic anaemia do not respond to standard forms of immunosuppressive therapy, such as adrenocorticosteroids and additional cyclophosphamide administration (Criner, 1980), there have been a number of reports showing significant improvement following antilymphocyte serum and antithymocyte globulin administration (Champlin et al. 1983; Fairhead et al. 1983; Miller et al. 1983; Camitta et al. 1983). In this regard it has been suggested that a response to administration of immunosuppressive agents may be predicted on the basis of in vitro testing (Thomas & Storb, 1984; Bacigalupo et al. 1981; Torok-Storb et al. 1984) but, at least using bone marrow, this has not been our experience (Jacobs & Randall, unpublished observation).

The decision to undertake this trial evaluating cyclosporin A in previously untreated patients with severe acute aplastic anaemia remains largely empirical. Available evidence for the action of this agent suggests that maximum efficacy would be anticipated at a time when antigen exposure first occurs (Lafferty et al. 1983) and this may account for the apparent lack of response in this group of patients.

The addition of antilymphocyte serum was designed to include at least one other agent considered to be efficacious in this situation (Champlin et al. 1983; Fairhead et al. 1983). The known effects of ALG (Greco et al. 1983) may be anticipated to be additive with the functional lesions produced by cyclosporin A in abrogating a cellular mechanism in aplastic patients. The results of treatment with both antilymphocyte serum and antithymocyte globulin are variable and this may, in part, be explicable by a number of factors, including dosage, duration of therapy, quality, and type of protein used (Thomas & Storb, 1984; Coiffier et al. 1984). The number of patients tested in our series is small and it is consequently not possible to draw any conclusion about the effect of either this particular product or the schedule used for its administration in the present study. However, the dosage used was lower than has been reported in trials where the outcome was more favourable (Champlin et al. 1983; Fairhead et al. 1983). Failure to obtain any response could have been due to the concurrent administration of cyclosporin A which may have modified the protein or its action, thereby rendering it ineffective. The subsequent administration of adrenocorticosteroids and anabolic androgens was included to ensure that any patients with hypoplasia rather than aplasia would not be compromised (Skarberg et al. 1973). This approach would appear to be justified in view of the two patients where a response was documented.

Cyclosporin A is acknowledged to have a range of toxic effects (Lampacis, 1983) and patients receiving this agent require scrupulous clinical and biochemical monitoring.

It appears that cyclosporin A as either a single immunosuppressive agent or in combination with antilymphocyte serum has no place in treating adults with severe acute aplastic anaemia and that the two responses occurring in this series are attributable to the subsequent administration of adrenocorticosteroids and anabolic androgens. It can, however,
not be discounted that in one of these individuals the antilymphocyte serum may have had a minor or contributing role in the response.

PREFORMED LYMPHOCYTOTOXIC ANTIBODIES DISAPPEAR FOLLOWING CYCLOSPORINE THERAPY

HEART TRANSPLANTATION IV, 362-363, 1985

INTRODUCTION
Sensitization in organ transplant recipients leads to difficulty in finding a compatible donor when retransplantation becomes necessary. This study presents our observations in two sensitized patients with heterotopic heart transplants (HHT) in whom lymphocytotoxic antibodies disappeared following the administration of cyclosporine (Cy). Our observations have suggested that Cy may possibly have an effect on B-cell activity in sensitized patients.

Case 1: A 14 year old boy, with no preformed antibodies against a panel of 21 donor lymphocytes covering all major HLAA, B and C loci, underwent HHT for end-stage familial cardiomyopathy. Immunosuppressive therapy consisted of azathioprine (Aza), methylprednisolone (mPred), and rabbit antithymocyte globulin (RATG). During the first three postoperative months he experienced two episodes of severe acute rejection, which were controlled with increased doses of mPred and RATG therapy. Eighteen months after HHT, his exercise tolerance steadily started to decline, requiring anti-failure therapy. The graft showed an advanced degree of coronary arteriosclerosis, and a retransplantation was planned. At this time, a test for T-lymphocytotoxic antibodies in the patient's serum, using the standard NIH microlymphocytotoxicity test, was weakly positive. No previous tests for antibodies had been carried out since the time of HHT and no blood transfusion had been given since the operation. A month later, the antibody titre had increased. The patient's serum was positive against 25% of the same panel cells, and cytotoxicity against half of these cells. It was not possible to relate the antibodies to the first donor's HLA type. Five consecutive potential donors were found to be unacceptable in view of a positive donor-recipient lymphocytotoxic crossmatch. A sixth donor was found, with a negative crossmatch, and the patient underwent an orthotopic heart transplantation (OHT) two years after the HHT, the first graft being left in situ. The reason for choosing this procedure has been reported elsewhere. Until the time of retransplantation the patient was receiving Aza 2.5 mg/kg/day and mPred 0.3 mg/kg/day. Following OHT, immunosuppression consisted of cyclosporine (Cy, 12 mg/kg/day reduced to a maintenance dose of 5 mg/kg/day) and mPred (1 mg/kg/day reduced to 0.25 mg/kg/day at six months). Ten days after Cy therapy was initiated, the titre of the circulating antibodies dropped (15% positive against the panel, with only a 10% cytotoxicity). Subsequently, lymphocytotoxic antibodies were no longer present. The patient did not develop any episodes of acute rejection and remains well 15 months after OHT.

Case 2: This 14 year old patient with dilated cardiomyopathy had no preformed lymphocytotoxic antibodies against a panel of 21 donor lymphocytes when he underwent HHT. Immunosuppression consisted of Aza, mPred and RATG. After several moderate-to-severe acute rejection episodes, Aza was replaced with cyclophosphamide. He experienced no further acute rejection episodes, and remained active and well. By the end of the third postoperative year, the patient's effort tolerance began to decrease because of allograft arteriosclerosis. Six months later he was accepted as a candidate for retransplantation. At that time, weak lymphocytotoxic antibodies were demonstrated in his serum against the standard panel (Figure 1). Antibody titre steadily increased over the next two months (25% positive, with a 75% cytotoxicity). No screening for lymphocytotoxic antibodies had been carried out and no blood transfusion had been given since the HHT. It was not possible to confirm the relationship between these antibodies and the original donor's HLA type. Three donor hearts could not be used because of positive lymphocyte crossmatch. Cy (10 mg/kg/day) was added to the patient's regimen and the dosage was reduced over the next three months. During that period, no cytotoxic antibodies were detected. However, when whole blood Cy trough levels fell below 100 ng/ml, the lymphocytotoxic antibodies reappeared. Cy dosage was increased and again, ten days later no antibodies could be detected. Under Cy therapy the patient had negative crossmatches with four potential donors, but all the allografts were used in other patients who were more acutely ill. Eventually, the patient underwent a OHT, four years after his first operation. The procedure was the same as the one performed in Case 1. Immunosuppressive therapy consisted of Cy and mPred. The patient experienced one episode of moderate acute rejection, but otherwise has made uneventful progress, and remains well one year after the second transplantation. Since this second operation, no antibodies have been detected in his serum.
FIGURE 1: Case 2: Loss of lymphocytotoxic antibodies under Cy regimen. Temporary reappearance of antibodies when the dosage (... of Cy was reduced and Cy trough levels (...) fell below the therapeutic range. Following increased Cy dosage, the antibodies again disappeared.

(kt = second heart transplant procedure. The cross-hatched columns indicate the percentage of panel cells against which lymphocytotoxic antibodies were present.)

DISCUSSION
The immunosuppressive mechanism of Cy remains uncertain. The drug is known to inhibit the activation of the allograft-specific T-cell response, and to prevent activation of helper T-cells by inhibiting the production of interleukins by the inducer T-cell and the macrophage. Cy appears to spare suppressor T-cells. In vitro, there is evidence that Cy suppresses antibody synthesis by B-cells. In vivo, inhibition of T-dependent B-cells has been shown in the mouse. The administration of Cy in the two patients reported here coincided with the disappearance of T-lymphocytotoxic antibodies from their sera; in one patient (Case 2), the presence of antibodies appeared to be Cy dose-dependent. The other patient received increased doses of mPred during the period when the antibodies disappeared. Thus, these observations need to be interpreted with caution. Neither patient was highly sensitized, and panel reactive antibodies of the strength seen in these two cases may vary unpredictably. However, it is unusual for antibodies, even when relatively weak, to disappear quickly, and the association of this phenomenon with the introduction of Cy is of interest. In both cases, the same panel of 21 lymphocytes was used; changes in panel cells therefore can not account for the disappearance of the antibodies, and neither patient had received a blood transfusion since the HHT, which might have altered his antibody status. In neither case have antibodies been detected subsequently, despite the fact that the chronically rejected first transplanted heart, which might have been the source of the antibodies, remained in situ.

The presence of T-lymphocytotoxic antibodies in a patient awaiting transplantation reduces the pool of compatible donors. Although our observation requires confirmation in a large group of highly sensitized patients, it suggests that pretreatment with Cy may result in the disappearance of preformed antibodies, and may therefore increase the donor pool available to sensitized patients awaiting heart transplantation, where a delay may result in death, and in those awaiting renal transplantation, where it could allow earlier transplantation and reduce the pressure on hemodialysis facilities.

Reactivity of Pretransplant Cytotoxic Antibodies to a Selected HLA Panel Is Not Influenced by Cyclosporin A, With or Without Plasma Exchange

Charles R. Swanepoel, Michael J.D. Cassidy, Margaret May, Machteld Oudshoorn, Ernette du Toit, Lucille Wood, and Peter Jacobs

The University of Cape Town Leukaemia Centre and the Departments of Haematology (L.W., P.J.) and Medicine (Renal Unit), (C.R.S., M.J.D.C., M.M.) Groote Schuur Hospital, and the Provincial Laboratory for Tissue Immunology (M.O., E.d.T.), Observatory, South Africa

The influence of 6 weeks of cyclosporin A (CYA), followed by a further 6 weeks of this agent in combination with plasma exchange (PE), was defined on panel reactivity and titre of preformed cytotoxic antibodies in stable patients on haemodialysis awaiting renal transplantation. Nine individuals with antibodies to 30% or more of the donor panel were entered into the study, but three failed to complete the programme. Comprehensive data are available on the remaining six patients, one of whom was studied twice. The pattern of reactivity to the panel was unaltered, but antibody titres were significantly reduced (P < 0.006). In one patient, a lymphocytotoxic crossmatch performed between the patient and an HLA-haploidentical sibling in the last week of the trial was positive, suggesting that neither procedure was successful in removing an antibody directed against the HLA antigens of a family donor. Three cadaver renal transplants were performed during or after the trial, and while two of the grafts were unsuccessful, one survives at 60 months, with good function. From these data it is concluded that neither cyclosporin A nor its combination with plasma exchange have any effect on the panel reactivity of preformed cytotoxic antibodies, whereas the titres were significantly reduced. An important and serious side effect of the apheresis procedure was the loss of fistulae in two patients.

Key words: panel reactivity, renal transplantation, apheresis procedure

INTRODUCTION

Sensitization to the major histocompatibility complex antigens may preclude patients with renal failure from undergoing kidney transplantation. These individuals block dialysis stations and, where resources are limited, will deny otherwise suitable patients access to both this procedure and subsequent renal transplantation. Such sensitization may occur as a natural phenomenon [1], following pregnancy [2], transplantation, or blood transfusion [3], although the availability of recombinant human erythropoietin [4] may replace the latter and thereby abolish this form of immunisation.

A number of options have been evaluated for the removal of antibodies once they have been formed, in an attempt to salvage patients and render them suitable for transplantation, including plasma exchange and steroids with or without azathioprine, cyclophosphamide, or cyclosporin A (CYA) [5–8]. Despite success having been limited to those patients where cytotoxicity was directed against one or two of the major HLA antigens [5,6], it seemed important enough to prospectively re-examine the effect of CYA on its own when combined with plasma exchange (PE) on both the spectrum of reactivity of the preformed cytotoxic antibodies and their titre.

PATIENTS AND METHODS

Entry required the presence of preformed cytotoxic antibodies reacting to more than 30% of a donor panel comprising 30 cells selected to represent the major HLA phenotypes. All patients who had absence of renal function, were red cell transfusion independent, free of sepsis, and had no history of prior liver disease. The protocol was approved by the University of Cape Town and Groote Schuur Hospital Ethics and Research Committee, and entry required informed consent. Patients underwent standard haemodialysis three times a week and in the

first 6 weeks received only CYA at a dose of 4 mg/kg twice a day. Thereafter, dosage was adjusted to maintain whole blood trough levels between 200 to 400 ng/mL [9]. In a second phase, the CYA was continued and isovolaemic PE, using the Cobe Centry parallel-membrane filtration unit, preceded the haemodialysis. These procedures were carried out twice a week in the first 2 weeks and weekly thereafter. Using nomograms, 1.5 × the calculated plasma volume was replaced with 4% salt-free human albumin in saline, to which was added 6 mL of 10% calcium gluconate/L.

Laboratory investigations, which were carried out at entry to the trial and then at the end of each 6 week phase, included full blood count, measurement of serum calcium, and inorganic phosphorus and alkaline phosphatase levels. Serum parathyroid hormone (PTH) could only be measured in two of the patients.

The level of cytotoxicity, defined as a percentage of panel reactivity, was measured using lymphocytes from 30 HLA-typed donors. The titre of cytotoxic HLA-antibodies was determined by allowing serial dilutions of the patient serum to react with four individuals who had been selected from the panel by their having maximum reactivity with the undiluted patient serum. Subsequent antibody titrations were always performed against the same set of four cells. Sera were tested for IgG and IgM antibodies, using the reducing agent, dithiothreitol (DTT) [10]. Tests were carried out on a control group of seven patients on maintenance dialysis, also having > 30% panel reactivity and who were not treated with either CYA or PE.

STATISTICAL ANALYSIS

The Student t test was used to determine the significance of changes in panel reactivity, calcium, inorganic phosphorus, and alkaline phosphatase levels. The Mann-Whitney U test was used to check the significance of changes in titres of antibody.

RESULTS

Nine patients entered the trial (Table I), but three were withdrawn at 4, 7, and 4 weeks, respectively; one underwent renal transplantation; in the second, the fistula clotted and the patient developed sepsis and required transfusion; and the third, also because of blood transfusion requirements. A total of two patients lost their fistulas following PE. Seven studies were undertaken in six patients. There were no changes in the full blood count, serum calcium, or inorganic phosphorus levels. However, changes in the serum alkaline phosphatase were significant (P < 0.05) when pretreatment levels were compared to 6 weeks of CYA and PE. Parathyroid hormone levels were determined in two patients, and in both, the levels were above the normal range throughout the study period.

In the control group (n = 7), there were no changes in the percentage panel reactivity or in the HLA-antibody titre levels. In the patients, there was, similarly, no change in the percentage panel reactivity in the 3 month control period or in the period during which they were treated with CYA, with or without PE (Fig. 1). However, in two patients, there was a 73% and 46% drop over the 12 weeks of the study (Fig. 2), and both of these individuals underwent renal transplantation after completing the 12 weeks trial period.

The majority of the cases were initially sensitized by transplantation, and apart from patient no. 3, all had multispecific antibodies; the antibody class determined in five was predominantly IgG. Measurement of cytotoxic antibody titres showed no change in the 12 weeks prior

to study, but there was a significant fall after CYA and PE ($P < 0.006$) (Fig. 3).

Three patients were transplanted either during or soon after completion of the study (Table II). One patient, no. 3, with good kidney function survives 60 months after allografting, with a serum creatinine of 152 $\mu$mol/L; this was the only patient in the group who had antibody specificity restricted to the HLA antigen A24 and showed a 46% reduction in panel reactivity in response to the treatment (Fig. 2).

The lymphotoxicity cross-matching test was performed between one of the study patients and his HLA-haploidentical sibling during the last week of the study, while receiving CYA and on PE, and was shown to be positive.

**DISCUSSION**

Although the aim of the study was not to investigate the reason for the development of cytotoxic antibodies, where much larger numbers of patients would have been required, it nevertheless appears unlikely that they were naturally occurring [1]. Thus, in the present series, the majority of these reacted weakly with B-lymphocytes, but strongly and predominantly with T-cells. This finding contrasts with the rare, naturally occurring forms that have weak reactivity directed only against B-lymphocytes. Furthermore, while recognising a role for pregnancy in isoinmunisation, this mechanism could be confidently invoked only in one of the six females studied.

In the remainder, we consider renal transplant to have been the likely precipitating mechanism, with transfusions playing a complementary role.

Irrespective of the causative mechanism, it is notable that successful removal of HLA antibodies can be achieved using combined PE and immunosuppression [5,6]. In those cases, antibodies were directed only at one or two antigens, which again contrasts to the multiple specificity of antibodies in the current series. In our experience, percentage panel reactivity was unaltered by either manoeuvre, while titres were significantly reduced.

A = time spent waiting for a transplant prior to the trial; B = time spent waiting for a transplant after the start of the trial; Tx = transplantation; NF = never functioned; GF = good function.
Another possible explanation for the difference in results may well lie in the lesser intensity of our PE programme. Furthermore, CYA was used without additional steroids or other immunosuppressive agents. Of interest is a case report in which intensive PE did not alter antibody titres. This was probably related to repeated blood transfusions given to the patient during the course of study [7].

It has been suggested that CYA combined with PE has no influence on reducing sensitization [8]. It is possible that this combination may only be effective when the antibodies are specifically directed against one or two HLA antigens. In this regard, of the three patients in the present series who were transplanted, one survivor had antibodies restricted to HLA-A24 and the percentage panel reactivity of her antibodies showed a marked change from the level at entry to that after 12 weeks on combination CYA and PE. The remaining two patients who were transplanted never established graft function, and both had multispecific antibodies. It is of note that the three transplanted patients had waited unsuccessfully for an average of 24 months for a cadaver kidney before the start of the trial, whereas they underwent allografting on an average of 2.8 months after the study was initiated. It may well be that the combination of CYA and PE would have much greater benefit if initiated immediately when the problem is identified and, once the titre is reduced, the patient proceeds immediately to renal transplantation. Additionally, better results might be anticipated if patients were entered on the combination of CYA and PE when antibodies are directed against a single HLA antigen.

As part of a wider study examining the complications of PE, alkaline phosphatase was tested and found to fall significantly during the course of this investigation. This may be attributable to the mass removal of the enzyme by the exchange procedure, since it is unlikely to represent healing of osteodystrophy as serum calcium and PTH levels remained abnormal. It is noticeable that the opposite effect on this enzyme has been reported with CYA administration to patients undergoing renal allografts [11,12], where there was an increase in osteoblastic activity with resultant elevation in the plasma levels; we are unable to explain this discrepancy.

The failure to complete the study resulted when the patients proceeded to transplantation, required blood transfusions, or developed sepsis. Two patients lost their arteriovenous fistulae as a direct consequence of the PE procedure. This is a serious complication since the loss of a fistula may shorten the lifespan of a patient on dialysis.
It is concluded that the combination of CYA and PE significantly reduces antibody titre without influencing overall reactivity to a panel of cells selected to contain the most commonly occurring HLA antigens. Furthermore, this regimen was unable to reduce antibodies against family donor HLA antigens in the one case studied. Only a single patient has a functioning cadaver transplant 60 months after the trial. On the basis of these results, CYA, with or without PE, cannot be recommended as an effective means of altering multispecific cytotoxic antibodies or therefore as a basis for rendering renal graft function more successful in these individuals. However, the removal of anti-HLA antibodies remains a challenge for the future and the use of more selective techniques [13], perhaps including extracorporeal staphylococal protein A immunoabsorption, may be a practical alternative [14].

Cyclosporin A pretreatment of both donor and recipient undergoing allogeneic bone marrow transplantation

Peter Jacobs.
The Leukaemia Centre and the Department of Haematology, University of Cape Town and Groote Schuur Hospital, Observatory, Cape, South Africa

51 patients received allogeneic marrow from histocompatible and MLR non-reactive siblings. Post-transplantation methotrexate was associated with acute refractory graft-versus-host disease (GVHD) in 10/23 (43%) and caused death in 6. When cyclosporin was substituted for the methotrexate fulminating GVHD occurred in 2/28 (28%): both responded to methylprednisolone. When both donor and recipient were pretreated with cyclosporin GVHD of only mild degree developed in 6/20 (30%): 2 responded rapidly to methylprednisolone and in the remaining 4 mild cutaneous lesions persisted. The latter regimen was associated with no donor morbidity and approximately 50% of the recipients had easily reversible renal dysfunction. Thus, cyclosporin A appears to marginally reduce the incidence of acute GVHD and to facilitate response when additional methylprednisolone is required: additional pretreatment of the donor appears to reduce the severity of the acute syndrome. In none of these regimens was a beneficial effect observed on de novo GVHD.

Accepted for publication May 9, 1985

Allogeneic bone marrow transplantation is the preferred form of treatment for severe acute aplastic anaemia (1), is increasingly used for patients with both myeloblastic (2) and lymphoblastic (3) leukaemia, and is being evaluated in a variety of other diseases (4). Despite meticulous matching of siblings at the major histocompatibility complex and their non-reactivity in the mixed lymphocyte culture, both acute (5) and chronic (6) GVHD occur and together constitute a formidable barrier to the more widespread use of marrow grafting.

Attempts to prevent (1, 7) or abrogate (8, 9) GVHD have met with variable success and since the introduction of cyclosporin A its effect on transplantation in general (10) and especially marrow allografting (11) has been encouraging (12). However, while the incidence and severity of acute GVHD with its high morbidity and mortality and chronic GVHD with its relentless progression and mutilating side effects have not been totally eradicated, there appears to be advantage in further exploring the use of this unique immunosuppressive agent. Evaluation of

Professor Peter Jacobs
different regimens has been directed largely at the recipient (12) and no attention given to donor pretreatment. Since the acute disease may progress to the chronic form and because immunocompetent lymphocytes transferred from donor to recipient in the graft may have a role to play, a pilot study was carried out to test the possibility that additional cyclosporin A pretreatment of the donor may influence the expression of both acute and chronic GVHD following allogeneic bone marrow transplantation.

Material and methods

51 patients underwent allogeneic bone marrow transplantation on a programme approved by the Ethics Committee of the University of Cape Town and after donors and recipients had signed informed consent.

Initially, patients with refractory acute leukaemia were offered transplantation but subsequently only those in consolidated complete remission or having severe acute alastic anaemia were considered eligible. Sibling donors compatible at the major histocompatibility complex and non-reactive with their recipients in the mixed lymphocyte culture were used.

Severe acute aplastic anaemia was defined according to internationally accepted criteria (13) and patients were conditioned with 50 mg/kg of cyclophosphamide by i.v. injection on 4 consecutive days before transplantation (5). The patients with acute leukaemia were treated with a combination of V1P-213, cytosine arabinoside and doxorubicin (14), after which they were conditioned with cyclophosphamide, 60 mg/kg on 2 consecutive days, and 10 Gy total body irradiation at a maximum dose of 7 rads/min given 24 hs after the last dose of conditioning drug. All patients were managed in reverse isolation, received hyperalimentation and such antibiotic and allogeneic component support as was appropriate.

Three different immunosuppressive regimens were evaluated in the course of this study. In Group 1 (n = 23) cyclosporin A was not available and, following transplantation, patients received only methotrexate (5). In Group 2 (n = 8) cyclosporin A was commenced the day before infusion of the graft at an oral dose of 12.5 mg/kg twice a day for a week and then 6.25 mg/kg twice daily for the next week, after which adjustments were made to maintain plasma concentrations between 250 and 500 ng/ml by radioimmunoassay (15) at least once a week for the entire duration that patients received this immunosuppressive drug. In Group 3 (n = 20) both donor and recipient commenced cyclosporin A on the same dosage schedule 2 weeks before transplantation; patients remained on this agent for the same duration as those in Group 2. At all times plasma concentrations were monitored and doses were adjusted at least once every week to maintain levels in the same therapeutic range as in Group 2.

Biochemical measurements of renal and hepatic function, as well as electrolyte status and acid-base balance, were measured on alternate days in donors and recipients. Any increase in creatinine or urea, even whilst still in the normal range, was managed initially by small doses of oral furosemide, and failure to immediately reverse this trend required reduction in cyclosporin A dosage. In the donors as well as in the recipients after discontinuation of cyclosporin A, these measurements were continued on follow-up visits until their discharge from clinic.

Acute (5) and chronic (6) GVHD were defined according to established criteria. Both syndromes were treated by continued administration of cyclosporin A; in the acute disease methylprednisolone was added; in the chronic form additional high-dose pulsed methylprednisolone (9) was initially used and this was followed by long-term corticosteroids and azathioprine. The dose of the two drugs was variable and started at 0.5 mg/kg and 2 mg/kg of lean body mass, respectively. The methylprednisolone was gradually reduced, whereas the dose of azathioprine remained relatively constant and while the efficacy of this two-drug combination on the clinical course of the chronic GVHD was constantly reviewed, average duration is presently in excess of 9 months.

Results

Group 1: n = 23
These patients were treated with methotrexate for immunosuppression (5). 10 of the 23 patients (43%) developed classical severe acute GVHD within 6 weeks of transplantation, which was refractory to therapy and caused death in 6 patients. Of the remaining 4 patients, 1 died of Budd-Chiari syndrome, which may have been related to the long period of prior intensive chemotherapy, and 3 progressed to chronic GVHD, of whom 1 is alive with disfiguring cutaneous lesions, 1 died of disseminated tuberculosis without evidence of GVHD, and the
other died following a seizure but with severe skin lesions; autopsy failed to reveal the cause of death.

Chronic GVHD arose de novo, that is, without any prior acute disease, in 2 patients (9%) and has been self-limiting in both.

Group 2: \( n = 8 \)
These patients received cyclosporin A immunosuppression without donor pretreatment. Severe acute GVHD occurred in 2 patients (25%) and in both responded promptly to additional corticosteroids. 1 patient died from leukaemic relapse and the second from a ruptured cerebral aneurysm.

Chronic GVHD without an antecedent acute episode occurred in 3 patients (38%). 1 died from disseminated fungal infection with poorly controlled cutaneous Grade 1 GVHD. The other 2 developed minimal but characteristic skin lesions 3 months after discontinuing cyclosporin A. Both have responded to restarting cyclosporin A in conjunction with a single course of pulsed high-dose methylprednisolone.

Although the incidence of acute GVHD in the three groups (see Material and Methods) was respectively 43%, 25%, and 30%, these results are not statistically different \(( p > 0.05)\) \((24)\). However, in no patient receiving cyclosporin A did the acute disease progress to chronic GVHD and, furthermore, it was easier to control or reverse the acute clinical syndrome with the addition of corticosteroids.

The three groups, which were treated sequentially, received alternative forms of immunosuppressive therapy (see Material and Methods).
Group 3: n = 20
These patients and their donors were pretreated with cyclosporin A for 2 weeks before transplantation. 6 patients developed early GVHD 30%. In 2 this was mild and responded promptly and completely to corticosteroid therapy; 1 patient subsequently died from massive gastrointestinal tract haemorrhage and the second patient is currently well. In 4 further patients the disease was also mild, being defined as Grade 1 cutaneous changes, diarrhoea less than 500 ml in 24 h, and without abnormality on liver biopsy. However, in none of these patients could this clinical syndrome be reversed on therapy and all died within 3 months; 3 from infection and 1 from massive haemorrhage from a duodenal ulcer.

Chronic GVHD occurred de novo in 2 patients (10%) after they had discontinued their cyclosporin A and both have responded to one pulse of high-dose methylprednisolone.

Engraftment and Survival
Engraftment is defined as the time taken from transplantation to reach a granulocyte count of $0.5 \times 10^9/l$ or a platelet count of $25 \times 10^9/l$. These findings are substantiated by a bone marrow aspiration and trephine biopsy which showed greater than 15% of haematopoietic cell repopulation. The median time to achieve these criteria for the three groups was 21 (range 9–26), 14 (range 6–33), and 13 (range 7–16) d respectively.

Actuarially predicted survival curves (Figure 1) show little difference for median survival, with a non-significantly higher plateau for patients in Group 3.

Toxicity
In none of the donors did biochemical tests of renal function rise outside the normal range during the 2 week period of cyclosporin A administration. The donors were all fully reassessed, including biochemical measurements, before discharge and again within 1 month after discontinuing cyclosporin A therapy. Furthermore, in a separate series of individuals with severe acute aplastic anaemia without a transplant option, cyclosporin A was used as the primary form of immunsuppression either singly or in combination with antilymphocyte globulin; in 12 individuals monthly follow-up for an average period presently in excess of 9 months has shown no late disturbances in biochemical tests of renal or hepatic function.
In recipients receiving cyclosporin A, transient elevation of blood urea and creatinine was seen in 50% of the patients in Group 2 and 3. Any increment in these biochemical measurements, despite their remaining within the normal range, was managed by treating the patient with 40 mg furosemide daily or twice a day. Failure to immediately reverse the trend required reduction in the dose of cyclosporin A being given. No examples of progressive deterioration or irreversible dysfunction were observed using this approach.

Discussion

In Group 1 patients underwent allogeneic bone marrow transplantation before cyclosporin A was available and methotrexate was used as the only post-transplantation immunosuppressive agent (5). The incidence of severe GVHD was 43%, and in 6 out of 10 patients was directly contributory to their death. In a further 7 patients who died as a consequence of fulminating bacterial infection, although without the classical cutaneous or hepatic stigmata of this syndrome, it may have played a subsidiary or contributory role. However, in these individuals clear separation from the underlying consequences of their primary disease, prior chemotherapy, cyclophosphamide conditioning or radiotherapy was not possible. Of these 10 patients in Group 1 who had classical severe GVHD 3 of the survivors progressed to extensive cutaneous lesions which, although they could be controlled with corticosteroids and azathioprine therapy, created a major and seriously disfiguring complication. The single survivor in this group, now beyond 3 yr, has noted slow reversal of the skin lesions at a time when he is off all therapy.

In Groups 2 and 3 cyclosporin A replaced methotrexate. The novel fungal metabolite is attractive, particularly following allografting, since it is free of myelosuppressive effects as well as the metabolic consequences that accompany prolonged administration of corticosteroids. Its major acute side effects are related to predictable but reversible changes in renal function and, less frequently, to alterations in biochemical tests of liver function. It is not lympholytic, is thought to influence an early step in the immune response, probably by interfering with T-lymphocyte action and, as a result, blocking the generation of effector cells by preventing the recognition of foreign or transplanted antigen (16). Available evidence suggests that cyclosporin A should be administered to the patient before infusion of the graft, but despite testing a number of different schedules no apparent advantage was evident for one over the other (12).

In Group 2, cyclosporin A was therefore commenced at least 24 h before transplantation, and while the numbers are small the incidence of severe acute GVHD was reduced; 25% as compared to 43% in Group 1. A second and more striking feature was the ease with which diarrhoea and deteriorating renal and liver function were reversed in both patients with high-dose steroids (9), although the skin changes responded more slowly. One other observation of interest was the emergence of de novo chronic GVHD in 3 patients (37%), 2 of whom had certainly discontinued their cyclosporin A in the 8 wk before the first mucocutaneous lesions appeared. Here again, resolution occurred within 2 wk of restarting the immunosuppressive drugs (8) and this contrasts with our experience in methotrexate-treated patients. 2 patients died from fungal infection, and while this might be the consequence of immunosuppression resulting from cyclosporin A therapy, its contribution cannot confidently be separated from the effects of the underlying disease, cyclophosphamide conditioning, or possibly even radiotherapy (17).

In Group 3 both the recipient and the donor were pretreated with cyclosporin A on the basis of experimental studies (18) when such a modification to the schedule further diminished the incidence of severe acute GVHD over a matched group of rabbits where only recipients received this agent from the time of allografting. Whilst recognising that the prevailing concept for the action of cyclosporin A requires only its physical presence to impair T-lymphocyte help, there is
no proof that this is its only or even major action. Alternatively, it is not clear whether a longer period of time may not be necessary for in vivo exposure of the donor cells to the immunosuppressive agents to achieve maximum effect. The latter theoretical possibility appears to find support in the mild GVHD occurring in 6 of the 20 patients being transplanted on this schedule and its immediate reversal in 2 upon addition of prednisone. In the other 4 individuals the onset of clinical course was indistinguishable from the 2 who responded, but their cutaneous lesions progressed despite addition of corticosteroids and without ever developing more than 500 ml of diarrhoea in 24 h or abnormalities in liver function or changes on biopsy. Death occurred in these 4 patients due to disseminated aspergillus in 2, bacterial infection in 1 and massive haemorrhage from a duodenal ulcer in 1. Although only skin lesions were present as objective evidence for acute GVHD, this observation is subject to the same reservation that applies to our patients in Group 1: thus, while expression of the clinical syndrome could have been modified by cyclosporin A, it may nevertheless have been present and played a subsidiary or contributory role to the eventual demise of the patients. In 2 additional patients the chronic cutaneous form of GVHD became evident only after cyclosporin A had been discontinued. This pattern of response is similar to the 2 patients in Group 2 whose skin lesion also appeared only after therapeutic levels were no longer present in the plasma. Both patients responded dramatically to high-dose methylprednisolone but are left with areas of increased skin pigmentation.

Since the experience in the three groups was accumulated chronologically, a number of further questions require consideration. Firstly, the patients are not absolutely matched since those in Group 1 contained a number of individuals with refractory leukaemia, whereas this indication for transplantation had been discontinued by the time patients were entered into Group 2 or Group 3 of the study. A second point to emphasize is that the schedule for cyclosporin A administration to the recipient differs between Group 2 and Group 3, with patients in the latter group receiving 14 d pretreatment as opposed to only 1 d in Group 2. It is therefore possible that the duration of recipient pretreatment may account for the apparently superior results seen in Group 3. In this regard, it should be noted that the remainder of the transplantation procedure remains unchanged during the course of these studies. To define the role of donor treatment a prospective randomised trial is now in progress comparing 14 d of cyclosporin A administration before allografting to recipient only with outcome when both donor and recipient receive the identical schedule.

The time to achieve engraftment appears shorter in the two groups receiving cyclosporin A, although the difference between patients in Group 2 and Group 3 is not significant. This shortening in the time taken to engraftment is consistent with other experience (19).

The overall results of bone marrow transplantation in this series are less satisfactory than reported by others, and in this regard infection played a major role in morbidity and mortality. The reason for this is that the data reported are derived from our early transplant figures when many of the patients were referred in less good clinical condition than would now be required for entry on to the allograft programme. In addition, the poor results in aplastic anaemia are clearly related to the extensive prior transfusion with sensitization that had taken place in this group of patients and which would currently exclude referred individuals for grafting. Interstitial pneumonia was approximately equally distributed between the groups but accounted for less than 20% of the infectious deaths.

In a programme where donors are exposed to the additional risk of cyclosporin A over and above general anaesthetic and the unpleasant procedure of bone marrow collection, it is essential that side effects be reduced as far as possible (20–23). In our experience prompt attention to any changes in biochemical tests of renal function avoided nephrotoxicity (17). In addition cyclosporin A administration as the primary form of treatment to patients with severe acute
 aplastic anaemia lacking the option for marrow transplantation has shown transient and easily reversible nephrotoxicity; the average period of follow-up is presently in excess of 9 months and neither persistence nor late development of abnormalities in biochemical tests of renal or hepatic function have emerged (Jacobs et al, unpublished observation).

It is concluded that cyclosporin A may have a role to play in bone marrow transplantation. When it is given only to recipients as the sole immunosuppressive agent there is an apparent decrease in the incidence and severity of acute GVHD. These schedules are not completely effective in preventing the acute syndrome but, should this occur, it is easier to control with methylprednisolone. This was not our experience when methotrexate was used. Although it appears that cyclosporin A has a major effect on T-lymphocyte helper function, it is theoretically possible that a longer period of donor cell exposure may be necessary. This hypothesis was tested by pretreating donor and recipient with cyclosporin A. In these preliminary observations, it appears that marginal reduction in the incidence of acute GVHD may be possible but more strikingly is the apparent decrease in the severity of this syndrome. Furthermore, it also appears as though the number of patients progressing from acute to chronic GVHD may be reduced, whereas de novo chronic GVHD is unaffected. These results suggest that such a schedule of donor pretreatment may warrant further evaluation.

Acknowledgements

This study was supported by the University of Cape Town Leukaemia Centre and Staff Research Fund, the Medical Research Council and the National Cancer Association. The cyclosporin A used was generously donated by Sandoz Laboratories, Switzerland.

I thank Gail Randall and Linda Eglinton for cyclosporin A assay, Keren Edwards and Jackie Davies for research and secretarial assistance, and Chief Professional Nurse Lucille Wood for help with patient care. I express appreciation to colleagues who have referred patients and participated in management, particularly Dr. D. W. Dubovsky, Dr. Christina Geddes, Dr. L. M. Kernoff, and Dr. Ingrid le Roux. Dr. Ernette du Toit and her staff carried out the tissue typing. Thanks are due to registrars and nursing staff from the Transplantation Unit for expert care, Dr. Helen S. King for radiotherapy, and the Chief Medical Superintendent of Groote Schuur Hospital for permission to publish.

15. SEPARATION AND CRYOPRESERVATION OF HAEMATOPOIETIC STEM CELLS FROM HUMAN CADAVER BONE MARROW

S. Horak, L. Wood, P. Jacobs

The University of Cape Town Leukaemia Centre and the Department of Haematology, Groote Schuur Hospital

The normal discoid erythrocyte deformed rapidly during storage and virtually disappeared by Day 9 (0.12%). At this stage the following cells were present: Type B discocytes, Type IA, IB and IC echinocytes, one group of Type II echinocytes, and Type IIIA and IIIB echinocytes. By Day 21 the only red cell types remaining were Type IC, II, IIIA and IIIB echinocytes, Type I and II spherocytoids and echinocytes.

17. THE EFFECT OF CYCLOSPORIN ON HUMAN LYMPHOCYTES IN VITRO

C. van Eeden, S. Horak, P. Jacobs

The University of Cape Town Leukaemia Centre and the Department of Haematology, Groote Schuur Hospital

Cyclosporin is a novel immunosuppressive agent widely used in widespread clinical use. It acts by impairing the ability of T-helper lymphocytes to release lymphokines, including interleukin 2, thus to respond to appropriate antigenic stimulation. Since therapy is controlled by monitoring whole blood radioimmunoassay, it is a study undertaken to relate these levels to immune suppression, reflected in lymphocyte response to mitogens and alloantigen. Technically, human peripheral mononuclear cells were separated by density gradient centrifugation, washed twice in tissue culture medium, and a suspension of 1 x 10^6/ml cells prepared. Dose and time response curves were determined for cyclosporin concentrations ranging from 0.5-2400 ng/well, using assays calibrated to obtain optimal response to different mitogens and alloantigen. Profound suppression of H² incorporation into DNA under these conditions occurred at a concentration of 100 ng/well: equivalent to a plasma level of 2000 ng/ml. Time-course experiments demonstrated this effect to be maximal when cyclosporin was added to the cultures up to 6 hours following exposure to the antigens. It is therefore concluded that cyclosporin is capable of suppressing lymphocyte function at therapeutic concentrations and that this effect is critically time-dependent. 18. PROBLEMS ENCOUNTERED BY A MEDICAL TECHNOLOGIST DEALING WITH VETERINARY HAEMATOLOGY

A. van Heerden

Faculty of Veterinary science, University of Pretoria.

Due to the current small number of veterinary clinical laboratories in South Africa, both within the industry and in the field of haematology. However, many have realized that there are significant differences between the Haematology of man and that of animals. These differences often lead to confusion. I intend to illustrate the most important interspecies variations in the morphology and proportions of the different types of leucocytes. In addition I will discuss and illustrate the most common blood parasites to be found in our domestic animals.
CICLOSPORINE IN HAEMATOLOGIC PERSPECTIVE

NICOLAS NOVITZKY and PETER JACOBS

The University of Cape Town Leukaemia Centre and the Department of Haematology, Groote Schuur Hospital, Observatory, 7925, Cape, South Africa

(Received 17 July 1992; in final form 28 August 1992)

Immunosuppressive drugs play an important role in the management of autoimmune diseases and are crucial for graft survival in organ transplantation. Cytotoxic agents are limited by varying degrees of myelosuppression and corticosteroids by widespread metabolic complications. Attempts to dissociate these unwanted side effects from the desired modulation of humoral and cell-mediated mechanisms led to the development of ciclosporine. This fungal undecapeptide directly impairs, in a dose-dependent fashion, the function of CD4 or T-helper lymphocytes, with important consequences throughout the immune system, leading to a profound suppressive effect.

This unusual molecule favours engraftment following bone marrow transplantation, but used on its own has not fulfilled its early promise in abolishing acute graft-versus-host disease (GVHD) and is currently combined with other agents for this purpose. In broader haematologic context, its administration improves the outcome in some patients with aplastic anaemia and pure red cell aplasia, and its role is being evaluated in other immune disorders. Toxicity is primarily the impairment of renal and hepatic function, with attempts currently in progress, therefore, to improve monitoring and, in addition, to develop other analogues. It is concluded that the use of ciclosporine is well established in haematology, but in marrow allografting it remains less effective than in transplantation of solid organs.

KEY WORDS: Ciclosporine, immunosuppression, graft vs. host disease, aplastic anaemia.

INTRODUCTION AND HISTORICAL BACKGROUND

The demonstration in dogs that survival of renal homografts could be prolonged following the administration of 6-mercaptopurine marked the beginning of an era examining immunosuppression in transplantation. The early work using conventional cytotoxic drugs was characterised by substantial side effects, notably in the bone marrow, with consequent granulocytopenia and a high infection rate. Attempts were made to dissociate therapeutic benefit from myelotoxicity, with the prototype substance being ciclosporine, a cyclic undecapeptide that was isolated from certain strains of Fungi imperfecti. Initial claims for a relative lack of marrow suppression at clinically effective doses were confirmed and this feature became the basis for its use in transplantation. The agent was subsequently successfully employed in managing a variety of autoimmune conditions, parasitic infections and more recently, at a molecular level, to modulate the behaviour of cytotoxic drugs in tumour cells. Not surprisingly, an extensive literature has accumulated and the present review describes the pharmacology and mechanisms of action as the basis for

Supported by the University of Cape Town Leukaemia Centre and Staff Research (Foote and Cancer) Fund, the Gwendoline Moore Trust, the Medical Research Council, the National Cancer Association, and the Michael Chanani, Kaliski and M.A. Richardson Bequests.
toxicity, which can be reduced by careful monitoring. The recommended practice is to adjust dosage based on whole blood levels to compensate for variable absorption from the gastrointestinal tract. This approach does not take into account the relative role of the parent substance as opposed to metabolites and represents a compromise since it is not known how best to directly measure the total suppressive effects on the immune system.

High performance liquid chromatography (HPLC) is a well established technique which measures individually the parent substance and the various metabolites. This can be automated so that many samples can be determined with accuracy and precision, although the cost is high. This method may have advantages where specific pharmacokinetic investigations are being carried out, particularly when liver function is compromised or following hepatic transplantation. Conversely, since nephrotoxicity occurs with some of the metabolites, measurement of all the immunologically related products is likely to be more relevant in this clinical setting.

Radioimmunoassay (RIA) has been widely developed for use with serum or whole blood. The correlation between these two methods is good, although with RIA values are 30% to 70% higher, attributable to the presence of cross-reacting metabolites. Given these circumstances, it is important to specify the technique used for dosage recommendation based on derived pharmacokinetic values. Furthermore, since a number of the metabolites have some immunosuppressive properties, RIA may also provide a better index of total functional activity for any given amount of ciclosporine administered. With this assay, therapeutic levels for renal transplantation were found to range between 200 and 800 ng/mL and for the prevention of GVT in bone marrow transplantation were above 250 ng/mL. Meticulous observation of renal function and appropriate dosage adjustment is needed should creatinine levels rise or clearance rates fall; flexible titration in dosage is preferable to fixed regimens.

Trough levels measured by RIA prior to the next dose correlate with serum creatinine, episodes of renal rejection, nephrotoxicity, seizures and hepatotoxicity in renal and bone marrow grafting.

Some of the earlier assays employed polyclonal antibodies, whereas the availability of a mouse monoclonal protein raised against the parent compound gives values which are comparable to HPLC in the limits of detection and sensitivity, with a correlation of variation equal to or less than 7% in a similar sample volume.

A point of practical importance is the recognition that ciclosporine reversibly binds to plastic material, such as indwelling catheters, and spurious increases in drug level may result when samples are taken from the same line through which the drug was administered. A different lumen or direct venepuncture may be important.

MECHANISM OF ACTION – IMMUNOLOGIC

The central molecular event in ciclosporine-mediated immunosuppression is inhibition of interleukin-2 (IL-2) production by the CD4 positive subset of T-lymphocytes, and this occurs in a dose-dependent manner. Additional actions are attributable to an effect on macrophages and T-independent B-cell functions. We have shown in vitro (Jacobs; unpublished) that ciclosporine significantly inhibits the incorporation of tritiated thymidine into T-enriched mononuclear cell populations.
toxicity, when cholesterol concentrations are reduced to below 3.1 mmol/L.\(^{17}\)

**METABOLISM**

Metabolism occurs mainly in the liver via the inducible cytochrome P-450 system, with prominent biliary excretion of both residual parent substance and degradation products. However, enterohepatic circulation is limited\(^{15}\) and less than 10% of the metabolites appear in the urine. During catabolism, structural modifications consist of mono- and di-hydroxylated derivatives, N-demethylation and intramolecular cyclization,\(^{18}\) although the primary analogues excreted are the monohydroxylated derivatives M17, M1 and the N-demethylated product M21.

In humans, ciclosporine is the main component found in plasma, amounting to approximately 50% of the total area under the concentration time curve.\(^{16}\) However, due to a preferential distribution of this product and its metabolites, whole blood levels are generally higher than plasma concentrations, but are accounted for by only 27% of the parent substance.\(^{19}\) It is now evident that an enteroocyte first-pass phenomenon exists, probably also via P-450 catabolism, and this may further account for individual variability or fluctuations that reflect bowel damage or altered function.\(^{20}\)

**DRUG INTERACTION**

Many drugs will influence the metabolism of ciclosporine through their action on the cytochrome system, notably, cimetidine, ketoconazole, erythromycin, the oral contraceptives, androgens, methylprednisolone and some calcium channel blockers, all of which increase blood levels by competition for common metabolic pathways. Conversely, certain antibiotics, such as rifampicin, phenobarbital, phenytoin, carbamazepine and valproate, induce the cytochrome system, thereby decreasing the effective levels of this immunosuppressive agent.

**ELIMINATION**

Plasma clearance is tri-exponential, with half lives of 0.1, 1.1 and 16 hours\(^{15}\) and, in the steady state, systemic clearance is 6.5 mL/min/kg, with substantial inter-individual variation.\(^{21}\) This value is inversely related to the volume of distribution and age, being most significant under 10 years,\(^{22}\) with a 40% greater clearance, and children therefore require more frequent and higher doses. A similar finding is seen in bone marrow transplant recipients in comparison to solid organ grafts, where a lesser amount of drug is needed, with the difference being explicable on lower haematocrits in the former group, since red cells provide important ligands for ciclosporine binding.\(^{22}\) Conversely, clearance is slower in the elderly and in patients with decreased lipoprotein concentration and liver dysfunction.\(^{23}\)

**THERAPEUTIC MONITORING**

Although ciclosporine is an effective immunosuppressive agent, it has significant
toxicity, which can be reduced by careful monitoring. The recommended practice is to adjust dosage based on whole blood levels to compensate for variable absorption from the gastrointestinal tract. This approach does not take into account the relative role of the parent substance as opposed to metabolites and represents a compromise since it is not known how best to directly measure the total suppressive effects on the immune system.

High performance liquid chromatography (HPLC) is a well established technique which measures individually the parent substance and the various metabolites. This can be automated so that many samples can be determined with accuracy and precision, although the cost is high.24 This method may have advantages where specific pharmacokinetic investigations are being carried out, particularly when liver function is compromised or following hepatic transplantation. Conversely, since nephrotoxicity occurs with some of the metabolites, measurement of all the immunologically related products is likely to be more relevant in this clinical setting.25

Radioimmunoassay (RIA) has been widely developed for use with serum or whole blood.26,27 The correlation between these two methods is good, although with RIA values are 30% to 70% higher, attributable to the presence of cross-reacting metabolites. Given these circumstances, it is important to specify the technique used for dosage recommendation based on derived pharmacokinetic values. Furthermore, since a number of the metabolites have some immunosuppressive properties, RIA may also provide a better index of total functional activity for any given amount of ciclosporine administered. With this assay, therapeutic levels for renal transplantation were found to range between 200 and 800 ng/mL and for the prevention of GVHD in bone marrow transplantation were above 250 ng/mL.28 Metabolic observation of renal function and appropriate dosage adjustment is needed should creatinine levels rise or clearance rates fall; flexible titration in dosage is preferable to fixed regimens.

Trough levels measured by RIA prior to the next dose correlate with serum creatinine, episodes of renal rejection, nephrotoxicity, seizures and hepatotoxicity in renal and bone marrow grafting.29,30

Some of the earlier assays26,27 employed polyclonal antibodies, whereas the availability of a mouse monoclonal protein raised against the parent compound gives values which are comparable to HPLC in the limits of detection and sensitivity, with a correlation of variation equal to or less than 7% in a similar sample volume.31,32

A point of practical importance is the recognition that ciclosporine reversibly binds to plastic material, such as indwelling catheters, and spurious increases in drug level may result when samples are taken from the same line through which the drug was administered. A different lumen or direct venepuncture may be important.33,34

MECHANISM OF ACTION – IMMUNOLOGIC

The central molecular event in ciclosporine-mediated immunosuppression is inhibition of interleukin-2 (IL-2) production by the CD4 positive subset of T-lymphocytes, and this occurs in a dose-dependent manner. Additional actions are attributable to an effect on macrophages35 and T-independent B-cell functions.36 We have shown in vitro (Jacobs; unpublished) that ciclosporine significantly inhibits the incorporation of tritiated thymidine into T-enriched mononuclear cell populations
stimulated by mitogens and is efficient in the mixed lymphocyte reaction at concentrations as low as 100 ng/mL; this is a level that falls within the clinically therapeutic range. Furthermore, in our studies, this function was shown to be dependent on the presence of the agent from the beginning of the culture and at adequate concentrations, whereas its later addition had virtually no effect on DNA synthesis. The reversible impairment of IL-2 production extends to other lymphokines, including gamma interferon and interleukin-4 due to down-regulation of m-RNA transcription within the CD4 lymphocyte population. Interestingly, there does not appear to be concurrent inhibition of clonal proliferation in response to exogenous IL-2 by cells expressing receptors for this specific cytokine. Ciclosporine acts on cytotoxic T-lymphocytes indirectly by decreasing the IL-2-dependent proliferative responses and may also inhibit the precursor cytotoxic cells from acquiring or, more likely, down-regulating receptors. It has been shown that suppressor T-cell activities are relatively resistant to its action and, therefore, while the final molecular or cellular pathway remains to be elucidated, it might reasonably be speculated that imbalance between the unresponsive helper and the unrestrained suppressor functions accounts for the unique immunosuppressive activity of this substance.

When these molecular events are examined in the intact cell, a clear sequence emerges in which ciclosporine appears to diffuse into the liquid crystalline phase through the cell membrane, with recognisable consequences at a number of different levels. Thus, in the cytosol, interaction occurs between two calcium-dependent enzymatic complexes in the form of calmodulin and cyclophilin. Both of these have the protein-kinase activity that is known to be involved in signal transduction to the nucleus, leading to DNA synthesis, that initiates cell division in resting lymphocytes. In vitro studies have defined binding with a higher affinity for cyclophilin at 10.9 KD, leading to inhibition of the associated transcriptional pathway shared by most lymphokine genes in a dose-dependent manner. Ciclosporine selectively and in a linear fashion inhibits incorporation of tritiated thymidine by the isolated lymphoid nuclei, but this phenomenon occurs independently of blood concentrations. This represents another site of action, leading to direct modulation of lymphokine gene regulators, with inhibition of transcription of early phase T-cell activation genes (IL2, IL3, IL4, IFNalpha, TNF, GM-CSF and c-myc oncogene) that are essential for lymphocyte growth and differentiation. In contrast, this agent appears to directly interrupt the cell cycle at the G1-S interface, although once genes have been activated, the ciclosporine has no effect on sequential events.

The combination of these various molecular processes results in this substance exerting a significant influence on the thymus by decreasing the number of thymocytes indirectly through inhibition of lymphokine-induced maturation and directly by arresting the maturation of cells expressing the α and β T-cell receptors. The disruption of self-recognition facilitates the survival of precursors for autoreactive clones and possibly the acceptance of foreign grafts; withdrawal of the agent may then precipitate T-cell mediated autoimmune responses and so explain the development of GVHD after drug discontinuation in patients undergoing allogeneic bone marrow transplantation. Ciclosporine does not inhibit monocyte phagocytic functions directly, either in vitro or in vivo, but markedly disrupts the lymphokine-dependent T-cell lymphocyte macrophage interaction for the expansion of the immune response. At higher doses,
antigen presentation by macrophages seems to be directly affected, probably through associated prostaglandin E2 (PGE2) release.\textsuperscript{46}

**MECHANISMS OF ACTION – NON-IMMUNOLOGIC**

In a patient with lymphoblastic leukaemia (ALL), the concomitant administration of etoposide and cyclosporine resulted in the eradication of a previously refractory malignant infiltration of the bone marrow.\textsuperscript{47} In vitro studies seem to support at least two mechanisms for such a reversal of resistance to cytotoxics. In a pleotropic drug resistant subline of T-ALL, cyclosporine reversed the primary refractoriness to vincristine and daunorubicin, but had little activity in the drug sensitive paternal line. This action was unrelated to changes in the daunorubicin accumulation.\textsuperscript{48} Follow-up studies revealed that in a way similar to verapamil, cyclosporine restored the membrane potential of the resistant cells to those characteristic of the parent drug-sensitive tumour line.\textsuperscript{49}

In the multidrug resistant P388 cell line, this undecapeptide and some of its metabolites, in a dose-dependent fashion seems to increase the intracellular accumulation of the anthracycline, leading to a complete restoration of the chemotherapeutic response to this cytotoxic agent. The mechanism in this case seems to involve competition for an outward drug transport system that operates in the multidrug resistant cells.\textsuperscript{50} Although both verapamil and cyclosporine appear to be effective in overcoming drug resistance in malignant cells, evidence shows that cyclosporine\textsuperscript{46} is able to do this at clinically acceptable drug levels in the serum, with verapamil leading to unacceptable toxicity. This action appears to be compounded by a combination of these agents.\textsuperscript{50,51,52}

**CLINICAL STUDIES**

The in vitro observations have been applied increasingly to clinical practice and in each example animal experimentation has played a prominent role although, as experience has accumulated, some parallels as well as substantial differences between species have emerged.

**BONE MARROW TRANSPLANTATION**

These procedures have become firmly established as treatment options in aplastic anaemia, severe combined immunodeficiency, the acute and chronic leukaeamias and genetic disorders, including thalassaemia.

Three unresolved problems are, firstly, relapse with the haematologic malignancies, secondly, graft rejection despite careful matching and intense immunosuppressive conditioning regimens, and, thirdly, the emergence of reverse rejection or GVHD. In this latter situation, immunocompetent cells from the donor graft recognise antigenic disparity with the recipient and initiate firstly acute and then a chronic inflammatory response directed against target cells in the skin, mucosa of the gastrointestinal tract and biliary endothelium.\textsuperscript{53} Experiments in a mouse model showed that haematopoietic and lymphorcticular reconstitution followed infusion of
incompatible spleen cells and the emergence of GVHD was delayed after ciclosporine administration. In rats, this agent favoured the development of specific tolerance between donor and recipient. Our own studies in rabbits showed not only an improved survival, but a decrease in histologically proven GVHD in animals receiving this agent. Similar results have been reported by others. In extensive studies in dogs a high graft failure occurred among ciclosporine-treated animals, and although no deaths appeared to be directly related to GVHD, long-term tolerance was not induced. Subsequently, it was noted that methotrexate in combination with ciclosporine overcame the failure to engraft, with establishment of long-term effective haematopoiesis.

This experience with ciclosporine in allogeneic bone marrow transplantation is of interest, but none of the schedules reported under experimental circumstances uniformly abrogate GVHD, although incidence and severity appear to be favourably influenced.

Clinically it has been demonstrated that the cutaneous manifestations of established GVHD benefit in the short-term following ciclosporine administration. When this agent was given prophylactically for 14 to 48 weeks after grafting, a favourable outcome was documented, but in a proportion of patients GVHD followed its withdrawal.

In two prospective randomised trials conducted at the University of Washington comparing ciclosporine to methotrexate prophylaxis for GVHD in patients with acute nonlymphoblastic leukaemia (ANLL) in first remission and chronic myeloid leukaemia (CML) in the chronic phase, no significant difference was found regarding the incidence of acute GVHD or survival. However, patients receiving ciclosporine had a faster marrow engraftment, less mucositis and required fewer platelet transfusions. The disadvantages consisted of nephrotoxicity, tremors and hypertension. At follow-up between 3.2 and 6.2 years, both agents were seen to be comparable regarding the probability of survival, death from GVHD, incidence of interstitial pneumonitis, leukemic relapse and long-term survival.

Similar conclusions were reached by a Nordic controlled study regarding prevention of significant GVHD, although engraftment was faster, but in the subsequent report a significant increase in the leukaemic relapse rates in the ciclosporine group was found. Long-term survival and performance scores were similar in both groups.

A prospective Australian study showed comparable results, where relapse rates from leukaemia were found to be significantly higher in the ciclosporine group, and although survival was reduced, this was not significant. In a retrospective analysis involving 2036 recipients of HLA matched sibling bone marrow for acute leukaemia and aplastic anaemia, both ciclosporine and methotrexate were equally effective at preventing GVHD and superior to no prophylaxis. Sex disparity of female donors to male recipients was the most significant factor associated with acute GVHD.

In a further predictive analysis of risk factors for grade II–IV acute GVHD, the Seattle group demonstrated a reduction of this complication for every 100 ng/mL rise in the trough serum ciclosporine concentration of the previous week. The risk was 1.0, 0.6 and 0.2 for blood concentration of less than 100, 100 to 199, and 200 or more ng/mL of this immunosuppressive agent. However, due to the wide overlap in the ciclosporine serum levels, decreased readings had little predictive value for individual patients.

Acute GVHD proved to be the most significant factor for the development of the chronic variety of this phenomenon. The latter was also associated with a decreased
survival, and patients treated with either ciclosporine or methotrexate seemed to have a favourable outcome.

These studies have confirmed the value of ciclosporine as an effective agent in human bone marrow transplantation. Compared to methotrexate it had the advantages of faster engraftment and less mucositis, but was associated with frequent renal dysfunction, requiring blood level monitoring. The incidence and severity of acute GVHD had not been altered though, and there has emerged a rise in the leukemic relapses.

Following work on the canine model,60 the Seattle group conducted two randomised studies. In aplastic anaemia, standard methotrexate was less efficient than its combination with ciclosporine in preventing grade II–IV acute GVHD which did so without impairing sustained engraftment. However, chronic GVHD was increased when both drugs were used together. A possible explanation for this finding is that prevention of the initial mortality from the acute variant may have left a larger population at risk for development of this chronic complication.70-73 In ANLL,74 this combination was again superior to ciclosporine alone, with improvement in early survival and without a significant increase in the early relapse rate. Follow-up studies have shown that leukemic recurrence is adversely affected.73 Grade IV of this immune phenomenon was not observed in the combination group, whereas it arose in 29% when the agents were used singly.

Further analysis of patients transplanted for leukaemia showed that disease-free survival had been significantly better with the combination of methotrexate and ciclosporine in comparison to ciclosporine alone.73 Thus, when ciclosporine is combined with methotrexate for GVHD prophylaxis, three observations emerge. Firstly, the acute disease is reduced, with an improvement in the early mortality. Secondly, the chronic variant appears as a de novo phenomenon instead of evolving progressively from the acute changes. Thirdly, the latter developed after the withdrawal of the drug. It might therefore be of interest to extend the period of immunosuppression from 6 months to one year or longer, as is customary in solid organ transplantation.74 This was initially suggested by Baigalupo75 and recently reported by a Nordic group, confirming additional reduction in chronic GVHD.76

The inclusion of other agents to this combination has provided conflicting results. When prednisolone with ciclosporine was retrospectively compared to the same drugs individually or with additional methotrexate at a reduced dose, a protective effect was obtained against significant GVHD without obvious increase in the relapse rate.77 However, in a prospective study by the Seattle group this combination did not improve survival over the standard two-agent prophylaxis and, paradoxically, an increase in the incidence of GVHD was reported in the group receiving corticosteroid with infusion of the graft.78

Chronic GVHD, characterised by intrinsic immunosuppressive effects and the emergence of autoimmune phenomena, has been correlated with a protective effect from leukemic relapse, giving rise to the term graft-versus-leukaemia (GVL).79 This observation has been more clearly defined in animal models, but controversy persists as to whether the mechanisms for GVHD and GVL are identical. There are suggestions that when careful immunophenotypic studies are carried out, subtle differences in the composition of T-cell populations characterise the two immunologic phenomena.80

The ex vivo purging of lymphocytes from the bone marrow unequivocally reduces
the incidence of acute and chronic GVHD,\(^\text{81}\) and in a recent study use of the monoclonal antibody, Campath IgG 2b virtually abolishes this phenomenon.\(^\text{82}\) However, at least in some studies, an increase in leukaemic relapses have been reported,\(^\text{83}\) most strikingly in patients with chronic granulocytic leukaemia (CGL).\(^\text{84}\) There is the opinion that effective immunosuppression with ciclosporine-containing combinations may also lead to leukaemic relapse comparable to that associated with T-cell depletion (Personal communication: R Clift). It is nevertheless of interest that in CGL leukaemic recurrences form T-cell depleted grafts can be rescued by unfractionated second transplants without the need for intense preconditioning and when this is followed by standard ciclosporine and methotrexate prophylaxis for GVHD, substantial relapse-free survival is possible.\(^\text{85}\) This data and the evidence that even donor lymphocytes may reverse the relapse of a T-cell depleted graft point to GVL having a prominent effect in the control of the disease.\(^\text{86}\)

This issue is at present unresolved, and the challenge remains to determine precisely any distinction that may exist in the population of lymphocytes responsible for the two immunological syndromes. In the meantime, clinical trials in combination with appropriately designed laboratory studies should seek to clearly segregate the effects of ex vivo manipulation of grafts by means of monoclonal antibodies, either singly\(^\text{87}\) or as a cocktail. This should then be compared, in a controlled fashion, to other modalities, looking at the emergence of GVHD or GVL in matched groups of patients receiving unfractionated marrow grafts. Effective post-transplantation immunosuppression should be achieved with agents that on the one hand successfully abrogate the secondary disease and on the other retain the desired protective effects against leukaemic relapse.

SYNGENEIC GRAFT-VERSUS-HOST DISEASE

The conditions required for GVHD reactivity were postulated 20 years ago by Billingham\(^\text{88}\) and included three essential criteria: genetically determined histocompatibility differences between donor and recipient, immunocompetent cells in the graft capable of mounting an immune reaction against foreign histocompatibility antigens of the host and the inability of the host to recognise and initiate an immune response against the graft. GVHD has been reported after identical twin transplantations\(^\text{88}\), but this reactivity was limited to three weeks only, with resolution of all manifestation by 28 days. A similar condition has also been described following autologous bone marrow transplantation in 8% of cases.\(^\text{89}\)

Animal studies demonstrated that GVHD can be consistently induced after syngeneic grafting following lethal irradiation and withdrawal of ciclosporine. This phenomenon would start after a week, with typical manifestation in the skin, gut and liver.\(^\text{90}\) There was a rapid progression to the chronic variety within a week, with the usual histologic features.

Immune phenotyping studies in the acute variety revealed infiltration of target tissues with immature thymocytes. In the chronic form, both immature and mature T-cells were present.\(^\text{91}\) Since syngeneic GVHD seemed to confer a protective effect from malignant recurrence, as determined in an animal model,\(^\text{92}\) a pilot study was undertaken to deliberately induce this syndrome in a group of subjects undergoing marrow transplantation for resistant malignancies.\(^\text{93}\) Although all four developed this complication, only two required immunosuppressive therapy. It remains to be
determined if a corresponding effect can also be directed at solid tumours and, if so, can it then be applied to individuals with poor prognosis malignancies?  

APLASTIC ANAEMIA

Soon after the initial trials of bone marrow transplantation for aplastic anaemia were performed it was observed that when patients were conditioned with cyclophosphamide a proportion of individuals rejected the infused marrow and autologous recovery of the haemopoiesis would follow. Based on the observation in vitro that in aplasia immune mechanisms may suppress haematopoiesis, a number of studies demonstrated the effectiveness of high-dose methylprednisolone, antilymphocyte globulin and ciclosporine. However, since monoclonal antibodies against T-cells have proven to be ineffective in this disease, the exact mechanism for the action of ciclosporine remains to be established. Antilymphocyte globulin is an impure protein and, in vitro, displays both suppressive and stimulatory activities. A theoretical interaction between these two opposing actions may explain the observed responses.

In two prospective trials comparing this agent to antilymphocyte globulin, both were found to be equally effective in the acute phase and useful as salvage therapy in those unresponsive to the immunoglobulin preparation. Responses seem to be more rapid if corticosteroids or other immunosuppressive drugs are employed in combination with ciclosporine, but in some this outcome will not be sustained. Patients with granulocyte counts below \(0.2 \times 10^9/L\) generally derive less benefit from this form of therapy and similarly for treatment with antilymphocyte globulin. A recent controlled study has suggested that the addition of ciclosporine to an antilymphocyte globulin and prednisone-containing regimen is most effective in this severe category. However, the outcome of patients in the ALG arm was less good when compared to data from other series, leaving unclarified the role of the fungal agent in these patients, particularly when doses of ALG exceed 100 mg/kg.

PURE RED CELL APLASIA (PRCA)

A variety of immunosuppressive manipulations have been shown to be effective in this disorder of the red cell precursors, including cytotoxic agents, splenectomy, corticosteroids, antilymphocyte globulin and high dose gammaglobulin in fusion.

Ciclosporine is also active in the primary variant, when used alone or in combination with corticosteroids; in a subgroup, maintenance therapy may, however, be necessary to sustain improvements in erythropoiesis. When this condition is associated with chronic lymphoid leukemia or the Diamond Blackfan syndrome, good responses were achieved, even when patients were insensitive to steroids. Due to the rarity of the disease, this collective experience is based on retrospective studies and case reports. As a result, no dependable recommendation can be made for its use in these patients.
OTHER IMMUNE HAEMATOLOGIC DISORDERS

Immunologically mediated cytopenias may be the result of disturbances in either cellular mechanisms or by the elaboration of specific antibodies, which may then be detected on cell surfaces and exemplified by neutrophil or antiplatelet antibodies.\(^{118}\) Thus, in thrombocytopenic purpura (ITP) the conventional treatment is the use of immunosuppression with corticosteroids. In treatment failures, splenectomy has a high salvage rate and in a small number of relapses cytotoxic drugs will be effective in approximately 60% of patients.\(^{119}\) Of interest are those individuals who remain symptomatic following the failure of conventional treatment, and here innovative approaches are appropriate. In several case reports\(^{120-122}\) ciclosporine has resulted in improving platelet counts, although long-term maintenance of therapeutic blood levels of the agent is needed. In this context, the high cost of ciclosporine needs to be balanced against the indications for therapy in these patients, many of whom are asymptomatic or with platelet counts that are not life-threatening. In those who have developed refractoriness to platelet transfusions by isoinmunisation, ciclosporine has been shown to decrease the antibody concentration on cell surface, related to changes in the CD4 to CD8 lymphocyte ratios,\(^{123}\) leading to improvement in transfused platelet counts.

Other anecdotal reports have suggested response in immune neutropenia, associated with large granular lymphocytes,\(^{124,125}\) in adult onset cyclic neutropenia,\(^{126}\) or in Felty’s syndrome.\(^{127}\) In all these situations the same caveats apply to the use of expensive and potentially toxic agents on the basis of minimal information and, in the absence of properly controlled prospective studies, routine use cannot be recommended. In haemophiliac patients who have acquired antibodies to factor VIII, particularly in those refractory to the combination of plasma exchange, corticosteroids and cytotoxic immunosuppression therapy, there are intriguing suggestions that ciclosporine may have a role to play,\(^{128}\) but here again the need for protracted maintenance therapy would suggest a more balanced approach.

TOXICITY

Acute and chronic toxicity has been documented in many animal models over a wide range of oral and parenteral administration schedules. Nephrotoxicity is by far the most frequent side effect and has been described in autoimmune disorders where kidneys are apparently quite normal.\(^{129}\) Of greater importance, however, are the effects observed when ciclosporine is administered to patients undergoing bone marrow transplantation after intense preconditioning. Here, animal studies\(^{130}\) and case reports support the observation that cyclophosphamide and total body irradiation can induce renal damage at the clinically employed doses.\(^{131,132}\) The histological findings included mesangiolysis, severe arteriolonecrosis, hyalinization, luminal proliferation and thrombosis, with these changes evolving over several weeks.

Further compounding the picture is the fact that febrile patients concurrently receive several nephrotoxic drugs, including aminoglycoside antibiotics and loop-acting diuretics, thus rendering incrimination of purely ciclosporine related renal dysfunction notoriously difficult. Acute toxicity is frequently associated with elevated ciclosporine serum levels, but in most instances biochemical tests of renal
dysfunction are reversible upon reduction of the dose or discontinuation of the treatment. On the other hand, and in our experience, renal function was significantly disturbed when this agent was given over prolonged periods of time, despite meticulous monitoring of blood levels.

Clinical experience shows that in normal individuals, within four weeks of initiating therapy, a proportion will develop elevations in serum creatinine concentration, body weight and systemic blood pressure together with functional alteration of the intrarenal haemodynamics.

Bolus injections of this agent to rats induce similar changes, associated with catecholamine release and increase in the vascular resistance, leading to the suggestion that continuous infusion over 4 to 24 hours reduces these side effects. Tubular dysfunction due to ciclosporine toxicity causes impairment in the secretion of urea, reduced excretion of sodium, potassium, phosphate, bicarbonate reabsorption and hyperchloremic acidosis. Hypomagnesemia and renal magnesium wasting have been found, with significant hypertension, and were unrelated to ciclosporine blood levels, but both this agent and corticosteroid administration have been implicated. Replacement of magnesium may be of significant value in the management of blood pressure raised under these circumstances.

Although drug levels may not be predictive for the individual patients developing GVHD or renal toxicity, levels above 250 ng/mL generally correlate with renal dysfunction. Patients having undergone grafting and reasessed after 6 months of ciclosporine immunosuppression showed abnormal renal functions but when again examined at 1 year, 6 months after stopping this treatment, this had reverted to pretreatment values. However, experience in solid organ transplantation indicates that 10% of those exposed to this agent for prolonged periods (±10 years) may nevertheless develop irreversible renal damage.

Renal impairment with red cell fragmentation frequently seems to be related to GVHD and ciclosporine prophylaxis, but infrequently with methotrexate. Features of disseminated intravascular coagulation have also been described and reversal has followed reduction of the ciclosporine dose. The microangiopathy may be severe, but the histologic picture differs from that of classic haemolytic uremic syndrome or thrombotic thrombocytopenic purpura.

Hepatotoxicity is characterised by rising bilirubin, and in our experience of individuals undergoing allogeneic bone marrow transplantation two points emerged. The altered biochemistry rarely occurred in the absence of prior disturbances in renal function and adjustment of ciclosporine dose led to a rapid reversal in the bilirubin levels. Studies in animals showed the histologic picture to be that of centrilobular fatty change, hepatocyte necrosis with numerous autophagic vacuoles, and a dilated endoplasmic reticulum. Chronic drug administration induced hepatic dysfunction associated with an increased incidence of cholelithiasis.

In a large proportion of patients a marked increase in the serum triglycerides levels was described, without obvious evidence of liver abnormalities. Interestingly, however, one case that became symptomatic with visual and neurologic abnormalities reversed only with emergency plasmapheresis.

Although ciclosporine is not believed to cross the intact blood brain barrier, neurologic side effects are common. The most frequent are tremors and painful acral paresthesias. Occasionally, convulsions and confusional status have been described. Rare serious complications such as motor, cord and cerebellar syndromes arise, but reverse after discontinuation of the drug. On CT scanning this neurotoxicity
CICLOSPORINE IN HAEMATOLOGY

seemed to be associated with enhanced water content in the brain\cite{9}, as demonstrated by densimetric measurements.

Miscellaneous side effects have been extensively described and include hypertrichosis, increased incidence of infection, gingival hyperplasia, anorexia, nausea and vomiting.\cite{1146}

CONCLUSIONS

Ciclosporine has been shown to be an effective immunosuppressive agent and research into its unique mechanism of action has helped to understand many of the intricate pathways in the immune response. In haematologic practice the main use is in bone marrow transplantation. Here, its benefits have been enhanced by combination with other agents, such as corticosteroids or methotrexate, particularly in reducing the severity of acute GVHD. However, in some circumstances this appears to be offset by increasing leukaemic relapses and it therefore remains to determine its role in comparison to alternative options, that include in vivo T-cell depletion and ex vivo manipulation of the graft by exposure to a growing range of monoclonal antibodies. In aplastic anaemia, survival approaches that achieved with antilymphocyte globulin and additionally may salvage antilymphocyte globulin resistant patients. However, the quality of haematopoiesis differs from that achieved with transplantation in that response rates with the immunomodulation are less stable and there is an increase in incidence of clonal diseases that includes paroxysmal nocturnal haemoglobinuria, myelodysplasia and leukaemia being reported.

Other clinical studies have been largely anecdotal and suggest that in a variety of blood dyscrasias thought to have an immunological component, some improvement is possible in response to ciclosporine administration. Currently, data from prospective controlled studies are unavailable and until these are carried out, the use of this agent in patients with immune thrombocytopenia or pure red cell aplasia will be largely determined by individual preference.

Similarly, in malignancies the concomitant prescription of ciclosporine with some of the cytotoxic agents suggests that acquired drug resistance may be decreased and trials using this approach in myeloma and acute leukaemia are needed to confirm its practicality.

Although ciclosporine is widely used, its attraction is offset by its unquestioned toxicity, even when blood levels are meticulously monitored. Therefore, the immediate issue to be resolved is the detailed mechanism by which it exerts these side effects so that the best balance can be achieved between safety and the desired immunosuppressive effects.

Rationale and Influence of Cyclosporin A Donor Pretreatment

Peter Jacobs

Groote Schuur Hospital
Cape Town, Republic of South Africa

I. INTRODUCTION

Allogeneic bone marrow transplantation is the preferred form of treatment for aplastic anemia (1), lethal immunodeficiency and storage diseases (2), as well as acute (3,4) and chronic granulocytic leukemia (5). The initial, and often less than critical, enthusiasm for this procedure has been tempered by recognizing that substantial morbidity and mortality occur, with much of this attributable to GVHD. Paradoxically, since this latter unique immunologic entity may be associated with a beneficial antileukemic effect (6), attempts are being made to define its direct role, segregate associated but distinct mononuclear cell mechanisms, and then to harness and direct the way in which the specific effect or mechanism can be employed. Selective removal or functional impairment of subpopulations within the lymphocyte and monocyte fraction contained in the graft may vary cytolytic destruction of the skin, gastrointestinal tract, and biliary endothelium, while concurrently favoring the emergence of tolerance and varying degrees of immunologic reconstitution.

The basis for understanding these problems resides in a sequence of events that was recognized and described more than 30 years ago as the graft-vs-host reaction (GVHR) (7-9), in which three essential components have been delineated. First, the host must be incapable of rejecting the foreign bone marrow; second, a degree of histoincompatibility must exist between donor and recipient; and third, the infused graft must be immunologically competent and contain T lymphocytes. There is evidence that the effects of T lymphocytes are mediated by cytokines (10-14), and conceivably GVHD can serve as a model for autoimmune diseases (15-17).

In the context of bone marrow transplantation, each of the three steps mediating GVHR is amenable to manipulation.

First, there is little difficulty in achieving a high percentage of graft acceptance. Generally transplant recipients are prepared by immunosuppressive chemotherapy alone
or in combination with irradiation. Cyclosporin A, especially if used in combination with methotrexate, may have a graft-facilitating effect (18).

Second, absolute histocompatibility between donor and recipient should theoretically preclude the development of GVHD. However, and apparently in defiance of classical transplantation dogmas, this entity may follow syngeneic (19) or autologous grafting (20). One explanation is that the conditioning regimens to which the recipient is exposed may bring about an imbalance between autoreactive lymphocytes and suppressor cells, and studies from humans and rodents support this concept (12). Among HLA-identical allogeneic transplant recipients, 30% to 50% develop GVHD (21).

Third, the composition of the graft can be modified to facilitate hematopoietic reconstitution and simultaneously to modulate the mononuclear cells mediating the immune response. This can be achieved in two different ways. Effector cells may be quantitatively impaired by ex vivo purging with a single monoclonal antibody, such as Cam- path-1 (22) or a cocktail (23), both of which may be directed against a relatively wide range of cells. Conversely, it may be more rational to select biological reagents that selectively remove the helper-inducer as opposed to the helper-suppressor subsets (24,25). However, there may be retarded immunologic recovery, leaving recipients susceptible to infection or recurrence of neoplastic disease (26). Accordingly, it is attractive to consider the alternative approach in which the entire spectrum of mononuclear cells in the graft is infused, but a qualitative or functional lesion is produced, the intensity of which can be titrated to damp down the emergence of GVHD, permitting the development of tolerance. One agent that can potentially function in this way is cyclosporin A. In bone marrow transplantation it has been employed with relatively limited success as the sole postgraft means of treating the recipient. Virtually no data are available on ex vivo incubation with the collected marrow. Alternatively, it can be used to pre-treat the donor and the recipient, with subsequent reduction in dose to achieve the desired effect in the latter.

The present studies were aimed at establishing the feasibility of the latter approach in preventing acute GVHD and, concurrently, to document any risk to the donor of short-term exposure to this agent.

II. CYCLOSPORIN A

Cyclosporin A was discovered in early 1972 in the Research Laboratories of Sandoz Ltd in Basel. It is a hydrophobic cyclic peptide consisting of 11 amino acids with a molecular weight of 1203. The active compound is a fungal metabolite derived from cultures of Cylindrocarpon lucidum or Trichoderma polysporum (27). This agent has recently been extensively reviewed (28,29).

Available evidence localizes the action of cyclosporin A to the inductive phase of response in the immunocompetent cells as they encounter antigenic challenge. Cell division, by way of contrast, does not appear to be affected and, furthermore, no lymphocytoxic effects are demonstrable. The reduction of lymphoblast numbers, which may be striking in vitro, probably reflects prevention of stimulation rather than elimination of blast cells by cytolytic mechanisms (30). Expressed in another way, the primary effect of this agent is directed against the earliest cellular events in the lymphocyte that follow mitogenic stimulation and finds expression by preventing transformation into the blast cell.

Cyclosporin A does not in all models lead to selective clonal deletion, but rather to the induction of a temporary suppressive state that is reversible when treatment is termi-
nated (31,32). The availability of monoclonal antibodies may help resolve this difficulty. For example, CD4\(^+\) T lymphocytes are now divisible into helper-suppressor, or CD4\(^+\)2H4\(^+\), in contrast to helper-inducer, or CD4\(^+\)4B4\(^+\), subpopulations (24,25).

III. EXPERIMENTAL STUDIES

A. Rabbits

New Zealand white (NZW) and R strain animals, having an average weight of 2 kg, were used throughout. They were individually housed and received an unrestricted supply of water, containing prophylactic sulphaquinoxaline sodium (Embasin, May and Baker, Dagenham, England), and a standard rabbit diet (Epol, Johannesburg) medicated with Amprolium (Merck and Company, Inc., USA). Temperature and weight were regularly charted. A full blood count and differential were carried out twice weekly. The biochemical profile was monitored regularly.

B. Radiation Technique

The rabbits were rendered aplastic by delivering 1200 cGy total body irradiation from a cobalt source placed 100 cm above the midplane of the prone but anesthetized animal. Radiation rates between 40 and 80 cGy/min were shown not to differ significantly. We have previously demonstrated (33) that uniform and irreversible aplasia is produced without unacceptable complications. Specifically, no gastrointestinal tract lesions were demonstrated. Furthermore, there was no difference between this technique and fractionating the radiotherapy, as suggested by others (34,35). In occasional animals unexplained death occurred within 24 hours after radiotherapy, ascribed to "radiation shock." In another series of experiments the alternative radiation dose rate at 8 cGy/min was examined, but this regimen was not found to be associated with less toxicity than the more rapid exposures.

In a series of controlled experiments, one or both of the femurs were shielded with lead, and in another group autologous reconstitution was undertaken to monitor both optimal rates of hematopoietic recovery and isolate possible complications of the radiotherapy and transplantation procedure itself.

C. Allogeneic Bone Marrow Transplantation

Thirty-six hours after completing lethal whole body irradiation, the animals underwent allogeneic bone marrow transplantation. Between 2 and 4 \(4 \times 10^8\) nucleated cells per kilogram were infused from R females into NZW males. Standard mixed lymphocyte cultures (36) to demonstrate nonidentity at the major histocompatibility complex were not uniformly successful. However, using a modified technique (37), antigenic disparity was demonstrated between the two strains; this was most striking when mitomycin-treated lymphocytes derived from the mesenteric lymph node were used as antigen and appendixal lymphocytes as responding or target cells. Results at day 3 gave stimulation indices between 3.5 and 13.9. Even the latter technique does not produce absolutely uniform results, and we have subsequently demonstrated that mixed lymphocyte reaction, with minor modifications, can reliably predict histoincompatibility (Jacobs and Paulsen, unpublished).
D. Cyclosporin A Administration

Rabbits were given 10 mg/kg daily of cyclosporin A by intramuscular injection for 28 days following transplantation. Plasma levels were monitored by high-pressure liquid chromatography.

E. Results

1. Radiation Controls

Irradiated animals developed increasing pancytopenia, with platelet and granulocyte counts reaching their nadir between days 4 and 6 (Fig. 1), and all the rabbits died. Median survival (Fig. 2) was 6.8 days (SE ± 0.08; range 2-11 days).

Autopsy studies at intervals showed rapidly decreasing bone marrow cellularity, and death was uniformly due to infection, with widespread colonies of bacteria present in all organs. Minimal associated hemorrhage was present in the gastrointestinal tract of occasional rabbits. There was profound loss of lymphoid tissue throughout the gut, thymus and spleen (38).

2. Femoral Shielding and Autograft Rescue

In animals having one or both femora shielded, reduction in white cell and platelet counts were comparable to those observed in radiation controls, but peripheral values returned rapidly to reach normal by day 21 (Fig. 1). The bone marrow, when studied serially, showed clonal regeneration of the previously aplastic medullary spaces, and histology was normal by day 30.

In the autografted animals who received $2 - 4 \times 10^8$ nucleated cells/kg, peripheral blood values were indistinguishable from those observed with femoral shielding (Fig. 1). Median survival (Fig. 2) was not reached at any time during this study, and only an occasional death occurred.

![Graph](image_url)

**Figure 1** Peripheral blood granulocyte and platelet count. The fall in circulating levels and their subsequent return to normal is not statistically different in the three groups of animals. Data are expressed as a percentage of mean basal values and plotted against elapsed time in days. (Reproduced with permission of the Editors and Publishers of Experimental Hematology Today 1981, S. Karger AG, Basel.)
Cyclosporin A Donor Pretreatment

![Graph showing survival rates](image)

**Figure 2** Observed survival in rabbit experimental studies. The median survival for irradiated controls was 6.8 days. Following allogeneic bone marrow transplantation without immunosuppressive agents, survival was 15 days and none were alive at 100 days, whereas in allografted animals receiving cyclosporin A, median survival was 40 days and 33% were alive and well at 100 days. The incidence of histologically proven GVHD in the allografted controls was 80% and in the cyclosporin A-treated animal this was below 25%. (Reproduced with permission of the Editors and Publishers of Experimental Hematology Today 1981, S. Karger AG, Basel.)

Anemia aggravated by repeated blood sampling was prevented by the use of microtechniques. In these animals, as opposed to radiation controls, daily oral prophylaxis with 10 ml trimethoprim combined with 50 mg sulphamethoxazole decreased deaths from infectious episodes and is routine practice in the animal transplantation program.

3. **Allogeneic Bone Marrow Transplantation**

In the allograft controls 2-4 × 10^8 nucleated cells/kg resulted in granulocyte and platelet reconstitution patterns in the peripheral blood that was comparable to that demonstrated by animals undergoing radiation with femoral shielding or after autografting (Fig. 1). The same findings were present with bone marrow on serial histologic studies.

Since the study was designed to examine the effect of cyclosporin A on the incidence and severity of GVHD, the rare animal dying before engraftment could be demonstrated was excluded from analysis.

The clinical findings in the allografted recipients were dramatically different from those in the autograft controls. Gross weight loss was the striking feature, and at day 40 respective values were 0.8 and 2.8 kg. There was, in addition, patchy but characteristic extensive hair loss. Diarrhea was a variable feature, with cultures generally being negative.

Survival of control animals (Fig. 2) was 10% at day 40 and 0% at day 100. The cause of death was typically infection in the respiratory tract, with nasal discharge of pus. Pneumonia was often present, with widespread destructive abscess formation being a feature. Histology of the skin, gastrointestinal tract, and liver were diagnostic of GVHD. In the skin, aggressor lymphocytes were present in the epidermis, and spongiosis was prominent, particularly at the dermoepidermal junction. In the gastrointestinal tract loss of
glands and patchy to total mucosal denudation were most striking in the small bowel. The liver showed infiltration of lymphocytes, loss of the limiting plate and destruction of bile ducts by lymphocytes. Generalized lymphoid atrophy was evident in the spleen, lymph nodes, and thymus. These features were similar to those reported both in man (39) and in experimental animals.

4. Cyclosporin A-Treated Recipients
Two striking features were evident in these animals. First, they were uniformly in superior clinical condition, with weights not significantly different from autograft control animals. Hair distribution was normal and diarrhea was not present. The second was the markedly different survival rate between allografted controls and rabbits receiving cyclosporin A after bone marrow transplantation (Fig. 2). At day 40 10% of the allograft controls were alive compared to 44% of those receiving cyclosporin A. This difference was even more obvious at 100 days, when none of the controls survived but 33% of those that had been treated were alive and well, with normally functioning donor grafts.

Of particular note was the fact that the histologically recognizable features of GVHD, which characterized the allografted control animals, were present in only 25% of animals receiving cyclosporin A. Furthermore, in the latter group death due to typical GVHD was unusual and was often attributable to an incidental cause, such as perforated gastric ulcer. However, infection did occur and was most commonly due to bronchopneumonia and septicemia; it is presently not clear whether the latter may be unusual expressions of GVHD modified by cyclosporin A therapy.

5. Cyclosporin A Pretreatment of Donors and Recipients
In experiments where donors were pretreated for 7 days with cyclosporin A and the recipients continued to receive this agent for 28 days after transplantation, the survival curves (not shown in Fig. 2) were not statistically different from those where only the recipients were treated. Furthermore, examination of the tissues in this group and cause of death were also similar to the cyclosporin A-treated recipients.

F. Comments
Three points are relevant. First, in the cyclosporin A-treated allograft recipients, the death rate appeared to accelerate after day 28 when this agent was discontinued. It, therefore, remains possible that longer periods of drug administration are necessary. These findings are entirely compatible with the suggestion that the action of this unique immunosuppressive agent is not to produce lasting tolerance produced by selective clonal deletion, but is a transient phenomenon related to the presence of critical concentrations in the body (31,32). Furthermore, there are interesting parallels between this observation and those reported in a human transplantation study (40,41).

Second, in contrast to experience reported with a similar model (Speck, personal communication, 1980) biochemical disturbances or other gross toxicity attributable to the cyclosporin A were not found.

Third, and perhaps in partial explanation for the lack of major side effects in our animals, was the absence of significant concentrations of this agent in the plasma when examined by high pressure liquid chromatography. It remains possible, therefore, that the dosage administered may have been inadequate or the batch used had less biological activity than we had anticipated. This query is the subject of further study. Nevertheless, it can be concluded that there is an unequivocal and marked reduction in acute
GVHD and that striking prolongation in survival can be achieved with plasma concentration of cyclosporin A that may be lower or less critical than published evidence would suggest. Indeed, it remains to be proven that plasma levels are the most valid reflection for the immunosuppressive properties of this agent and concentration in cellular compartments or control by functional assays, such as mitogen response, may be more appropriate. Nevertheless, the measurements are clearly the best means currently available for monitoring patient compliance and drug absorption, and, therefore, to anticipate the development of toxicity.

IV. CLINICAL STUDIES

Difficulties exist in the prevention (42,43) or abrogation of GVHD (44,45), and while cyclosporin A is beneficial in a number of transplant situations (46), including marrow grafting (41,47), it is less than totally effective and appears approximately equivalent to methotrexate (48). It does not appear that the incidence or severity of the acute syndrome, with its high morbidity and mortality, or that of the chronic variant, with its relentless progression and mutilating side effects, can be eradicated with this agent alone. These observations raise the question that at least the acute disease might reflect transfer of immunocompetent lymphocytes with the graft and that such a situation might, theoretically at least, be amenable to donor pretreatment. In view of the limited side effects observed in animals and while recognizing that any responses in man may be different, it seemed appropriate to examine additional donor pretreatment with cyclosporin A in a clinical bone marrow transplantation program.

A. Materials and Methods

Fifty-one patients underwent allografting on a program approved by the Ethics and Research Committee of the University of Cape Town and Groote Schuur Hospital. Donors and recipients were fully informed and their participation required signed consent.

Initially, patients with refractory acute leukemia were offered the procedure but subsequently only those in consolidated complete remission or having severe acute aplastic anemia were considered eligible. Sibling donors compatible at the major histocompatibility complex and nonreactive with their recipients in the mixed lymphocyte culture were used.

Severe acute aplastic anemia was defined according to internationally accepted criteria (49) and patients were conditioned with 50 mg/kg of cyclophosphamide by intravenous injection on four consecutive days before transplantation (50). The patients with acute leukemia were treated with a combination of stoposide, cytosine arabinoside, and doxorubicin (51), after which they were conditioned with cyclophosphamide, 60 mg/kg on 2 consecutive days, and 1000 rads total body irradiation at a maximum exposure rate of 7 rad/min given 24 hours after the last dose of conditioning drug. All patients were managed in reverse isolation, and received hyperalimentation and such antibiotic and transfusion support as was appropriate.

Three different immunosuppressive regimens were evaluated in the course of this study (52). In group 1 (n = 23) cyclosporin A was not available, and following transplantation patients received only methotrexate (50). In group 2 (n = 8) cyclosporin A was commenced the day before infusion of the graft at an oral dose of 12.5 mg/kg twice a day for a week and then 6.25 mg/kg twice daily for the next week, after which adjustments
were made to maintain plasma concentrations between 250 and 500 ng/mL by radioim-
monoassay (53) at least once a week for the entire duration that patients received this
immunosuppressive drug. In group 3 (n = 20) both donor and recipient commenced
cyclosporin A on the same dosage schedule 2 weeks before transplantation; patients re-
mained on this agent for the same duration as those in group 2. At all times, plasma con-
centrations were monitored and doses adjusted at least once every week to maintain levels
in the same therapeutic range as in group 2.

Biochemical measurements of renal and hepatic function, as well as electrolyte
status and acid-base balance, were measured on alternate days in donors and recipients.
Any increase in creatinine or urea values, even while still in the normal range, was man-
aged by small doses of oral furosemide, and failure to immediately reverse this trend re-
quired reduction in cyclosporin A dosage. In the donors, as well as in the recipients,
these measurements were continued on an outpatient basis.

Acute (50) and chronic (54) GVHD were defined according to established criteria.
Both syndromes were treated by continued administration of cyclosporin A; in the acute
disease methylprednisolone was added; in the chronic form additional high-dose pulsed
methylprednisolone (45) was initially used, followed by long-term corticosteroids and
azathioprine. The dose of the two drugs was variable and started at 0.5 mg/kg and 2 mg/
kg of lean body mass, respectively. Methylprednisolone was gradually reduced, whereas
the dose of azathioprine remained constant; the efficacy of this two-drug combination
on the clinical course of the chronic GVHD was constantly reviewed; average duration
was generally in excess of 9 months.

B. Results

1. Methotrexate-Treated Patients

As shown in Table 1, these patients (group 1; n = 23) were treated with methotrexate for
immunosuppression (50). Ten of the 23 patients (43%) developed classical severe acute
GVHD within 6 weeks of transplantation, which was refractory to therapy and caused

death in six patients. Of the remaining four patients one died of Budd-Chiari syndrome, which may have been related to the long period of prior intensive chemotherapy, and three progressed to chronic GVHD, of whom one is alive with disfiguring cutaneous lesions, one died from disseminated tuberculosis without evidence of GVHD, and the other died following a seizure but with severe skin lesions of GVHD; autopsy failed to reveal the cause of death.

Chronic GVHD arose de novo, that is, without any prior acute disease, in two patients (9%) and has been self-limiting in both.

2. Cyclosporin A-Treated Patients
These patients (group 2; n = 8) received cyclosporin A immunosuppression without donor pretreatment. Severe acute GVHD occurred in two patients (25%) and in both responded promptly to additional corticosteroids. One patient died from leukemic relapse and the second from a ruptured cerebral aneurysm.

Chronic GVHD without an antecedent acute episode occurred in three patients (38%). One died from disseminated fungal infection with poorly controlled cutaneous grade I GVHD. The other two developed minimal but characteristic skin lesions 3 months after discontinuing cyclosporin A. Both have responded to restarting cyclosporin A in conjunction with a single course of pulsed high-dose methylprednisolone.

3. Cyclosporin A-Treated Patients and Donors
These patients (group 3; n = 20) and their donors were pretreated with cyclosporin A for 2 weeks before transplantation. Six patients developed early GVHD (30%). In two this was mild and responded promptly and completely to corticosteroid therapy; one patient subsequently died from massive gastrointestinal tract hemorrhage and the second patient is currently well. In the other four patients the disease was also mild, being defined as grade I cutaneous changes, diarrhea less than 500 mL in 24 hours and without abnormality on liver biopsy. However, in none of these patients could this clinical syndrome be reversed on therapy and all died within 3 months—three from infection and one from massive hemorrhage from a duodenal ulcer.

4. Engraftment
Engraftment is defined as the time taken from transplantation to reach granulocyte counts of 0.5 × 10^9/L or a platelet count of 25 × 10^9/L. These findings were substantiated by a bone marrow aspiration and trephine biopsy, which showed greater than 15% of hematopoietic cell repopulation. The median time to achieve these criteria for the three groups was 21 days (range 9-26), 14 days (range 6-33), and 13 days (range 7-16), respectively.

Actuarially predicted survival curves (Fig. 3) show little difference for median survival, with a nonsignificantly higher plateau for patients in group 3.

5. Toxicity
In none of the donors did biochemical tests of renal function rise outside the normal range during the 2-week period of cyclosporin A administration. The donors were all fully reassessed, including biochemical measurements, before discharge and again within 1 month after discontinuing cyclosporin A therapy. Furthermore, in a separate series of individuals with severe acute aplastic anemia without a transplant option (55), cyclosporin A was used as the primary form of immunosuppression either singly or in combination with antilymphocyte globulin; in 12 individuals monthly follow-up for an average period
Figure 3  Survival of bone marrow transplantation patients. Actuarially predicted survival curves showed no significant difference between patients receiving methotrexate alone (group 1; n = 23), those in which recipients only received cyclosporin A (group 2; n = 8), and where donors and recipients received cyclosporin A pretreatment and the recipients, in the post transplant period, continued with the same agent (group 3; n = 20). (Reproduced with permission of the Editors and Publishers of The Scandinavian Journal of Haematology, Munksgaard International Publishers Ltd, Copenhagen, Denmark.)

in excess of 9 months showed no late disturbances in biochemical tests of renal or hepatic function.

In recipients receiving cyclosporin A, transient elevation of blood urea and creatinine was seen in 50% of the patients in groups 2 and 3. Any increment in these biochemical measurements, despite their remaining within the normal range, was managed by treating the patient with 20-40 mg furosemide daily or twice a day. Failure to immediately reverse the trend required reduction in the dose of cyclosporin A being given. No examples of progressive deterioration or irreversible dysfunction were observed using this approach.

C. Comments

From these preliminary studies only three observations can be made. First, these overall results from bone marrow transplantation are less satisfactory than reported by others and those currently being achieved in our own program. This reflects the referral of patients during the early years of this program at a time when their clinical condition was poor, and, therefore, at least in those with aplastic anaemia, extensive prior transfusions may have further compromised the outcome.

Second, and based on these results, it appears as though the administration of cyclosporin A to the recipients alone reduced the incidence of acute GVHD and improved the response to its management when additional methylprednisolone was required.

Third, the additional pretreatment of the donor, albeit the number of patients transplanted was small, had the further benefit of reducing the severity of clinical manifestations.
In both of the latter two groups, and particularly where donors were pretreated, it is noteworthy that meticulous monitoring of plasma levels and prompt management of changing hepatic biochemistry made it possible to use this agent without unacceptable morbidity.

Finally, in the clinical context, no beneficial effect from either cyclosporin A regimens could be demonstrated on de novo chronic GVHD.

V. SUMMARY AND CONCLUSIONS

The use of bone marrow transplantation in clinical practice is rapidly increasing. It is the preferred method of treatment in some instances and in others forms an integral part of current management programs, particularly in hematologic malignancies. A major deterrent to allografting is the morbidity and mortality associated with acute and chronic GVHD. The approach to this problem is not uniform. In patients with aplastic anemia, the objective is to eliminate this entity completely. Conversely, and perhaps paradoxically, in patients with leukemia there may be a need to retain a controlled level of GVHD in order to harness an associated and beneficial immunologic effect on preventing relapse (56). If this is to be achieved successfully, then a greater understanding of the various components of acute and chronic GVHD are needed so that these can be manipulated to selectively enhance those that lead to immunologic destruction of residual tumor cells and suppress cytotoxic processes that cause unwanted destruction of normal tissue. However, there remains controversy as to the relative contributions from cellular populations that directly mediate one or other events, in contrast to humoral mechanisms that reflect monocyte or lymphocyte activation. Indeed, it is not only possible but likely that both arms of the immune response mechanism may be acting in concert.

There are a number of new and novel approaches currently being examined that include the exposure of the graft to ultraviolet irradiation (57,58), selective depletion of a wide variety of cells with monoclonal antibodies having differing specificities, or variation in the posttransplant immunosuppressive regimens. Each of these have met with differing degrees of success, but none have uniformly led to the control of GVHD. In the quest for alternative regimens with less cytotoxic effects, cyclosporin A has been extensively studied. Although the induction of a qualitative lesion in T-helper lymphocytes was demonstrated in vitro and while initial in vivo studies were encouraging, frustratingly, much of the early promise has not been fulfilled. On the theoretical basis that the acute syndrome may be amenable to better control with longer periods of effector cell exposure to this unique biologic agent, donor pretreatment followed by the administration of cyclosporin A to the recipient was examined in both an experimental rabbit model and a clinical bone marrow transplantation program. The results of the former studies showed no clear-cut benefit over its administration to the recipient alone. In contrast, clinical studies, while limited by the historical nature of the trial design and the small number of patients entered, provided some evidence for a decrease in the incidence and severity with donor pretreatment which could be achieved without demonstrable morbidity.

It might reasonably be concluded, at a time when all possible means are being explored for the control of GVHD (59), that this schedule justifies further study. It can be hypothesized that manipulation of exposure time and titration of dosage would lend flexibility to modulating the acute and chronic forms of this unique phenomenon. Thus, additional donor pretreatment may have a role in retaining the beneficial antileukemic
effects whilst concurrently preventing untoward damage to other organ systems in the recipient. Furthermore, with programs being rapidly expanded to include the use of mismatched siblings or phenotypically identical but unrelated donors, it also offers a wider choice in suppressing some of the very early events in the acute syndrome.

ACKNOWLEDGMENTS

We thank Dr. P. Hartman Stahelin and Professor Jean Borel for HPLC determination of cyclosporin A and Jackie Davies for help with preparation and typing of the manuscript. Assessment of converting from intravenous to oral administration of cyclosporin A in pediatric allogeneic hematopoietic stem cell transplant recipients

JS Choi1,2, SH Lee3, SJ Chung3, KH Yoo4, KW Sung4 and HH Koo4

1Division of Pharmaceutical Services, Samsung Medical Center, Seoul, Korea; 2Graduate School of Clinical Pharmacy, Sookmyung Women’s University, Seoul, Korea; 3College of Pharmacy, Seoul National University, Seoul, Korea; and 4Department of Pediatrics, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea

We studied the administration method during a transition period from continuous intravenous (i.v.) infusion to oral administration of cyclosporin A (CsA). Thirty-two pediatric hematopoietic stem cell transplant (HSCT) recipients, between the ages of 8 months and 15.6 years (median 7.1 years) participated in this study. The pharmacokinetic properties of CsA was evaluated during the transition period from i.v. to oral CsA. The daily oral dose of CsA was three times higher than the i.v. dose. Oral dosing began immediately after the continuous infusion was discontinued. Whole-blood CsA concentrations were measured by a monoclonal fluorescence polarization immunoassay (FPIA). The mean ± s.d. value of bioavailability (F), maximum concentration (Cmax), half-life (t1/2) of CsA were 43.1 ± 14.4%, 1135.3 ± 340.6 ng/ml and 3.1 ± 1.2 h, respectively. Mean clearance (CL) ± s.d. was 480.9 ± 103.7, 414.9 ± 137.1 and 320 ± 51.8 ml/h/kg in patients <20, 20–40 and >40 kg of body weight, respectively. The CsA CL of younger children was significantly greater than for older children (P = 0.044). CsA trough levels were maintained within the therapeutic range throughout the transition period. Therefore, our findings suggest that the immediate administration of an oral formulation, after discontinuation of the continuous infusion, would be practical and effective for routine clinical use.

Bone Marrow Transplantation (2006) 38, 29–35. doi:10.1038/sj.bmt.1705402; published online 22 May 2006

Keywords: pharmacokinetic; cyclosporin A; hematopoietic stem cell transplantation; pediatric

Introduction

Among the variety of immunosuppressants available, cyclosporin A (CsA) has been the most extensively used drug to prevent or treat graft-versus-host disease (GVHD) in hematopoietic stem cell transplant (HSCT) recipients, since its introduction in the 1970s.1–6 It has been shown that CsA is effective in preventing and controlling acute and chronic GVHD in pediatric patients.7–8 However, the use of CsA in the clinical setting is complicated by significant intrapatient and interpatient variability in its pharmacokinetics.9,10 Prior reports have shown that there are several factors contributing to this variability, such as age, genetics, the physical condition of patients, type of transplant, post transplant time and concomitant medications.11 As was previously observed, the major cause for variability is the erratic absorption of CsA.12 Particularly, HSCT recipients have considerable difference in their gastrointestinal (GI) integrity, as compared to solid organ transplant recipients; these differences are in part caused by GI inflammation that develops after conditioning chemotherapy and radiation treatments and/or intestinal GVHD and viral infection.13–15 In addition, a significant factor for the interindividual variability is the patient’s intrinsic capacity to metabolize CsA.12 In general, many drugs administered to children are characterized by a substantially faster elimination than in adults; however, there are limited data on the pharmacokinetics of CsA in pediatric transplant recipients.16,17 Some studies have evaluated the pharmacokinetic properties of CsA in children undergoing organ transplantation.18,27 However, few published data are available for the pediatric HSCT population.28

Despite the widespread use of CsA, the administration method, dosage schedule and optimal dose of CsA have not been well established, and a variety of treatment protocols have been accepted at numerous transplantation centers.28 Several studies have suggested that the continuous intravenous (i.v.) infusion of CsA has been effective in preventing acute GVHD in HSCT recipients.29,30 Moreover, a continuous infusion is associated with a decrease in the incidence of serious CsA-related toxicities compared
with a short i.v. infusion. Based on these data, we administered CsA for a continuous i.v. infusion in the early period after stem cell transplantation; it was continued until the patient could tolerate oral dosing after recovery from treatment-related GI complications. The oral formulation was administered immediately after discontinuation of the continuous infusion with an attempt to maintain CsA levels and provide a practical management option.

The objectives of this study were to study the transition period between continuous i.v. infusion and oral CsA treatment by evaluating the pharmacokinetic properties of CsA in pediatric HSCT recipients.

Patients and methods

Patients

Children who received allogeneic HSCT and CsA for prophylaxis of GVHD at Samsung Medical Center were enrolled in this study. They had normal hepatic function (<1.2 mg/dl), SGOT and SGPT <3 × upper reference limit) and normal renal function (serum creatinine <1.5 mg/dl, infant criteria <0.6 mg/dl). All patients were treated with a study protocol that had been approved by the Institutional Review Board at Samsung Medical Center. Written informed consent was obtained from parents or guardians before the patients were allowed to enter the study.

Drug administration

Intravenous CsA (Cipol In®, 50 mg/ml, CKD, Korea) was started the day before stem cell infusion at a dosage of 5 mg/kg per day as a loading dose; it was given as a continuous infusion through an indwelling catheter. CsA injection was continued, at 3 mg/kg per day, from the day of stem cell infusion and then the dose was titrated to a level of 250–350 mg/ml. Thereafter, the oral formulation was substituted for the i.v. formulation when the patient was able to tolerate oral medications, after they recovered from treatment-related GI complications. The daily oral dose was administered immediately after discontinuation of the continuous infusion, three times the i.v. dose, in two equally divided doses, at 12 h intervals. Soft gelatin capsules (Cipol N®, 25 100 mg/cap, CKD, Korea) or an oral solution (Neoral® 100 mg/ml, Novartis) were administered, depending on their preference and developmental capability. All patients received anti-fungal prophylaxis with fluconazole, pneumocystis carinii prophylaxis with cotrimoxazole and anti-viral prophylaxis with acyclovir.

Blood sampling

Blood samples were collected during the transition period from i.v. to oral dosing. Whole blood (2 ml) was collected into tubes, with ethylenediaminetetraacetic acid (EDTA) as an anticoagulant. Blood was taken 24 h before the transition, simultaneously from both the peripheral veins and the indwelling catheter lines, at 0 (just before transition), 1, 2, 3, 5, 7, 12 and 24 h after transition via the peripheral lines. As CsA can bind to the plastic tubing of a central line, blood samples were obtained from another lumen that was not involved in the infusion. The first 2 ml of blood was discarded when specimens were drawn from both peripheral veins and indwelling catheter lines. All blood samples were refrigerated until analysis. The results were determined within 48 h after sampling.

Analytical method of cyclosporin A concentration

Cyclosporin A concentrations, in whole blood, were measured at the biochemistry laboratory in this center by monoclonal fluorescence polarization immunoassay (FPIA) using commercially available assay kits (TDx, Abbott Laboratories, USA). The operating range for this method is 0–1500 ng/ml but the lower limit of detection is 25 ng/ml. The precision of this method was evaluated using three control concentrations of 150, 400 and 800 ng/ml. The within-run coefficients of variation were 1.3, 1.2 and 1.3%, respectively. The within-run coefficient of variation was estimated to be less than 2.5%. The analytic method used in this study, monoclonal FPIA, showed cross-reactivity with some CsA metabolites; however, it was chosen because the results are practically applicable in the clinical setting, and they provide good reproducibility.

Pharmacokinetic analysis

Pharmacokinetic modeling and parameter estimates were performed using WinNonlin version 3.1 (Pharsight Corporation, USA). Utilizing the raw data, such parameters as volume of distribution (Vd, ml/kg), absorption rate constant (Ka, h⁻¹), lag time (Tlag, h), bioavailability (F, %) and clearance (CL, ml/h/kg) were estimated from the pharmacokinetic model. Then, the elimination rate constant (Kel, h⁻¹) and elimination half-life (t1/2h) were derived from the primary parameters using the following formulae, respectively: Ke = CL/Vd, t1/2h = 0.693/Kel. The peak concentration (Cmax) and the time to reach maximum concentration (Tmax) were accepted as the observed values.

Statistical analysis

Comparisons of the pharmacokinetic parameters between two groups according to CsA formulations were performed using the two-sided Wilcoxon’s rank sum test. For three groups according to patient body weight, the Kruskal-Wallis test was used. Wilcoxon’s signed rank test was used to compare the difference of CsA concentrations, in the paired samples, taken simultaneously from both peripheral vein and indwelling catheter sites; the difference in CsA concentrations 24 h before and after the transition time between i.v. and oral treatments were determined. All evaluations were performed using the software package SAS version 8. A P-value of less than 0.05 was considered to imply statistical significance.

Results

Patients

Between April 2002 and November 2003, a total of 33 patients were included in this study. One child was excluded in the final analysis due to the child’s failure to take the
whole oral dose on the study day. The clinical characteristics are summarized in Table 1. There were 9 girls and 23 boys with a median age of 7.1 years (range: 0.8-15.6). The body weights ranged from 9 to 74.7 kg. The mean number of days until conversion from i.v. to oral CsA was 25.3 ± 6.2 days after the stem cell infusion. Twenty-one patients received soft gelatin capsules, and 11 patients were given the oral solution. Of the 32 patients who were enrolled in the study, two patients did not provide concurrent samples from the peripheral veins and indwelling catheter lines.

Pharmacokinetic parameters
The mean concentration for CsA in the whole blood versus time for 32 patients, is illustrated in Figure 1; the related pharmacokinetic data is summarized in Table 2. The interindividual variation in lag time (Tlag) was 60.4% and estimated bioavailability varied between 12.2 and 69.5% (mean 43.1 ± 14.4%). After oral administration, the time to peak concentration (Tmax) was between 0.4 and 3.6 h (mean 1.9 ± 0.8 h) after conversion. The volume of distribution ranged from 750 to 4884.9 ml/kg (mean 1871.3 ± 823 ml/kg). The mean for the total clearance was 436.9 ± 124.1 ml/h/kg and the half-life was 3.1 ± 1.2 h.

Comparison of pharmacokinetic absorption parameters by formulations
Patient characteristics for the two groups according to formulations and comparison of their pharmacokinetic absorption parameters are shown in Table 3. There were no significant differences between CsA soft gelatin capsules and solution in oral absorption for measurements evaluated such as Tlag, Bioavailability, Cmax and Tmax.

Comparison of pharmacokinetic parameters by body weight
The patient characteristics for the three groups divided by body weight (<20, 20-40 and >40 kg) are presented in Table 4. None of the comparisons between parameters studied were significant except for drug clearance. Mean clearance (CL) ± s.d. was 480.9 ± 103.7, 414.9 ± 137.1 and 320 ± 51.8 ml/h/kg in patients <20, 20-40 and >40 kg of body weight, respectively. The CsA CL of younger children was significantly greater than for older children (P = 0.044).

Comparison of concentrations in samples obtained simultaneously from different sites
Comparisons of CsA levels were determined from paired specimens taken simultaneously via the peripheral vein and

Cyclosporin A concentrations with transition from intravenous to oral administration

The average i.v. dose of CsA taken before conversion was 3.4 ± 0.9 mg/kg per day and the oral dose after conversion was on average 9.7 ± 2.5 mg/kg per day. The Cmax mean value after conversion was 1135.3 ± 340.6 ng/ml. The mean CsA concentrations 24 h before and after the i.v.-oral transition time was 332.3 ± 95.7 ng/ml and 214.5 ± 75.8 ng/ml, respectively, (P < 0.0001). The mean CsA levels 48, 72, and 96 h after transition were 287.5 ± 150.5 ng/ml, 292.6 ± 116.4 ng/ml and 272 ± 166.1 ng/ml, respectively.

Discussion

Graft-versus-host disease remains a major limiting factor for a successful result after allogeneic HSCT; it affects mortality, morbidity and quality of life. These factors are particularly significant for pediatric patients where the growing body and multiple organ systems are especially...
vulnerable to the consequences of GVHD. CsA-based immunosuppression has been the most frequently used regimen for prophylaxis and treatment of GVHD in pediatric patients undergoing HSCT, as well as for adults. However, there remains little consensus on the administration, scheduling, dosage, and monitoring of CsA. There are some limited data on the pharmacokinetics of CsA in pediatric HSCT recipients as compared to adult transplant recipients; guidelines for CsA therapy, in the pediatric population, are derived from experience with the clinical protocols used for adults. Therefore, a comprehensive understanding of the pharmacokinetics of the CsA in the pediatric HSCT recipients is needed for the development of optimal treatment protocols and valid strategies for therapeutic monitoring.

Following its oral administration, CsA is variably and incompletely absorbed in the GI tract. The mean bioavailability of CsA in adult SCT patients is reported as 34% with a range of 20–50%. The bioavailability of the oral formulation of CsA, in pediatric transplant recipients, is as highly variable as that of the adult population. In our present study, the mean bioavailability of CsA in pediatric SCT recipients was 43.1 ± 14.4%. These observed values were a little higher than those reported for pediatric renal transplant patients, 21.8% and pediatric liver transplant patients, 37.6 ± 14.5%. The reason for this difference, between kidney transplants and our study patients, may be due to age and small bowel length. Another study has reported that small bowel length is a significant factor for CsA absorption. In the report by Hopp et al., the study patients had a mean age of 1.76 (1.08–2.53); they were younger children compared to our study patients, and therefore, they may have had a lower bioavailability.

The time to reach Cmax (Tmax) in this study was 1.9 ± 0.8 h; this is similar to the values reported for other pediatric HSCT groups, 2.4 ± 1.1 h as well as for pediatric renal transplant recipients, around 1–2 h. As previous studies have reported, the Tmax for HSCT recipients has shown that absorption is delayed in comparison to that measured in solid organ allograft recipients; it is thought that the differences are due to the presence of GI inflammation caused by mucositis or GVHD. However, we conducted part of our study at a later point in the post transplant period, when GI inflammation was improved; the pharmacokinetics of CsA in HSCT recipients may correspond more closely to those for solid organ transplant recipients during the period of time studied in our investigation.

Comparison of the pharmacokinetic absorption parameters (Tmax, Bioavailability, Cmax, T75%) for the oral solution, there were no significant differences between the two formulations in renal transplant recipients or for the heart and lung transplant recipients. Our findings for pediatric HSCT recipients support previous reports concerning the bioequivalence of soft gelatine capsules and oral solution of CsA.

The total clearance of CsA tended to be greater in the pediatric transplant population when compared to the adult transplant groups and patients 0 to 10 years old had a significantly higher CsA CL than those >11 years old. In this study, mean clearance (CL) ± s.d. was 480.9 ± 103.7, 414.9 ± 137.1 and 320 ± 51.8 ml/h/kg in patients with <20 kg, 20–40 kg and >40 kg of body weight, respectively. Cyclosporin A CL of younger children was significantly greater than older children (P = 0.044).

In adults with normal renal and hepatic function, the mean elimination half-life has been reported to average between 8.4 and 27 h and in pediatric transplant patients, a shorter half-life has been reported to be between 4.2 and 7.5 h. In our pediatric HSCT recipients, the mean estimated elimination half-life was 3.1 ± 1.2 h. Owing to the shorter half-life and the higher clearance in the pediatric population, it has been suggested that dosing every 8 h may be more appropriate in children. Several pediatric solid organ transplant centers are using a three times daily dosing schedule instead of twice daily. It has been reported that the three times daily dosing schedule of CsA in children helped to avoid deleterious peak levels with less fluctuation in blood concentration; these results have been obtained without any significant change of the average concentration of CsA. The data in our study suggest that a three times daily dose is useful for pediatric HSCT recipients.

As CsA is a lipophilic molecule, it has been postulated that the drug is adsorbed onto the surface of indwelling catheters, and that it is subsequently leached off when the lines are used for blood sampling. Previous studies have shown that the levels of samples obtained from the lumen used for CsA administration, are significantly higher than those taken from a peripheral vein. In our study, the samples were obtained from an indwelling catheter lumen that was not involved in the CsA infusion; therefore, the mean concentrations for the samples taken 24 h before the transition simultaneously from a peripheral vein and the indwelling catheter, were 332.7 ± 91.8 ng/ml and 346.7 ± 121 ng/ml, respectively (P = 0.94). The results of our present observations confirm that samples should be drawn from a catheter-lumen that was not used for i.v. CsA infusion, are valid as alternative sites to a peripheral vein for accurate therapeutic drug monitoring.

A variety of CsA administration protocols have been developed and implemented at numerous HSCT centers. These practices range from a 1 h short infusion to a continuous infusion. Previous studies have shown that CsA administration as a continuous i.v. infusion may be more effective, and it is associated with less serious side effects than bolus CsA, for the prevention of GVHD in allogeneic SCT recipients. As a consequence, in some centers CsA is administered as a continuous infusion in the early period after stem cell transplantation. Thereafter, when patients were able to eat normally, usually around 25 days after HSCT, they were converted from i.v. CsA to an oral formulation. The oral formulation was administered immediately after discontinuation of the continuous infusion with the attempt to maintain CsA levels. In other studies, the mean or median Cmax have been reported as 1200–1500 ng/ml. In our study, the mean peak concentration of CsA (Cmax) after oral administration was 1135.3 ± 340.6 ng/ml, not excessive Cmax levels. Therefore, according to this observation, our administration method for the transition period is effective and practical for routine clinical use.
Additional study will further define more specific dosing intervals and conversion doses for oral treatment after continuous intravenous dosing is discontinued. Improved knowledge of doses and time intervals will allow for appropriate adjustments to be made on the basis of pharmacokinetic parameters.

REVIEW

Optimizing the use of cyclosporin in allogeneic stem cell transplantation

N Duncan1 and C Craddock2

1Pharmacy Department, Queen Elizabeth Hospital, University Hospital Birmingham NHS Trust, Birmingham, UK and 2Stem Cell Transplant Unit, Queen Elizabeth Hospital, University Hospital Birmingham NHS Trust, Birmingham, UK

Cyclosporin remains the most widely used immunosuppressive agent in patients undergoing allogeneic stem cell transplantation (SCT). The increased awareness of the impact of the intensity of post-transplant immunosuppression on determining outcome after allogeneic SCT has resulted in a re-examination of whether cyclosporin is currently being optimally used in this population of patients. Recent studies in solid organ transplantation have questioned whether the use of trough levels provides the most accurate reflection of the immunosuppressive actions of cyclosporin and alternative strategies to monitor cyclosporin dosage after liver and kidney transplantation are increasingly being used. As a result there is now interest in examining whether there is scope for translating these advances into the arena of haematopoietic transplantation. In this paper, we will review the rationale underlying the current schedules for dosing and monitoring cyclosporin after allogeneic SCT and identify specific areas in which the use of cyclosporin requires re-evaluation. These include evaluation of whether patient outcome would be improved by using peak cyclosporin levels to determine dosing schedules, analysis of optimal cyclosporin dosing schedules in patients undergoing reduced intensity allografts and investigation of surrogate markers of cyclosporin’s immunosuppressive activity.

Keywords: cyclosporin; allogeneic SCT; monitoring

Introduction

Pharmacological suppression of the donor-derived alloreactive immune response has played a central role in reducing the morbidity and mortality of graft-versus-host disease (GVHD), which still remains the major cause of toxicity after allogeneic stem cell transplantation (SCT). At the same time, it has become clear that the intensity of post-transplant immunosuppression is one of the most important determinants of relapse risk through its impact on the potency of an immunologically mediated graft-versus-leukaemia (GVL) effect. This is particularly relevant in patients undergoing allogeneic SCT using a reduced-intensity conditioning (RIC) regimen, where a GVL effect represents the dominant anti-leukaemic mechanism. Accordingly, there is now a developing interest in tailoring the intensity and duration of post-transplant immunosuppression according to the perceived risk of GVHD and disease relapse in an individual patient.

In the past few years considerable refinement has occurred in the pharmacologically mediated immunosuppressive strategies utilized in recipients of solid organ transplants. This has occurred through the use of more precise methods of monitoring established agents, principally cyclosporin (CsA), which have been shown to reduce the risk of graft rejection in the setting of both kidney and liver transplantation. This experience suggests that there may be scope for translating the advances that have been made in the field of solid organ transplantation to recipients of allogeneic haematopoietic stem cells. This review will focus on the basis for current immunosuppressive strategies in patients undergoing allogeneic haematopoietic SCT and discuss whether there is room for improving both the monitoring and the delivery of pharmacologically mediated immunosuppression in this population of patients.

The role of cyclosporin and other immunosuppressants in graft-versus-host disease prophylaxis

Cyclosporin has become the most widely used agent for the prevention of GVHD in patients undergoing allogeneic SCT after initial studies by Powles9 demonstrated that its administration, in conjunction with methotrexate, resulted in a substantial reduction in the incidence and severity of acute GVHD and had a positive impact on survival. This pioneering work was subsequently confirmed by randomized controlled trials from the Seattle group.2 In recent years a number of newer immunosuppressants have entered clinical practice and have been compared to the standard CsA plus methotrexate regimen (Table 1).5 The maximum experience has been gained with tacrolimus, a calcineurin inhibitor that is chemically unrelated to CsA. Two large randomized phase III trials of tacrolimus plus methotrexate versus CsA plus methotrexate have been published, both of which showed a significantly reduced incidence of

Abbreviations: CSA = cyclosporin; Tac = tacrolimus; aGVHD = acute GVHD; cGVHD = chronic GVHD; MTX = methotrexate; MMF = mycophenolate mofetil; MUD = matched unrelated donor.

Acute GVHD in patients receiving tacrolimus. However, there was no difference in the incidence of chronic GVHD in either study and in the study involving patients undergoing a sibling allograft, overall survival was in fact worse in the tacrolimus plus methotrexate arm. As yet, only one small randomized phase III trial of mycophenolate mofetil as GVHD prophylaxis has been published. Mycophenolate mofetil in combination with CSA resulted in similar rates of GVHD and a comparable overall survival to cyclosporin plus methotrexate but was better tolerated in terms of faster engraftment and less mucositis. Encouraging results have also been reported with sirolimus, a macrocyclic lactone immunosuppressant that is structurally similar to tacrolimus.

Despite these developments, the combination of CSA and methotrexate remains the standard approach by GVHD prophylaxis in the majority of transplant centres. However, there is still uncertainty as to the optimal schedule for dosage, administration and monitoring of CSA. A survey of 87 centres by the European Group for Blood and Marrow Transplantation showed inconsistency in both timing of CSA infusion and variations in the range of dose from 1 to 20 mg/kg/day. Reference ranges also varied widely between 100 and 1000 μg/l. There was also a lack of standardization in assay techniques with both whole blood and serum being used for measurement and a number of different assay methods being employed. A recent survey of UK practice involving 19 transplant centres produced results similar to those described above revealing target concentrations for CSA ranging from 85 up to 800 μg/l.

Although there is clearly uncertainty surrounding the optimal use of CSA in the setting of GVHD prophylaxis, accumulating data attest to the potential clinical benefits of close attention to CSA dosing schedules and monitoring. In an important study in which patients undergoing a sibling allograft were randomized to 0 or 5 mg/kg/day CSA, Bacigalupo demonstrated a significantly higher rate of acute and chronic GVHD in patients receiving 1 mg/kg CSA. This was offset by a decreased risk of relapse in patients receiving low-dose CSA, resulting in improved disease-free survival in this group of patients. Other groups have shown that close monitoring of CSA can produce benefits in terms of a reduced incidence of acute GVHD while extended CSA administration has the capacity to reduce the risk of chronic GVHD. More recently it has been demonstrated that post-transplant immunosuppression using CSA permits durable engraftment of allogeneic stem cells using a non-myeloablative regimen. In the setting of allografts performed using a RIC regimen, where the dominant anti-tumour effect of the allograft is exerted by an immunologically mediated GVL effect, CSA is rapidly tapered post transplant. However, the optimal dosing schedule and duration of CSA administration in patients undergoing RIC allografts and the impact on relapse and GVHD are unknown, and requires urgent further study. This is particularly true in patients in whom T-cell depletion using alemtuzumab or anti-thymocyte globulin is used, where relapse is the most important cause of treatment failure and reduction in CSA dose intensity may represent an important, and largely unexplored, approach towards improving outcome. Clearly therefore CSA plays a critical role in determining the outcome of allogeneic SCT using both myeloablative and RIC regimens and this has led to renewed interest in refining the current techniques available for monitoring both the blood level and the pharmacological activity of CSA after allogeneic SCT.

Pharmacology of CSA

Cyclosporin was first introduced into clinical practice in 1978 and has become the cornerstone of immunosuppression in the settings of solid organ (renal, hepatic and cardiac) and SCT. Cyclosporin exerts its immunosuppressive effects through suppression of calcineurin-mediated T-lymphocyte activation and accumulating evidence demonstrates that peak levels of CSA correlate best with the degree of calcineurin inhibition achieved. Consequently, factors determining peak as well as trough levels of CSA may significantly impact on the degree of immunosuppression produced by patients receiving this agent post transplant. This is of particular importance given that CSA pharmacokinetics are highly variable, with factors such as transplant type, patient age and concurrent drug therapy all influencing blood concentrations of the drug. Variable absorption of oral CSA is well documented, and can result in marked differences in bioavailability between patients. In the SCT setting, absolute bioavailability of oral CSA may vary from 20 to 50%. However, in the first few days post transplant, mucositis caused by the pre-transplant conditioning regimen impairs absorption of CSA from the upper gastrointestinal tract. In addition,
oral mucositis can make it difficult for the patient to tolerate an oral formulation. Consequently, administration of the drug by the intravenous route until mucositis has resolved is standard practice in almost all transplant centres. Cyclosporin is extensively metabolized, with the liver being the main site of metabolism. Age and hepatic function can impact on CsA clearance and drugs commonly used in the setting of SCT such as phenytoin, itraconazole, fluconazole and macrolide antibiotics can also influence the metabolism of CsA. For example, phenytoin can reduce CsA concentrations by 50% via induction of hepatic microsomal enzymes.

Given the marked interpatient variability in CsA pharmacokinetics and the importance of maintaining a balance between underdosing (and thus increasing the risk of GVHD or rejection) and overdosing (and thus increasing the risk of toxicity), blood-level monitoring has for many years been the standard practice for patients receiving CsA in the solid organ and SCT settings. Trough-level monitoring was first introduced into clinical practice in the early 1980s and despite its widespread usage over the subsequent two decades, there has remained a degree of uncertainty as to whether this approach is the most appropriate way of performing drug monitoring of CsA. In the setting of GVHD prophylaxis, a number of authors have demonstrated an inverse relation between trough CsA levels and incidence of GVHD. However, other authors have failed to demonstrate a significant relationship between trough concentrations and aGVHD and conflicting findings have also been reported when studying the association between CsA levels and the risk of nephrotoxicity. Given that there appears to be a lack of a strong association between trough CsA concentrations and measures of both efficacy and toxicity in the SCT setting, it is instructive to focus on the solid organ transplantation literature, where the issue of how best to monitor CsA has generated significant interest in the past two decades.

Cyclosporin monitoring in the setting of solid organ transplantation

Early studies using oral CsA in solid organ transplantation suggested that trough concentrations correlated with clinical outcomes, both in terms of rejection and nephrotoxicity and also that the correlation with trough levels was better than with the maximum concentration (Cmax). Consequently, trough-level monitoring became the standard practice, although concern remained that this technique was still an imperfect tool. This was illustrated by data showing that the rates of acute rejection and nephrotoxicity in patients with trough CsA concentrations within a defined therapeutic range remained 59 and 63%, respectively. Subsequent work showed that trough CsA levels did not correlate with drug exposure as estimated by the area under the concentration time curve (AUC), and others demonstrated that the correlation between trough levels and clinical outcomes was relatively poor in the settings of renal, liver and heart transplantation.

These concerns led to increased interest in developing alternative monitoring strategies for CsA and a number of studies demonstrated the benefit of AUC monitoring as a superior indicator of drug exposure and clinical events in the setting of renal transplantation. However, full AUC monitoring is a time consuming and relatively impractical process, so efforts were made to simplify its determination. This led to the development of sparse-sampling algorithms, which used two or three time points as surrogate markers for exposure to CsA and were found to correlate with AUC. The logical progression of this approach was to find a single time-point measure which correlated best with AUC and a number of studies showed that a sample taken 2h after an oral dose of CsA (C2) was the most accurate single marker of exposure with a correlation coefficient of >0.80 across a variety of transplant populations.

In addition to demonstrating an association between C2 and AUC, it was also noted that there was good correlation between C2 and Cmax. The emerging evidence that calcineurin inhibition correlated well with CsA levels, with maximal inhibition occurring during the period of highest CsA concentration, provided a further pharmacodynamic argument for utilizing C2 monitoring in the post-transplant setting.

A number of trials have employed C2 monitoring in solid organ transplantation and demonstrated superior outcomes in terms of rejection rates and acute toxicities compared to trough-level monitoring. This has led some to conclude that C2 monitoring is now the optimal method of monitoring oral CsA in the setting of de novo renal and hepatic transplants. Consequently, C2 monitoring is being increasingly employed in the management of solid organ recipients with a recent survey of renal transplant centres finding that almost half the respondents were now measuring C2 concentrations.

Improving strategies for immunosuppression after allogeneic haematopoietic stem cell transplantation

In the past 5 years, the monitoring of oral CsA in the setting of solid organ transplantation has undergone significant change, based on concerns regarding the validity of the traditional system of trough-level monitoring. Given the marked interpatient variability in the absorption of oral CsA and the findings that the peak CsA concentration correlates well with maximum inhibition of calcineurin, the move towards C2 monitoring seems logical from both pharmacokinetic and pharmacodynamic perspectives. In the SCT setting, where it is clear that our current practice of trough-level monitoring still results in unacceptably high levels of aGVHD, there is scope to explore the potential of monitoring the drug (both i.v. and oral) via alternative measures of exposure or activity. For example, it will be important to determine whether the AUC or peak level, rather than the trough level, provides a more accurate measure of post-transplant immunosuppression. Importantly, whatever pharmacokinetic marker is employed, there remains the concern that this may not accurately reflect the functional activity of the drug, and this has led a number of groups to investigate the use of calcineurin activity as a marker of immunosuppression after allogeneic SCT. Significantly, it has been reported that the risk of
developing of acute GVHD correlates with the degree of calcineurin inhibition in the mononuclear cells of patients in the first 2 months post transplant and this potentially important observation requires validation in a larger cohort of patients. There is also emerging evidence that there is significant inter-patient variation in the degree of calcineurin inhibition produced by a consistent dose of CsA, emphasizing the importance of correlating biological measures of calcineurin inhibition with clinical outcome.

Conclusions and future directions

In conclusion, it is clear that CsA plays a central, and sometimes underestimated, role in optimizing outcome after allogeneic SCT. This is particularly the case in the setting of RIC allotrafts, where CsA's impact on the potency of the alloreceptove response plays a critical role in modulating the GVL effect post allotraft. However, despite its importance in determining outcome, there is little consensus concerning how CsA is administered or monitored. In light of the emerging evidence from solid organ transplants that peak levels of CsA may determine clinical alloreactivity, a reassessment of monitoring strategies with respect to GVHD and disease relapse is now important in the setting of both myeloablative and RIC allotrafts. For example, we would propose that studies are undertaken to address the issue of whether peak-level monitoring may be superior to trough-level monitoring in SCT patients receiving both i.v. and oral cyclosporin. In addition, in light of the fact that relapse remains the major cause of treatment failure after RIC allotrafts, randomized controlled studies examining both the dose intensity and duration of CsA administration after allogeneic SCT are now indicated. These studies are of particular importance given the current limitations in intensifying the preparative regimen without compromising the ability of RIC allotraft protocols to extend the age at which allogeneic SCT can be safely performed. It is therefore clearly time to re-evaluate the optimal use of one of the oldest drugs in the transplant armamentarium.

- Cyclosporin dose intensity is an important and readily manipulable determinant of the incidence of GVHD post allogeneic SCT and plays a particularly important role in determining outcome after RIC allotrafts.
- Dose intensity of cyclosporin should be adjusted according to the perceived risk of disease relapse and GVHD.
- Trough levels of cyclosporin correlate poorly with the degree of immunosuppression and outcome in solid organ transplantation.
- In the setting of solid organ transplantation there is increased interest in the use of peak-level monitoring of oral cyclosporin.
- Optimal strategies for monitoring cyclosporin dose intensity in the setting of stem cell transplantation remain to be defined and require randomized studies in the setting of both myeloablative and RIC allotrafts.

Cyclosporine short infusion and C2 monitoring in haematopoietic stem cell transplant recipients

MP Hendriks1, NMA Blijlevens1, AVMB Schattenberg2, DM Burger2 and JP Donnelly1

1Department of Haematology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands and 2Department of Clinical Pharmacy, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands

Blood concentrations of cyclosporine A (CsA) ≥ 800 µg/l measured 2h post-dosing, the C2 concentration, is necessary to obtain a maximal pharmacological effect and correlates well with transplant-related complications such as transplant rejection and toxicity. In an open crossover study CsA blood levels were measured during 24h to generate a pharmacokinetic profile on days 1, 8 and 15 after starting CsA infusion in 21 haematopoietic allogeneic stem cell transplant recipients who were receiving intravenously CsA 3mg/kg/day either by continuous infusion or by 2h infusion given every 12h. C2 levels after the 2h infusion correlated better than C1 or C3 levels with the area under the concentration-time curve from 0 to 4h (r² = 0.62). C3 levels ≥ 800 µg/l were also achieved for 20 out of 24 (83%) of cases after the 2h infusion of CsA without any increase of CsA-related toxicity but for only three of the 23 patients (13%) after continuous infusion. Therefore, we recommend CsA infusions in 2h during transplant and perform C2 monitoring to obtain therapeutic C2 levels ≥ 800 µg/l.

Keywords: cyclosporine; HSCT; C2; AUC; safety

Introduction

Cyclosporine A (CsA)-alone or in combination with methotrexate is widely used for graft-versus-host disease (GVHD) prophylaxis among haematopoietic allogeneic stem cell transplant (HSCT) recipients.1 CsA binds to the cyclophilin of lymphocytes resulting in calcineurin inhibition which, in turn, leads to reduced interleukin-2 (IL-2) levels and inhibition of T-lymphocyte proliferation. The CsA acts in a concentration-dependent rather than a time-dependent fashion and it has been shown that the greatest pharmacodynamic effect occurs within the first 2h of exposure (C2) at peak CsA levels of 800–2285 µg/l which result in 70–96% calcineurin inhibition and maximum suppression of IL-2 release from T cells.2,3 C2 monitoring has been adopted for renal, liver and heart transplant recipients as the 2h peak concentration correlates well with the area under the concentration-time curve (AUC) from 0 to 4h after giving the drug and that this predicts the occurrence of acute rejection and nephrotoxicity. C2 monitoring is also associated with clinical benefits like a reduction in graft rejections after solid organ transplantation.4,5 Surprisingly, data on pharmacokinetics and target C2 levels are lacking in HSCT patients. Moreover, there is no consensus about how CsA should be administered with some centres giving 1 or 2 intermittent infusions and others continuous 24h infusion.6 Hence, we decided to determine whether administering CsA at a daily dose of 3 mg/kg/day intravenously (i.v.) in 2h (short infusion) twice-daily achieved C2 blood levels of at least 800 µg/l and whether it was feasible and safe.

Patients and methods

Patients

From June 2001 till August 2002, 22 patients undergoing allogeneic HSCT for various haematological malignancies after myeloablative preparative regimens gave their informed consent to participate in the study. Subjects were eligible if they were aged between 18 and 65 years, were to receive an HLA-matched, MLC-negative, partial T-cell depleted (98%) allogeneic HSCT, had never been exposed to cyclosporine before. Patients were excluded if they had a body mass index (BMI) above 30 kg/m², had received systemically active azoles within the 2 weeks before HSCT or had elevated serum creatinine levels in excess of 220 µmol/l at study entry. On admission a polyurethane quadruple lumen catheter (Arrow-Howes Quad-Lumen Central Venous Catheterization Set with Blue FlexTip Catheter, Arrow International, Reading, USA) was inserted in the right or left subclavian vein. Antimicrobial prophylaxis and therapy was given in accordance with our standard of care. All patients received ciprofl oxacin 500 mg b.i.d. orally as prophylaxis. This was stopped and changed to meropenem 1 g t.i.d. i.v. the day after transplant and continued until the end of neutropenia. Fluconazole 200 mg
once daily was only given to patients shown to be colonized with susceptible *Candida* species. No other azole antifungal agents were given as prophylaxis.

**Study design**

The study was approved by the Ethics Committee and was an open crossover study in which half of the trial subjects were to receive cyclosporine 1.5 mg/kg/day by continuous infusion over 12 h twice daily for the first 7 days then by a 2-h infusion of the same dose twice daily for the next 7 days (Group A). The other half of the trial subjects were to receive the same dose of cyclosporine by a 2-h infusion twice daily for the first 7 days then by continuous infusion over 12 h twice daily for the next 7 days (Group B).

A random allocation list was prepared by the pharmacist before inclusion of the first patient started and each individual treatment allocation was placed in a series of sequential, numbered sealed envelopes. The pharmacist was contacted once a patient fulfilled all the inclusion and exclusion criteria and the next consecutive envelope was opened to reveal the treatment group that had been allocated. Administration of CsA began on the day of transplant (study day 1) with the drug being given exclusively via the median lumen twice daily at 0900 and 2100 hours.

**Cyclosporine blood level monitoring: C₀ and AUC**

After discarding the first 5 ml of blood, blood samples of 10 ml were drawn via the distal lumen of the catheter on study days 1, 8 and 15 just before the first infusion of CsA ( trough level ) and 1, 2, 3, 4, 6, 8, 12 and 24 h after to obtain a pharmacokinetic profile on each of these days, according to the method described by Luke et al. Prom. CsA blood concentrations were measured using a monocular whole blood assay (TDX Abbott Laboratories, North Chicago, IL, USA). This assay detects 25-1500 μg/l of CsA with a coefficient of variation of less than 4%.

**Safety**

Laboratory measurements were performed daily and included creatinine, electrolytes, glucose and liver function tests. Serum protein and magnesium were measured twice weekly. Serum creatinine was also scored using the method described by Lindholm et al. which considers an increase of the serum creatinine value greater than 20% within a 7-day period as nephrotoxicity. Concomitant medication and parenteral fluid administration were recorded. Vital signs and body weight were noted at recruitment and four times daily until day 28. Furosemide was given when the body weight increased by >2 kg over the admission weight. The Common Terminology Criteria for Adverse Events v3.0 (CTO) were used to score adverse events. Each patient was followed for up to 3 months after starting CsA to enable registration of major transplant-related complications as acute GVHD according to the Glucksberg criteria or death.

**Statistical analysis**

The Student’s two-tailed t-test was used to compare numerical data and the χ²-test was used to compare frequencies of toxicity as scored by the CTC criteria between the two groups. This test was also used to compare differences in the occurrence of direct CsA infusion-related side effect that is all blood samples taken at the correct time and no CsA levels exceeding 1500 μg/l. The AUC₀₋₉h and its relationship to CsA levels at 1 h ( C₁ ), 2 h ( C₂ ), and 3 h ( C₃ ) after starting the 2-h infusion was analysed using Prism 4 software (Graphpad Software Inc). P-values <0.05 were considered statistically significant.

**Results**

One patient was excluded because of prior azole drug usage. The characteristics at study entry of each group were similar and age, protein levels and BMI were comparable (Table 1).

**Cyclosporine blood level monitoring: C₀ and AUC₀₋₉h**

In group A, nine out of 33 profiles were excluded from analysis because CsA was not infused exactly as described in the study protocol (n=9) or because of missing blood samples (n=4). In group B, seven out of 30 profiles were excluded because CsA was not infused exactly as described.

Bone Marrow Transplantation
in the study protocol (n = 5) or because of missing blood samples (n = 2). To illustrate the difference of profiles generated during CsA short infusion and continuous infusion respectively, two evaluable profiles are shown in Figure 1.

In total, eight pharmacokinetic profiles were obtained after continuous infusion from patients in group A on day 1 and a further eight and seven, respectively, were obtained from patients in group B on days 8 and 15. Levels exceeding 800 μg/L were found in only three of 23 cases. By contrast 20 out of 24 available pharmacokinetic profiles following 2 h infusion showed a CsA ≥ 800 μg/L (eight on day 1 from group B and nine and seven, respectively, on days 8 and 15 from Group A). The four patients who received CsA short infusions and did not achieve CsA levels > 800 μg/L had CsA levels of 559, 684, 773 and 784 μg/L.

Fifteen profiles were available for CsA-analysis for six, six and three patients, respectively, on days 1, 8 and 15 after the 2-h infusion. CsA levels of CsA correlated better than did either C1 or C3 with the AUC CsA 24 h.

**Concomitant drugs**
Six patients in group A and four in group B were given fluconazole as prophylaxis. One patient in group A and two in Group B were given metoclopramide. No other drugs known to interact with cyclosporine were given during the study period.

**Incidence of acute GVHD**
Fifteen out of 21 (71%) patients developed acute GVHD of the skin, from which eight had grade 2 or higher.

**Safety**
Infusion-related side effects. Patients who received CsA in 2-h infusions did not experience significantly more adverse events than those who were given the drug continuously (Table 2). In the second study week 5 patients who had received short infusions and 1 patient given continuous infusion reported a burning sensation of hands or feet.

*If used, CTC grade 2 or higher was defined as toxicity.

**During the icteric phase, all patients developed total bilirubin CTC grade 3 or 4.

*P = <0.05.

during CsA administration. This was not a significant difference (P = 0.072) although it was the reason why one patient declined further short infusions of the drug.

Noninfection-related side effects. There were no significant differences between the 2 h administration and continuous infusion in nephrotoxicity or hepatotoxicity except that γGT, which was significantly higher (CTC-NCIC toxicity grade 2) during the first week of study (P = 0.031) in the group that received CsA continuously.

One patient in Group A experienced severe neurotoxicity CTC grade 2 that progressed to toxic-metabolic encephalopathy starting from day 8. This patient died on day 37 of respiratory insufficiency and acute GVHD. Another patient in Group B was readmitted on day 28 because of acute kidney failure (creatinine 575 μmol/l), which disappeared after interrupting treatment with CsA. In the second week of the study catheter-related venous subclavian thrombosis CTC grade 2 was diagnosed in four cases all in Group A (P = 0.034). This was unlikely the result of the short infusion of CsA though no other plausible explanation could be found.

Discussion

This study shows that CsA short infusions can safely induce C2 concentrations ≥800 μg/l in HSCT recipients. Moreover, C2 correlates well with the AUC0-48, which is a good indicator of exposure. Although CsA has been used routinely for prevention of GVHD (and graft rejection) in solid organ and stem cell transplantations since the early 1980s, it is still not known which dose and duration of treatment is optimal for HSCT recipients. Runtu et al. reported wide variation regarding CsA usage for prophylaxis and treatment of GVHD in a survey of 87 European Bone Marrow Transplant Centres. As a case in point, they found an initial median dose of 3 mg/kg CsA given i.v. with a range of 1–20 mg/kg. As previously stated, maximal suppression of IL-2 release from T-cells occurs within the first 2 h after CsA administration. Therefore, achieving a CsA peak concentration by infusing CsA 3 mg/kg in 2 h twice daily seems more rational than giving the drug by continuous infusion of 24 h.

The narrow therapeutic index of CsA makes it important to evaluate the real CsA dose a patient is exposed to. This is best represented by the AUC0-48, which in turn is most accurately predicted by CsA C2 levels. In renal, liver and heart transplant patients, there is already increasing evidence that C2 not only correlates well with the AUC0-48, and that C2 monitoring to ensure adequate levels resulted in lower incidences of rejection and nephrotoxicity. Unfortunately, there are no data to our knowledge about C2 monitoring among HSCT recipients. In our study, short infusion of CsA resulted in C2 levels ≥800 μg/l in 20 of 24 (83%) patients.
CsA samples were drawn through a multiple lumen polyurethane CVC which we had shown previously to be as reliable as drawing samples by venipuncture. 17

The incidence of acute GVHD of the skin we noted in this study is to be expected in T-cell-depleted allogeneic HLA-matched HSCT. However, analogous to the reduction of graft rejection and toxicity in kidney transplant patients, a reduction in GVHD in HSCT recipients can be expected if CsA dose will be adjusted to C2 levels.

This pilot study showed that C2 levels \( \geq 800 \mu g/l \) can be achieved by giving 3 mg/kg/day CsA in two divided doses i.v. in a 2 h infusion and that there was no significant difference in the incidence side effects or toxicity between the this mode of administration and the same dose given over 24 h by continuous infusion. We have now adopted this scheme and recommend increasing the dose of CsA if C2 levels of \( \geq 800 \mu g/l \) are not achieved as this correlates best with good exposure. However further investigation is clearly necessary in order to establish if C2 monitoring among HSCT recipients leads to the improved engrafting, decreased rejection, lower incidence of GVHD and less toxicity as has been shown for kidney, liver and heart transplant recipients.

Graft-versus-host disease

A prospective randomized trial comparing cyclosporine and short course methotrexate with cyclosporine and mycophenolate mofetil for GVHD prophylaxis in myeloablative allogeneic bone marrow transplantation

B Bolwell, R Sobecks, B Pohlman, S Andresen, I Rybicki, E Kuczkowski and M Kalaycio

Department of Hematology and Medical Oncology, Department of Biostatistics and Epidemiology, Taussig Cancer Center, The Cleveland Clinic Foundation, Cleveland, OH 44195, USA

Summary:
Cyclosporine (CSP) and short course methotrexate (MTX) have been the gold standard for GVHD prophylaxis for decades. Problems associated with MTX include increased time to hematopoietic engraftment, mucositis, and other organ toxicities. The combination of CSP with mycophenolate mofetil (MMF) has been used successfully for the prevention of graft rejection and GVHD in nonmyeloablative transplantation. We performed a prospective randomized trial comparing CSP and MTX with CSP and MMF in myeloablative (busulfan based) allogeneic 6/6 matched sibling bone marrow transplantation (BMT). The group receiving MMF (n=21) had significantly less severe mucositis than did the group receiving MTX (n=19) (21 vs 65%, P = 0.008). Median time to neutrophil engraftment was more rapid in the MMF group (11 vs 18 days, P<0.001). The incidence of acute GVHD, as well as 100 day survival, was similar for both groups. The reduced toxicity of the CSP and MMF arm resulted in premature study closure. We conclude that a GVHD prophylaxis regimen of CSP and MMF after a myeloablative allogeneic preparative regimen is associated with faster hematopoietic engraftment, decreased incidence of mucositis, similar incidence of aGVHD, and comparable survival as compared to CSP and MTX. MATERIALS AND METHODS

Study design

Eligible patients included those with hematologic malignancy who were appropriate candidates for a myeloablative allogeneic BMT. All patients were required to have a 6/6 HLA matched related donor. All donors were required to undergo a bone marrow harvest. This protocol was reviewed and approved by the Cleveland Clinic Foundation’s Institutional Review Board, with informed consent obtained from all patients. Patients were prospectively randomized 1:1 to receive either CSP plus MTX or CSP plus MMF for GVHD prophylaxis. All patients received 300 mg/m² CSP by continuous infusion intravenously daily from day -1 until hematopoietic engraftment, and thereafter orally attempting to maintain a therapeutic trough level of 200. Patients randomized to MTX received a dose of 5 mg/m² intravenously on day +1, +3, +6, and +11 after allogeneic BMT. Patients randomized to MMF received 500 mg three times daily either intravenously or orally depending on the patient's ability to tolerate oral
medication with the first dose administered on day +1 after BMT and continuing until day +100.

Study end points included the incidence of acute GVHD, severity of mucositis, time to engraftment of neutrophils and platelets, and 100-day survival.

Definitions

Patients were divided into 'good risk' and 'poor risk' based on disease status at the time of transplant. Good risk was defined as any leukemia in complete remission, chronic myelogenous leukemia in chronic phase, chemotherapy-sensitive follicular lymphoma, aplastic anemia, or chemotherapy sensitive chronic lymphocytic leukemia. Poor risk was defined as any other disease status, including chemotherapy insensitive malignancies and refractory disease.

Bone marrow transplant preparative regimen and supportive care

The preparative regimen was busulfan and cyclophosphamide (busulfan 16 mg/kg orally, cyclophosphamide 120 mg/kg). All patients received allogeneic bone marrow from donors undergoing a bone marrow harvest. Patients were hospitalized for the delivery of high-dose chemotherapy and discharged after adequate hematological recovery. Platelet or RBC transfusions were routinely administered for a platelet count <15 x 10^9/l or hemoglobin <8.5 g/dl, respectively. All blood products were irradiated prior to infusion. Broad-spectrum antibiotics were administered for febrile neutropenic episodes. GGF was given on day +5 after allogeneic BMT. Patients who were serologically positive for CMV or who had donors who were serologically positive for CMV received ganciclovir prophylaxis after engraftment until day +100, and acyclovir thereafter. All patients received G-CSF 480 µg i.v. starting on day +1 until neutrophil engraftment.

All patients received the following prophylactic regimens for oral mucositis: Peridex mouthwash (15 cm³) t.i.d. and either mycostatin mouthwash t.i.d. or mycelex troche q.i.d. Engraftment was defined as follows: neutrophil engraftment was the day to an absolute neutrophil count of 500/µl on two consecutive days; platelet engraftment as the day to achieving a platelet count of 20,000/µl independent of platelet transfusions for 3 consecutive days.

Measurement of mucositis and GVHD

We used the modified OMAS mucositis tool to evaluate mucositis. The OMAS scale evaluates multiple regions of the oral cavity for erythema (none, mild, moderate, severe) and the presence of ulcerations or pseudomembranes. The scale ranges from 0 to 2.0; a score of 0.5 or greater is considered to be severe mucositis. Patients were evaluated for mucositis three times a week from admission to day +21. The severity of mucositis for an individual patient was defined as the maximum OMAS score recorded during the first 21 days post transplant. Acute GVHD was monitored weekly while patients were hospitalized for their allogeneic BMT, and at a minimum of weekly for the first 60 days, and a minimum of every 21 days for the first 100 days. Acute GVHD was graded using the NMDP scale for GVHD grading.

Statistical analysis

The primary end points for the study were incidence of acute GVHD and severe mucositis. We hypothesized that MMF would reduce the incidence of severe mucositis while not increasing the incidence of acute GVHD that is seen with MTX. The study was designed as a prospective, randomized study in which 80 patients were to be randomized 1:1 to receive MMF or MTX along with CSP for GVHD prophylaxis. The study was designed to detect an absolute difference of 35% in the incidence of severe mucositis between the two study arms (77% incidence with MTX, 47% with MMF) with 80% power using a two-sided significance level of 5%. No interim analyses were planned. However, due to slower than anticipated accrual, we decided to conduct an interim analysis after the first 40 patients were enrolled. The Lan and DeMets alpha-spending function with a Pocock stopping boundary was employed for this interim analysis. Using this approach, a nominal significance level of P<0.03 was needed for the results to be considered statistically significant. The major end points of the study were the incidence of severe mucositis and acute GVHD. The speed of hematopoietic engraftment was a secondary end point. If one arm of this trial resulted in a significantly more favorable result with respect to the incidence of severe mucositis or severe acute GVHD at the time of interim analysis, the study would be terminated. Categorical variables were summarized as frequencies and percentages, and compared between groups using the χ² test. Continuous variables were summarized as the median and range, and compared between groups using the Wilcoxon rank sum test. Survival, relapse, and relapse-free survival were calculated from the date of transplant. These outcomes were estimated using the Kaplan-Meier method and compared between groups using the log-rank test. All analyses were conducted using SAS® software (SAS Institute, Cary, NC, USA), and all statistical tests were two sided.

Results

In total, 21 patients received MMF and 19 patients received MTX. Patient demographics are shown in Table 1. The median follow-up of patients in the MMF arm is 23 months and 21 months in the MTX arm. The median dose of transplanted hematopoietic stem cells the patients received was similar in both groups: MMF patients received 2.53 x 10⁶ nucleated cells/kg (range 1.22-4.56) and MTX patients received 2.91 x 10⁶ nucleated cells/kg (range 1.06-5.45), (P=0.50). Bone marrow CD34+ cell dose was similar in both groups: MMF patients received 2.10 x 10⁶ CD34+ cells/kg (range 0.76-5.14); MTX patients received 2.43 x 10⁶ CD34+ cells/kg (range 0.76-5.34), (P=0.20). The degree of mucositis was significantly less in the MMF group. Median OMAS score was 0.25 (range 0-1.25) in the MMF group vs 1.0 (range 0-2.0) in the MTX group.

Bone Marrow Transplantation
Table 1  Patient demographics

| Variable | MMF  
| (n = 21) | MTX  
| (n = 19) |
|----------|------|------|
| Primary diagnosis | | |
| AML      | 16 (76%) | 13 (68%) |
| NHL      | 4 (19%)  | 1 (5%)  |
| MDS      | 1 (5%)   | 1 (5%)  |
| CMML     | 0       | 2 (10%) |
| CLL      | 0       | 1 (5%)  |
| HD       | 0       | 1 (5%)  |
| Risk category | | |
| Good     | 8 (38%) | 8 (42%) |
| Poor     | 13 (62%)| 11 (58%)|
| Median age at transplant (years) | 49 (19-60) | 46 (16-62) |
| Median months from diagnosis to transplant | 4.5 (1.8-37.2) | 4.1 (0.2-144.9) |

Figure 1  Mucositis post transplant: MMF vs MTX.

(P = 0.004) as shown in Figure 1. In addition, the MMF group had significantly less severe mucositis than the MTX group (21 vs 65%, P = 0.008). More patients in the MTX arm required narcotics to control pain associated with mucositis (94 vs 75%), and took narcotics for more days (15.5 vs 9.5) during the peri-transplant period. Additionally, 64% of patients in the MTX arm required TPN during the period of mucositis vs only 19% in the MMF arm.

Engraftment was faster in the MMF group. Median time until neutrophil engraftment was 11 days (range 8-24) with MMF vs 18 days (range 11-28) with MTX (P < 0.001). The median time until platelet engraftment was 19 days (range 13-44) in the MMF group vs 23 days (range 14-63) in the MTX group (P = 0.008). The combination of a more rapid engraftment and less severe mucositis leads to a shorter inpatient length of stay for the MMF group (median 27 vs 36 days, P < 0.001).

The incidence and severity of acute GVHD was similar in the two groups. The incidence of grade 0-1 acute GVHD was similar in the two arms (22% in the MMF arm and 26% in the MTX arm). The incidence of grade II-IV acute GVHD was 48% in the MMF arm and 37% in the MTX group (P = 0.49). The incidence of chronic GVHD was similar in both groups. For those who survived more than 100 days, the incidence of chronic GVHD was 63% in the MMF group and 64% in the MTX group (P = NS).

Interim analysis of the first 40 patients revealed that the use of CSP and MMF was associated with a reduced severity of mucositis, faster hematopoietic engraftment, similar incidence of acute GVHD events, and comparable survival (which resulted in premature study closure).

There was no significant difference in survival. The 6-month overall survival was 52% for the MMF group and 68% for the MTX group (P = 0.23); 6-month relapse-free survival was 48% (MMF) vs 53% (MTX), P = 0.53. There was no difference in rates of relapse between the two groups (38% MMF vs 47% MTX, P = 0.81, log-rank test). There was no difference in survival between the two groups when analyzing the good and poor risk groups separately.

In this high-risk group of patients, disease relapse was the most common cause of death, accounting for 47% of deaths in the MMF group and 50% of deaths in the MTX group. Other causes of death included acute GVHD (n = 2), chronic GVHD (n = 4), multisystem organ failure (n = 4), and other (n = 3).

The incidence of infections was similar in the two study groups. The incidence of CMV viremia post transplant was 43% in the MMF group and 47% in the MTX group. In total, 14 patients developed Gram negative bacteremia, seven in each study group. The most common organisms were pseudomonas aeruginosa (n = 4) and klebsiella pneumoniae (n = 3).

Discussion

It is well known that clinical GVHD is associated with a beneficial graft-versus-tumor effect. Unfortunately, excessive GVHD increases the morbidity and mortality associated with allogeneic BMT. Ideally, patients fare best who have mild to moderate GVHD without the toxicities of severe GVHD. Given the potential benefit of GVHD, it is not unreasonable to ask why any prophylaxis is used in HLA matched sibling transplantation in the first place. The reason is that in the absence of prophylaxis, the incidence of ‘hyperacute’ acute GVHD approaches 100% and is associated with overwhelming morbidity. Many strategies of GVHD prophylaxis have been explored, but the most common is the combination of CSP with MTX given on days 1, 3, 6, and 11 after allogeneic transplant. The combination appears to be superior than either agent used alone. A recent review from the EBMT showed that 93% of BMT centers used a combination of CSP and MTX for GVHD prophylaxis. While the initial dose of CSP is relatively uniform, aiming to achieve therapeutic blood levels, the dose of MTX varies, with doses ranging from 5 to 15 mg/m² used. Some centers also use a different schedule, dosing on days +2, +4, +8, and potentially +12. Finally, some centers utilize folic acid rescue after MTX.

Unfortunately, the use of a cytotoxic agent such as MTX has the potential to result in delayed engraftment. Additionally, MTX is frequently accompanied by mucositis, which may be quite severe. As a result, some centers omit the day +11 dose of MTX. One center has reported...
that the omission of the day +11 dose did not result in any negative long-term sequelae, but this report was contradicted by a subsequent report from another center.

MMF is a powerful immunosuppressive agent that inhibits the proliferation of T and B-lymphocytes. It has been used successfully to prevent and treat rejection in solid organ transplantation. Reports with limited patient numbers have shown efficacy of MMF, either alone or in combination with other agents, for GVHD prophylaxis as well as for the treatment of acute and chronic GVHD. Additionally, there appears to be synergism between MMF and CSP in preventing GVHD in dog models of transplantation. This had led to the well-reported use of the combination of CSP and MMF for the prevention of graft rejection, as well as for the prophylaxis of GVHD in nonmyeloablative allogeneic transplants.

In this setting, MMF is tolerated very well and this has allowed the nonmyeloablative transplant patients to frequently receive their care as outpatients.

The issue of mucositis in BMT is not trivial. It has been reported to contribute to a higher incidence of infection, and a longer inpatient length of stay in BMT patients. Increased regimen-related toxicity may be especially harmful to heavily pre-treated patients with refractory disease. Those patients frequently begin their transplants with periods of prior prolonged pancytopenia, and the added toxicity of mucositis induced by MTX may lead to serious clinical consequences. Thus, a GVHD prophylaxis regimen that reduces acute morbidities and achieves similar efficacy to CSP and MTX is noteworthy. In this prospective randomized trial we showed that patients receiving the combination of CSP and MMF had less severe mucositis, more rapid engraftment, and a shorter hospitalization, without an increased risk of infection. These clinically relevant results make the combination of CSP and MMF attractive in ablative transplants.

The primary limitation of this trial is the small sample size, and these results need to be verified in larger prospective randomized trials. Additionally, we used a busulfan-based preparative regimen, and it remains to be determined whether similar results would be achieved in patients receiving total body irradiation. We also did not use the most common dosage of MTX for GVHD prophylaxis. Most institutions use 15 mg/m² on day +1, followed by 10 mg/m² on days 3, 6, and 11; we used 5 mg/m² as described. This reduced dosage has been used at our institution, and others, for years, specifically designed to reduce the incidence and severity of mucositis associated with MTX. However, confirming the results of this trial in patients treated with a more common MTX dosing regimen would be beneficial. Another potential problem with this trial is the fact that we used mucositis as a primary end point that resulted in premature study closure. As a result, the study is not powered to detect significant differences in overall survival. Additionally, the follow-up is relatively short, and cannot adequately address potential differences in chronic GVHD. Finally, all of our donors used bone marrow and not peripheral blood progenitor cells (PBPCs). More rapid engraftment seen with PBPCs has the potential to yield different results.

An effective GVHD regimen that leads to reduced mucositis, faster hematopoietic engraftment, and the ability to be used in patients with hepatic or renal impairment is desirable. Additional studies designed to determine the efficacy of CSP plus MMF in other populations of patients undergoing myeloablative allogeneic BMT are warranted.

Cyclosporine, methotrexate, and methylprednisolone compared with cyclosporine and methotrexate for the prevention of graft-versus-host disease in bone marrow transplantation from HLA-identical sibling donor: a prospective randomized study

Tapani Ruutu, Liisa Voin, Terttu Parkkali, Eeva Juvonen, and Erkki Elonen

The role of corticosteroids in the prophylaxis of graft-versus-host disease (GVHD) is not well established. We conducted a prospective, randomized, open-label, single-center study about the effect of adding methylprednisolone (MP) to the widely used prophylactic regimen consisting of cyclosporine A and methotrexate. A total of 108 consecutive patients treated with allogeneic bone marrow transplantation from an HLA-identical sibling donor for malignant blood disease were entered into the study; 53 patients were randomized to receive MP and 55 were randomized not to receive prophylactic MP. The dose of MP was 0.5 mg/kg on days 14 to 20, 1 mg/kg on days 21 to 34, 0.5 mg/kg on days 35 to 48, and thereafter the dose was slowly tapered and the administration discontinued on day 110. In the group given prophylactic MP, the incidence of acute GVHD was lower (19% vs 56%, P = .0001), there was a trend toward a lower incidence of chronic GVHD among low-risk patients (P = .06), and during the first 4 months the time spent at hospital was shorter and there were fewer infections. The total amount of MP given was similar in the study groups because of a higher incidence of acute GVHD and its treatment in the group of patients not given prophylactic MP. There were no significant differences between the study groups in relapse rate or survival. In conclusion, the addition of MP to the combination of cyclosporine and methotrexate markedly reduced the incidence of acute GVHD without causing untoward effects. The timing of corticosteroid administration is probably important for the efficacy. (Blood. 2000;96:2391-2398)

Introduction

Graft-versus-host disease (GVHD) with its consequences is the most important complication of allogeneic bone marrow transplantation (BMT), and its prevention and treatment are crucial for the success of this form of treatment. Cyclosporine A and methotrexate have been most commonly used to prevent GVHD, and the combination of cyclosporine and a short course of methotrexate is the most widely used form of prophylaxis. Corticosteroids are the first-line treatment of acute GVHD, but their role in prophylaxis is not well established. Corticosteroids have been used for the prophylaxis of GVHD together with cyclosporine, methotrexate, cyclophosphamide, tacrolimus, antimetabolite, and monoclonal rFAB-combined antibodies in various combinations. Studies of the effect of the addition of corticosteroids to the combination of cyclosporine and a short course of methotrexate have generally shown no benefit. In a randomized study, Storb and coworkers found that the addition of methylprednisolone (MP) to the combination of cyclosporine and methotrexate increased the incidence of acute GVHD. In that study, the administration of MP was started on the day of transplantation and continued until day 35. If corticosteroid treatment was postponed until day 15, no increase of acute GVHD was seen. In another randomized study using a similar schedule, the addition of MP to the combination of cyclosporine and methotrexate had no significant effect on GVHD. We report here a randomized prospective study about the effect of adding MP to the combination of cyclosporine and methotrexate for the prophylaxis of GVHD in 108 recipients of an allograft from an HLA-identical sibling donor using a different administration schedule. In this study, the addition of MP to the prophylactic regimen resulted in a marked decrease in the incidence of acute GVHD.

Patients and methods

A total of 108 consecutive adult patients treated for malignant hematologic disorder with allogeneic BMT from an HLA-identical sibling donor at Helsinki University Central Hospital were entered into the study from January 1999 to January 1999. The characteristics of the patients and donors are shown in Table 1. There were no significant differences between the study groups. Histocompatibility typing of the donors and recipients was performed by serology.

As conditioning treatment for transplantation, the patients received cyclophosphamide in a dose of 60 mg/kg of body weight on 2 successive days and either total body irradiation (TBI) or busulfan. Fifty-three patients participated in a multicenter study of the Nordic BMT Group comparing TBI and busulfan in the conditioning for BMT. The low-risk patients not participating in the study were given TBI with one exception, in which busulfan was given because radiotherapy was not available within a reasonable time. The high-risk patients were given TBI or busulfan according to individual judgment, depending, for example, on previous radiotherapy and the availability of TBI. TBI was given in 6 2-Gy doses during 5 days, days -4 to 0 in relation to the transplant; 1 dose was given per day with the exception of 2 doses given on day 1. The total dose was 12 Gy (lungs shielded to 10 Gy), and the dose rate was 4 Gy per minute.

‡ indicates acute myeloid leukemia; CML, chronic myeloid leukemia; ALL, acute lymphatic leukemia; MDS, myelodysplastic syndrome; MM, multiple myeloma; NHL, non-Hodgkin's lymphoma; CLL, chronic lymphatic leukemia.

Busalifan was given in the dose of 1 mg/kg 4 times daily for 4 days, for a total dose of 16 mg/kg, on days -5 to -2, followed by cyclophosphamide in the above-mentioned doses on days -1 to -3.

All patients received a bone marrow graft. The mean number of nucleated cells in the graft was 3.0 x 10^10/kg of the recipient's body weight (median 3.0, range 1.9-4.4) in the group given MP and 3.0 x 10^10/kg (median 3.0, range 1.6-4.4) in the group not given MP for prophylaxis. The grafts were nonmanipulated with the exception of the removal of red cells and plasma in cases of ABO incompatibility.

Postgrafting immunosuppression consisted of cyclosporine and methotrexate with or without MP according to randomization. Cyclosporine treatment was initiated on the day before transplantation and given in the dose of 3 mg/kg per day as continuous intravenous infusion. This was continued until approximately 2 weeks post-transplantation, when the patient was able to take the drug by mouth. The oral dose was 3 mg/kg per day taken in 2 parts at 12-hour intervals. This dose was modified in cases of adverse effects and to keep the whole-blood cyclosporine concentration under the level of 200 μg/L. Cyclosporine administration was continued until 1 year post-transplantation and then tapered off in approximately 6 weeks.

Methotrexate was administered at the dose of 15 mg/m² of the body surface area intravenously on day 0 and 10 mg/m² on days 3, 6, and 11 after grafting. Six hours after each dose, the same-milligram dose of calcium folinate was given intravenously.

Fifty-three patients were randomized to receive and 55 not to receive MP. The randomization was carried out with closed envelopes in sets of 4, separately for patients ever and under the age of 35 years. The schedule of MP administration is shown in Table 2. The drug was given orally. Acute 14,15 and chronic 16-17 GVHD were graded according to previously published criteria. All cases of gastrointestinal GVHD were biopsy-proven. Liver GVHD was documented either by liver biopsy or by biopsy-proven gastrointestinal GVHD and simultaneous clinical and laboratory findings compatible with liver GVHD. Because our previous experience had shown that skin biopsies taken early at the onset of acute GVHD yielded too inconclusive results to be used as a basis of treatment decisions and because our policy to treat GVHD early and intensively hampered the use of later biopsies, skin GVHD was in most present cases diagnosed on clinical grounds. Acute GVHD was treated at its appearance, independent of the grade, with 10 mg/kg per day of MP divided into 4 doses intravenously. The dose was halved every 3 days thrice and then tapered according to the clinical situation. In corticosteroid-resistant cases, antilymphocyte globulin (Atgam, Unipha, Kalamazoo, MI) was used as second-line treatment. The treatment of chronic GVHD consisted of MP and, according to individual judgment, cyclosporine, thalidomide, psoralen plus ultraviolet A, and low-dose irradiation of lymph nodes.

Survival and relapse-free survival were calculated from transplantation to death from any cause and to relapse or death, respectively. Relapse of acute leukemia was defined as more than 5% blasts in an essentially normocellular marrow. The relapses of chronic myeloid leukemia (CML) included both hematologic and cytogenetic relapses. Disease progression after the achievement of minimal disease state of myeloma, lymphoma, or chronic lymphatic leukemia after transplantation was also included in the analysis of the risk of relapse. The differences between the groups in the total dose of MP given, cyclosporine concentrations, infections, hospitalization days, and transfused red cell and platelet (pooled random donor) units were tested with the Mann-Whitney U test.

Results

Engraftment

All patients showed engraftment, with the minimum requirement of reaching 1.0 x 10^6 neutrophils/L. Table 3 shows the recovery of the neutrophil and platelet counts in the study groups. One patient in each group received granulocyte colony-stimulating factor.

</table>

Neutrophil recovery was significantly faster in the group given MP, and there was a trend toward faster platelet recovery.

Treatment

MP was given according to the prophylaxis schedule to all patients randomized to receive this drug. The day +11 dose of methotrexate was given to 7 patients randomized to get MP or to 17 patients randomized not to receive MP because of severe mucositis or liver toxicity. The cyclosporine blood concentrations in the 2 study groups were compared at 1, 2, 3, and 4 months. There were no significant differences between the groups at any time (figures not shown).

Acute GVHD

The cumulative incidence of acute GVHD and the maximum grades are shown in Figure 1 and Table 4. A total of 19% of the patients given MP for prophylaxis had acute GVHD compared with 36% of those not given MP. The difference in the cumulative incidence of acute GVHD is highly significant, $P = .0001$. In the groups given and not given MP, the proportions of patients with grade II-IV acute GVHD were 7 of 53 (13%) and 20 of 55 (36%), respectively ($P = .0005$), and those of patients with grade III-IV acute GVHD were 3 of 53 (6%) and 9 of 55 (16%), respectively ($P = .08$). Among the patients given prophylactic MP, there was a marginally significantly lower incidence of corticosteroid-resistant acute GVHD defined as needing antilymphocyte globulin for second-line treatment because of nonresponsiveness to MP (2 vs 8 patients, $P = .05$). Four of the 10 cases of acute GVHD in the group given MP became manifest late, between days 54 and 73, later than any case of GVHD in the control group. Because patients given more cytotoxic therapy might show more tissue toxicity and possibly have a higher risk of GVHD, low-risk patients (acute leukemia in first remission and CML in first chronic phase) were studied separately. The difference in the cumulative incidence of acute GVHD was similar to that between the entire randomization groups and was highly significant (Figure 2; Table 4). Fifteen percent of the low-risk patients randomized to receive and 57% of those randomized not to receive MP developed acute GVHD of any grade, and the respective proportions of patients with grade II-IV acute GVHD were 2 of 33 (6%) and 13 of 37 (35%).

*Significance of the difference in cumulative incidence.
†See Table 1.
‡At risk for at least 100 days.
Chronic GVHD

A total of 102 patients survived more than 100 days and hence were at risk for chronic GVHD. Thirty-six percent of the patients given MP and 48% of those not given MP for prophylaxis developed chronic GVHD (Figure 3; Table 4). The difference did not reach significance, but among the low-risk patients the difference in the incidence of chronic GVHD was almost significant (30% vs 51%, P = .06) (Figure 4; Table 4). There was no difference between the study groups in the distribution of the limited and extensive forms of chronic GVHD.

The amount of MP administered

Because there was considerably more acute GVHD in the group randomized not to be given prophylactic MP, more MP was used for the treatment in this group. The mean total dose of MP administered during the first 4 months post-transplantation for prophylaxis and treatment was 55 mg/kg (median 35 mg/kg, range 20-260 mg/kg) in the group given MP for prophylaxis and 64 mg/kg (median 74 mg/kg, range 0-224 mg/kg) in the group with no MP in the prophylactic regimen. The difference is not significant, but there was a trend toward more MP being given to the patients randomized not to receive prophylactic MP.

Relapse

Figures 5 and 6 show the cumulative incidence of relapse for all and low-risk patients. The relapses in the total patient material include disease progression after the achievement of minimal disease state of myeloma, lymphoma, or chronic lymphatic leukemia after transplantation. Of the patients given and of those not given prophylactic MP, 17 of 53 (32%) and 16 of 55 (29%) relapsed, respectively. Among the low-risk patients, the relapse rates were 9 of 33 (27%) in the group given and 7 of 37 (19%) in the group not given MP (nonsignificant). Three of the relapses were cytogenetic relapses of CML: 1 in the group with MP and 2 in the group without MP. Thus, there were no significant differences in the relapse rates between the study groups.

Infections

Table 5 shows the infections observed in the study groups during the first 4 months and the first year after transplantation. Cytomegalovirus (CMV) infection was diagnosed in case of CMV viremia (early antigen-positive) and symptoms or signs likely to be caused by this infection. In deep fungal infection there was histologic or microbiologic documentation of fungus from a deep organ or fungemia. Septicemia were microbiologically documented. Pneumonias included all lung infiltrates, regardless of etiology, except lung abnormalities seen simultaneously with documented sepsis, deep fungal infection, or CMV infection as defined above. Most viral infections other than CMV were herpes simplex infections.

During the first 4 months, there were significantly fewer pneumonias, other bacterial infections, and deep fungal infections among the patients given MP for prophylaxis. The difference in pneumonias remained highly significant for the first year after transplantation. There was an almost significant trend toward fewer
CMV infections in the patients randomized to receive MP. There was no difference in the incidence of sepsis. The total number of infection episodes was markedly lower in the group given MP.

**Avascular bone necrosis**

Magnetic resonance imaging was carried out in patients with symptoms suggestive of avascular bone necrosis. This complication was diagnosed in 6 patients in both groups. There was no difference in the time of appearance of the complication, the median time post-transplantation being 13 months (range 6-54 months) among the patients given and 21 months (range 2-110 months) among those not given prophylactic MP.

**Blood transfusions and hospitalization**

Post-transplantation blood cell transfusions during the first 4 months and the first year are shown in Table 3. There was an almost significant trend toward fewer blood cell units given in the MP+ randomization group.

The time spent at the hospital during the first 4 months was significantly shorter among the patients given MP for prophylaxis (Table 3).

**Survival**

Figures 7 and 8 show the survivals of all and low-risk patients according to the study arm. At the time of the analysis, 32 of the 53 patients (60%) given MP and 28 of the 55 (51%) not given MP were surviving. Among the low-risk patients, the proportions of surviving patients were 25 of 33 (76%) for the patients given and 25 of 37 (68%) for those not given MP. The survivals did not differ significantly.

**Causes of death**

The principal causes of death are shown in Table 6. Relapse was the most common cause of death, followed by GVHD. There was no difference between the study groups; neither was there any difference in the causes of death among the low-risk patients. Five low-risk patients died of relapse in the group given and 6 in the group not given MP. Two low-risk patients in the MP+ group and 4 in the MP− group died of GVHD.

**Discussion**

Corticosteroids are effective in the treatment of most patients with acute GVHD and should therefore also be useful in the prophylaxis of GVHD. However, their role in the prevention of GVHD is not well established. Including the present study, the addition of corticosteroid to the most widely used prophylactic regimen, the combination of cyclosporine and methotrexate, has been evaluated in 3 fully published randomized trials with contradictory results. In the study of Storb and coworkers, the addition of MP to cyclosporine and methotrexate increased the incidence of acute and chronic GVHD in sibling transplantations, whereas in the study of Atkinson et al with small numbers of patients, no difference in GVHD was seen between the patients given and those not given prednisolone. In the present study, the addition of MP to cyclosporine and methotrexate highly significantly reduced the incidence of acute GVHD. In the study group given MP, 4 of the 10 cases of acute GVHD became manifest late, during the tapering of the MP dose. Late occurrence of acute GVHD among patients given corticosteroid was also observed in the studies by Storb et al and Atkinson et al.

*Difference between the numbers of patients with infection.
Another study showing no benefit of the addition of prednisone to the combination of cyclosporine and methotrexate has recently been published in the abstract form,\textsuperscript{18} but because details of the treatment, such as drug dosages and timing of administration were not given, this study cannot be further discussed here.

There were differences in the prophylactic scheme between the 2 previous studies and the present one, which are likely to explain the differences in the results. The most obvious difference is the timing of corticosteroid administration. In the previous studies, the corticosteroid treatment was initiated on the day of transplantation at a dose of 1 mg/kg per day; the dose was halved at 3 weeks and discontinued 30 to 35 days post-transplantation. In the present study, MP was started on day 14 after transplantation at 0.5 mg/kg per day, the maximum dose of 1 mg/kg per day was given on days 21 to 35, and thereafter the dose was slowly tapered and the administration discontinued on day 110. The reasoning behind this schedule was 2-fold: MP was initiated only after methotrexate administration was completed to avoid any interference with the effect of this drug, and the highest dose was scheduled to be given at the time of the highest risk of the appearance of symptomatic GVHD. In our previous experience, the median time of the appearance of acute GVHD in patients given cyclosporine and methotrexate prophylaxis was day 26 post-transplantation. The importance of the timing of corticosteroid administration is supported by the observation in the Seattle study\textsuperscript{16} that if the initiation of MP treatment was postponed to day 15, the increasing effect on the incidence of acute GVHD disappeared.

Another difference between the present study and the 2 previous ones is the dosing of cyclosporine. The intravenous dose at the early stage was the same, but after the switch to oral route we gave a much lower dose: 3 mg/kg per day compared with 12.5 mg/kg per day. We chose this low dose because preliminary information indicated that patients on low-dose cyclosporine may do at least as well as those on a higher dose and that increasing the intensity of GVHD prophylaxis may increase the relapse rate.\textsuperscript{19} We also had significant problems with thrombotic microangiopathy at the time of designing the present study. Lower cyclosporine doses might have increased the incidence of acute GVHD among the patients not given MP compared with the other studies. This does not, however, seem to be the case. Because we also treated grade I GVHD, which apparently differs from the policy applied in other studies, the comparison is not perfectly valid, but the incidence and severity of acute GVHD do not seem to be essentially different in the 3 studies. The incidence of grade II-IV acute GVHD among patients not given corticosteroid prophylaxis was 36% in both the Seattle study\textsuperscript{16} and the present one. There was less grade II-IV acute GVHD in the monocorticosteroid group of Atkinson et al\textsuperscript{11} than in the present study (15% vs 36%) but more grade I-IV GVHD (75% vs 56%). These differences may be partly explained by the often vague separation of grade I from grade II in clinical practice. Thus, the beneficial effect of the addition of MP in the present study does not appear to have been caused by an unduly high GVHD incidence in the control arm.

A further detail where the 3 studies may have differed is the use of folic acid rescue after methotrexate treatment, as in the present study. This detail is not usually reported but, according to a recent survey among European centers, approximately one third of the centers gave folic acid subsequent to methotrexate administration.\textsuperscript{1}

More patients in the group not given MP had day 111 methotrexate omitted because of toxicity—i.e., most cases severe mucositis—compared with the triple prophylaxis group. There were no obvious differences in the baseline characteristics of the study groups to explain the difference in toxicity, which might have been a mere chance occurrence. The difference in the methotrexate administration could have been one reason for the difference in the incidence of acute GVHD. However, there was a trend toward less acute GVHD among the patients not given the fourth dose of methotrexate compared with those given the full course; the incidence was 14% versus 21% in the group given MP and 41% versus 65% in the group not given MP, respectively. Therefore, the fact that fewer patients in the group not given prophylactic MP received the fourth dose of methotrexate does not explain the higher incidence of acute GVHD in this group.

A trend was observed toward less chronic GVHD in the group given prophylactic MP. Although this effect did not reach significance, the trend may indicate that a low dose of corticosteroids during the first 3 to 4 months after transplantation may have some prophylactic effect on chronic GVHD. This is logical because corticosteroid is the first-line treatment of chronic GVHD. Storb and coworkers\textsuperscript{10} observed an increase in chronic GVHD among patients administered prophylaxis with MP in addition to cyclosporine and methotrexate compared with those not given MP. Likewise, Deeg et al\textsuperscript{1} found that the addition of MP to cyclosporine prophylaxis increased the incidence of chronic GVHD. The causes of these unexpected findings and the difference from the results of the present study are not clear, but an obvious factor is the duration of MP prophylaxis. We gave MP until day 110 post-transplantation, whereas the administration was discontinued on day 35 in the study by Storb et al\textsuperscript{10} and on day 72 in the study by Deeg et al.\textsuperscript{3}

In some studies, the intensification of GVHD prophylaxis has been associated with an increased risk of relapse.\textsuperscript{20,21} In the present study, the addition of MP to the prophylactic regimen had no effect on the relapse rate. It may be noteworthy that we used relatively low cyclosporine doses.

ARDS indicates acute respiratory distress syndrome; DIC, disseminated intravascular coagulation.
There were fewer infections among the patients given MP for prophylaxis than in the control group. Because GVHD, especially chronic GVHD, is associated with immunosuppression, the low incidence of GVHD among the patients given prophylactic MP may at least partly explain the lower infection rate. Because pneumonia after BMT is often associated with immunologic processes, the reduction of GVHD may explain the lower rate of pneumonias. High doses of MP, more often used for the treatment of acute GVHD in the study group not given prophylactic corticosteroid, probably contributed to the higher incidence of infections.

The recovery of the neutrophil counts after transplantation was significantly faster among the patients who received MP prophylaxis, as also reported previously by Storb et al.10 This was seen despite the fact that more patients not given MP for prophylaxis had the last methotrexate dose omitted because of toxicity. The faster neutrophil recovery was probably caused by demargination because there was no significant difference in the platelet recovery. The nonsignificant trend toward fewer blood cell transfusions given to patients with MP prophylaxis may reflect the lower incidence of GVHD in this study group. GVHD is associated with cytopenias in a significant proportion of patients; the mechanisms may be manifold and complex.24,25 The significantly shorter hospitalization during the first 4 months in the group randomized to receive prophylactic MP was due to the lower incidence of acute GVHD and fewer infections.

The adverse effects of corticosteroids, particularly infections, hypertension, hyperglycemia, and avascular bone necrosis are well known, and they have to be taken into account when weighing the advantages and disadvantages of corticosteroid administration. In the present study, the prophylactic use of MP did not result in greater exposure to corticosteroids because there was markedly more acute GVHD in the control group and the doses used for treatment were higher than the prophylactic doses. As shown above, there were fewer infections in the group given MP prophylaxis. Blood pressure and glucose balance were not prospectively recorded. There were no differences in the incidence or time of the onset of avascular bone necrosis.

The treatment policy of acute GVHD applied in this study was aggressive. We treated even early (grade 1) acute GVHD with high-dose corticosteroids to stop effectively the GVHD process. While this policy may be more efficient in the treatment of acute GVHD than a more conservative approach, adverse effects may outweigh the benefits. In a registry study of the European Group for Blood and Marrow Transplantation (EBMT), it was found that patients treated for acute GVHD at centers applying a very intense treatment policy had a worse outcome than those treated at centers applying a more conservative approach.26 The treatment of all grades, including grade 1, at first signs with initially at least 10 mg/kg per day of MP resulted in poorer survival and higher mortality in infections and poor graft function than the treatment of only grade II+ acute GVHD with 2 mg/kg per day or less. Although these results were only suggestive due to the nature of the study, the findings indicated that a very intense treatment policy may not be optimal for the outcome. In the present study, the patients randomized not to receive MP did, in fact, receive as much MP on the average as those randomized to receive MP for prophylaxis because of markedly more GVHD and intense treatment.

The randomization was not stratified according to risk groups. Therefore, the analysis of the outcome of low-risk patients is a retrospective subgroup analysis. However, the distribution of low-risk patients in the randomization groups was balanced, and there were no significant differences between the low-risk groups. The analysis of the outcome parameters of these more homogeneous patient groups showed findings in line with the results obtained in the analysis of the entire treatment groups. It was especially useful to observe that there was no difference in the relapse rate among the low-risk patients given or not given MP for prophylaxis.

In conclusion, the present study showed that the addition of MP to the combination of cyclosporine and methotrexate markedly reduced the incidence of acute GVHD without causing untoward effects. Based on the results of 2 previous studies and the present one, it appears that the timing of corticosteroid administration is important for the effect. There was a trend toward less chronic GVHD among the patients administered prophylactic MP. The addition of MP had no effect on the relapse rate or survival.

Low-dose cyclosporine of short duration increases the risk of mild and moderate GVHD and reduces the risk of relapse in HLA-identical sibling marrow transplant recipients with leukaemia

S Carlens1,2, J Aschan1,3, M Remberger2, MS Dilber3 and O Ringdén1,2
1Centre for Allogeneic Stem Cell Transplantation, Departments of 2Clinical Immunology, and 3Haematology, Huddinge University Hospital, Huddinge, Sweden

Summary:

Low-dose cyclosporine (CsA), starting at 1 mg/kg/day i.v. with early discontinuation, and four doses of methotrexate (MTX), was given to 82 consecutive leukaemic patients receiving HLA-identical sibling marrow transplants. Retrospective controls (n = 40) received CsA, starting at 5–7.5 mg/kg/day i.v., given for 1 year, and MTX. In the low-dose group, the risk of acute GVHD grades I–II was 78% as compared to 57% among the controls (P < 0.01). The risk of acute GVHD grades III–IV was 2% and 5%, respectively (NS). Chronic GVHD occurred in 60% in the low-dose group and 24% in the controls (P < 0.001). Extensive chronic GVHD did not differ between the groups (3% vs 6%). In multivariate analyses, low-dose CsA was the only factor associated with acute GVHD grades I–IV (P = 0.02). Significant risk factors for chronic GVHD included low-dose CsA (P = 0.002) and CML (P = 0.03). Transplant-related mortality at 3 years post-BMT was 22% and 19%, in the low-dose group and controls, respectively (NS). The probability of relapse was 26% in the low-dose group and 53% in the controls (P = 0.06). In multivariate analysis, high-dose CsA was the strongest risk factor for relapse (P = 0.03). The 3-year relapse-free survival was 58% in the low-dose group and 43% in the controls (P = 0.1).

Keywords: relapse; immunosuppression; graft-versus-host disease; bone marrow transplantation

Cyclosporine A (CsA), together with a short course of methotrexate (MTX), is today the most commonly used protocol for the prevention of graft-versus-host disease (GVHD) after allogeneic BMT.1–4 The potent immunosuppressive effect and the pronounced side-effects of CsA have been described elsewhere in detail.5–7 CsA has often been given i.v. from the day before BMT in doses ranging from 3 to 5 mg/kg/day. However, up to 10–20 mg/kg/day has also been used in the earlier era of BMT.1,2,8 The schedules for administration vary between centres and have also been modified over time. Previous studies have shown that the use of high doses of CsA, to minimise the incidence of severe GVHD, not only correlates with increased organ toxicity, but also leukaemic relapse.9 This is believed to be caused by a diminished graft-versus-leukaemia effect (GVL).10–13 Low-dose CsA was also reported to reduce the relapse incidence and increase patient survival.9 Several methods are available for monitoring serum and blood levels of CsA.7 These levels have been reported by some investigators to correlate with the grade of GVHD,14 although others have shown no correlation.15,16 This discrepancy can be explained to some extent by a large inter-individual variation in bioavailability.7 The optimal dosage and duration of CsA treatment have yet to be found. Customarily, many centres have given CsA for 6 months post-BMT. Some studies have reported safe discontinuation of CsA at day 60 or 90 after BMT.14,17 In contrast, a study from our centre showed an increased incidence of chronic GVHD if CsA was discontinued after a median of 71 days, as compared to 1 year.18

In the present study, we aimed to compare the clinical outcome in leukaemic patients receiving low-dose CsA (starting at 1 mg/kg/day i.v.) aiming at 2 months’ duration with retrospective controls receiving CsA, starting at 5–7.5 mg/kg/day i.v. and given for 1 year. The CsA doses and serum levels during the first 3 weeks after BMT have been reported to be crucial to the development of GVHD and the GVL effect.9 Therefore we aimed to compare blood levels of CsA during this time period and analyse these in relation to the actual dose of CsA given and clinical outcome. We also wished to assess the impact of low-dose CsA on the incidence of GVHD and relapse in the presence of other, previously reported, potential risk factors.19–21

Materials and methods

Patients and donors

Eighty-two patients with leukaemia (AML, ALL and CML), receiving allogeneic stem cell grafts between February 1993 and June 1998, were included in the study group, all of them having HLA-A, -B and DR identical sibling donors and receiving the low-dose CsA protocol (starting at 1 mg/kg/day i.v., described below), in combination with MTX. This group was compared with retrospective controls (n = 40), transplanted between 1985 and 1993, and receiving CsA starting at 5–7.5 mg/kg/day i.v., in combination...
with MTX. The main clinical data of the patients (study group and controls) and their donors are depicted in Table 1.

**Conditioning**

The majority of patients (*n* = 111) were conditioned with CY 120 mg/kg and TBI 10 Gy in one setting, as previously described. Eleven patients were conditioned with a small BUCY regimen, consisting of BU 4 mg/kg p.o. in divided doses daily for 4 days, in combination with 120 mg/kg of CY (10 patients in the low-dose group and one patient among the controls). Before November 1988, all patients received 8-12 mg MTX or 20 mg Ara-C intrathecally (IT) twice before BMT to prevent CNS leukaemia. Post-transplant, IT MTX was given from day 32 and every other week until day 102. After 1988, only patients with ALL, AML M4 and M5 and/or with a history of CNS disease were given this treatment. To patients with previous CNS disease, IT MTX was thereafter given every 8th week until 24 months post-BMT.

**Immunosuppression and monitoring of CsA levels**

All patients received CsA in combination with four doses of MTX i.v., 15 mg/m² on day 1 and 10 mg/m² on days 3, 6 and 11. CsA treatment was initiated i.v. on the day before BMT. Patients receiving low-dose CsA were given 1 mg/kg/day i.v. divided into two or three doses from day -1. On day 1, or as soon as the patient could take CsA orally, 3 mg/kg/day was given divided into two doses. From 2 months after BMT, in the absence of GVHD, the CsA dose was gradually tapered. Among the retrospective controls, CsA treatment was started at 5-7.5 mg/kg/day. From day 1, or as soon as possible, CsA was given orally 12.5 mg/kg/day, and the highest tolerated CsA dose, with respect to serum creatinine levels, was given for 6 months. The dose was then gradually tapered and, in the absence of GVHD, discontinued after 1 year. In the low-dose group, CsA doses were adjusted according to blood levels and/or if toxicity was seen. We aimed at maintaining the CsA blood levels around 100 ng/ml. Three different methods for determining CsA blood levels have been used from 1985 up until today, without altering the reference values. Between 1985 and April 1988, the Sandimmun kit (formerly manufactured by Sandox, Basel, Switzerland) was used. From April 1988 until May 1997, we used the Cyclo-trac SP® (Inestar, Stillwater, MN, USA). Both of these methods were specific radioimmunoassays. Since May 1997, we use the EMIT 2000 Cyclosporine-specific Assay (Behring, Cupertino, CA, USA).

**Grading and treatment of GVHD**

Acute GVHD was graded from 0 to IV according to Glucksberg et al. Grade I acute GVHD was treated with 2 mg/kg/day of prednisolone for 1 week and the dose was then tapered. In patients with progressive symptoms, prednisolone was continued for a longer period. In some severe cases, methylprednisolone (0.125–0.5 g/day), ATG, additional MTX or PUVA were also given. Chronic GVHD was graded as limited or extensive. It was initially treated with CsA and steroids. If a response was not seen, some patients received TLI, PUVA, and more recently extracorporeal PUVA.

**Statistical analysis**

The results were analysed as of 15 October 1998, allowing for a median follow-up time of 38 months (range 5-68 months) in the low-dose group. Time to GVHD, relapse, survival, etc., were analysed by the life-table method with the log-rank test (Mantel-Haenszel), taking censored data into account. Non-parametric analysis was performed with the Wilcoxon’s signed rank test and the Mann-Whitney U test was used for paired and unpaired data, respectively. When analysing the risk of relapse and leukaemia-free survival (LFS), a separate subgroup analysis for patients in early and advanced disease was also performed. When evaluating risk factors for acute GVHD, the logistic regression model was used in uni- and multivariate analyses. All patients with a survival of at least 30 days were analysed and grades I-IV were regarded as the event. We evaluated the low-dose regimen among eight other risk factors, previously reported to be significant at our centre. These included donor and recipient age, sex-match (including immunised female-to-male recipient), time to engraftment and pretransplant herpes virus serology for CMV, HSV, VZV and EBV (Table 2). When analysing risk factors for chronic GVHD, relapse, and leukaemia-free survival, the Cox regression model was used for the uni- and multivariate analyses. Nineteen risk factors for chronic GVHD and six risk factors for relapse, previously reported to be significant in univariate analysis from our centre, were evaluated together with the low-dose regimen respectively (see Tables 3 and 4). When evaluating age as a risk factor for chronic GVHD a continuous variable was used. This is in contrast with the analysis of risk factors for acute GVHD where an age cut-off at 17 years was used.

The reason for this discrepancy is that the age factor is presented in the way that it was originally used in our previous two studies. 26 For chronic GVHD, all patients surviving at least 90 days after BMT, and therefore at risk, were included in the analyses. Multivariate analysis of risk factors for relapse was performed both from day 90 and from the day of transplant.

Four risk factors, previously reported to correlate with inferior FS, 21 were evaluated together with the low-dose regimen. These included acute GVHD grades II-IV, chronic GVHD, disease stage, transplant herpes virus serology for CMV, HSV, VZV and EBV, and TBI as compared to BU.

All CsA concentrations for the first 3 weeks after BMT were collected from patient records. The CsA dose and patient weight given on day 22 were also recorded. When analysing CsA concentrations, we calculated the geometric means for each individual patient for the first 3 weeks post-BMT. These means were then added, creating arithmetic means, weekly and overall for the first 21 days.

Results

CsA dose, serum levels and duration of treatment

In the low-dose group, patients had a median of seven CsA concentrations recorded during the first 3 weeks post-BMT (range 5-14). Among controls, the median number of CsA concentrations was 10 (range 0-17). In the low-dose group, where patients were to receive a p.o. dose of 3 mg/kg/day, the actual mean dose given on day 22 post-BMT was 4.6 mg/kg/day orally (range 0-11.8 mg/kg). Patients in the control group, who were to receive an initial p.o. dose of...
12.5 mg/kg/day, were actually given a mean dose of 12.7 mg/kg (range 0.250.250 mg/kg) (P < 0.001).

Mean blood levels in the low-dose group for weeks 1, 2 and 3 were 152, 156 and 162 ng/ml, respectively. In the controls with a long CsA course, the corresponding mean blood levels of CsA were 518, 543 and 605 ng/ml (P < 0.001).

Patients in the low-dose group had a median duration of CsA treatment of 6.6 months (range 2.5–42.6), compared to 11.7 (range 0.7–48.8) months in the control group (P = 0.01).

**Acute GVHD**

Patients receiving low-dose CsA ran an actuarial risk of acute GVHD grades I–II of 78%, compared to 57% in the control group (P < 0.01) (Figure 1). However, the incidences of acute GVHD grades III–IV were similar, 2% vs 5%, in the low-dose group and controls, respectively (NS) (Table 5).

In logistic regression using univariate analysis, low-dose CsA, as compared to high-dose, was the only significant risk factor for acute GVHD grades I–IV (P = 0.02) (Table 2). Donor age more than 17 years, as compared to younger donors, showed a trend towards significance (P = 0.08) and was therefore included in the subsequent multivariate analysis. However, only low-dose CsA maintained its significance in the multivariate analysis (P = 0.02) (Table 4).

**Chronic GVHD**

The actuarial risk of chronic GVHD was 60%, as compared to 24% in the controls (P < 0.001) (Figure 2). However, as depicted in Table 2, the risk of extensive chronic GVHD was the same in the two groups. In Cox regression univariate analysis, low-dose CsA (P < 0.01), recipient (P = 0.02) and donor age (P = 0.02) were significant factors associated with chronic GVHD. CML, as compared to acute leukaemia, and preceding acute GVHD (grades I–IV) were borderline significant (P = 0.06 and P = 0.06, respectively) and therefore were also included in the stepwise multivari-
Significant factors in multivariate analysis comprised high-dose CsA \( (P = 0.03) \), a more advanced disease \( (P = 0.04) \) and acute leukaemia \( (P = 0.05) \). Chronic GVHD did not maintain its significance in the multivariate analysis (data not shown). For this reason, multivariate analysis of risk factors for relapse, calculated from the day of transplant, is shown only (Table 4).

For 3-year LFS and actuarial patient survival the figures were 58% and 63% in the low-dose group, as compared to 43% and 50% among controls \( (P = 0.1 \) and \( P = 0.1 \), respectively) (Figure 4). Patients with early disease had an LFS of 63% in the low-dose group as compared to 42% in the control group \( (P = 0.6) \). For patients with advanced disease, the probabilities of LFS were 45% and 25%, in the low-dose group and the controls, respectively \( (P = 0.06) \). The only factor that was significantly associated with a superior LFS, in uni- and multivariate analysis was the presence of chronic GVHD \( (P = 0.02) \).

Discussion

Patients receiving GVHD prophylaxis with low-dose CsA ran a significantly higher risk of developing acute GVHD grades I-IV and less in those with a high control group. The mean dose of CsA given was 4.6 and 12.7 mg/kg/day orally in the two groups, respectively. In the low-dose group, we aimed to give 3 mg/kg/day orally. The increased dosage may be due to the fact that the CsA doses tended to increase in some patients developing acute GVHD. The median CsA level in blood was, therefore, also higher, 150 ng/ml, rather than 100, which was planned. CsA doses in the control group were given on the basis of the standard tolerable dose with respect to serum creatinine levels. One may therefore assume that this corresponds approximately to the mean CsA dose of 12.7 mg/kg/day seen in the control group. In a previous report by Bacigalupo et al., 81 allografted patients with acute leukaemia were randomized to receive CsA 1 or 5 mg/kg/day i.v. from day -1 to day +20. The actuarial risk of developing acute GVHD grades II-IV did not differ significantly between the groups in their study. However, in a Cox model, when stratifying for age and the CsA dose, the risk of acute GVHD grades II-IV was significantly higher among older patients (>20 years) and among patients receiving CsA 1 mg/kg/day. Multivariate analysis in our study showed that low-dose CsA was the only significant risk factor for developing acute GVHD grades I-IV. Unlike many other centres, we started to treat acute GVHD already at grade I. 14 This may partly explain why there were no differences in severe acute GVHD (grades III-IV) between our two groups.

Low-dose CsA was the strongest predictive factor for leukaemic relapse, when included in multivariate analysis \( (P = 0.03) \). These findings confirm those reported by Bacigalupo et al. 20 Concomitant treatment with cyclophosphamide and ciprofloxacin, during the pre-transplant conditioning, has been shown to correlate with an increased risk of relapse. 21 However, this risk factor was only present in the control group and could therefore not be evaluated separately in our analyses. Chronic GVHD was not significantly associated with an increased risk of relapse in multivariate analysis. One may speculate that when patients are given a significantly lower level of immunosuppression, the impact of chronic GVHD, as a risk factor for relapse, is of less importance. Interestingly, Bacigalupo et al. reported no difference in the risk of chronic GVHD between the high- and low-dose groups, in spite of a significant difference in relapse risk.

Figures for 3-year relapse-free survival and overall patient survival were in favour of our low-dose regimen, although differences between the groups did not reach significance. This may be due to the low number of patients. With more patients and a longer follow-up time, LFS may be significantly different, because TRM was the same in the two groups.

The duration of the CsA treatment was 6.6 and 11.7 months in the low-dose group and controls, respectively. We found that early discontinuation of CsA in the low-dose group was often complicated by ongoing mild acute GVHD, which prolonged the course of CsA. There have been reports where early discontinuation of CsA has not been associated with an increased risk of chronic GVHD. 16,17 In contrast, a previous study from our centre showed an increased incidence of chronic GVHD, if CsA was discontinued after a median of 71 days, instead of 1 year. 14 A recent study showed that preceding acute GVHD is often of less importance for the development of chronic GVHD than was found earlier. 30 This may be due to the use of MTX combined with CsA, in contrast to monotherapy. In line with this, early discontinuation of CsA contributed to an increased risk of developing chronic GVHD, as shown in our study (60% among low-dose patients vs 24% among controls), hence not merely an effect of low CsA dosage. The optimal LFS in leukaemic patients is seen in patients who develop grade 1 acute GVHD. 30 Since 21% of the patients did not develop acute GVHD at all, there may still be reason to reduce the CsA dose further, and/or discontinue CsA earlier in some patients.

We conclude from these data that a low-dose regimen with CsA, starting at a dose of 1 mg/kg/day i.v., in combination with four doses of methotrexate (MTX), is an advan-
tageous approach for recipients of HLA-identical sibling marrow transplants, with leukemia. The risk of mild acute GVHD and limited chronic GVHD increased in the low-dose group. This enhances the GVL effect, which subsequently reduces the risk of leukemic relapse post-BMT. This regimen appears safe because the risk of acute GVHD grades III-IV, TRM and extensive chronic GVHD did not increase.

CHAPTER 5

CAMPATH MONOCLONAL ANTIBODIES

THE SECOND LOCAL INNOVATION
The Cambridge connection, as it has come to be widely known, proved to be a major research opportunity in the understanding and, equally important, management of immunologically mediated complications arising from allogeneic grafting\textsuperscript{150-152}. This was made possible through collaboration, which is actively ongoing, with Professor Herman Waldmann and Doctor Geoff Hale who have relocated their laboratory to Oxford\textsuperscript{153-155}. In the early studies it was demonstrated that reverse rejection or graft-versus-host disease in both acute and chronic forms could be markedly reduced by the presence of a specific immunoglobulin designed to blunt an initial phase of immune competence through paralysis of the T-helper lymphocyte population\textsuperscript{156-158}.

In parallel with the clinical studies being correlated, collectively analysed and then reported through the Campath users group that brought together investigators from many centres worldwide\textsuperscript{159-164} our early endeavours in the rabbit model, designed to further dissect this interrelationship\textsuperscript{162-164}, started to reveal an interesting new phenomenon.

Thus it was demonstrated that significant impact could be made on rejection. Not entirely surprisingly was the hypothesis that immune injury to recipient keratinocytes, biliary endothelium and enterocytes particularly of the small intestine that defined the acute graft-versus-host disease would turn out to be markedly reduced. These findings were first noticed with the initial IgM monoclonal antibody that was lytic and reduced visible numbers of lymphocytes. Comparably however was dramatically altered function with the next generation of IgG proteins that were opsonic also altering the course of this devastating adverse effect\textsuperscript{165-167}.

In a seminal laboratory study, widely accepted as landmark, we showed that, for the first time ever, an entirely different approach was possible and even more effective. Thus, by exposing the incoming graft \textit{ex vivo} or \textit{in vitro} to the same classes of this family of proteins\textsuperscript{20,168,169}, acute GVHD virtually disappeared.

Furthermore this pattern was preserved with the humanised variant designated as Campath 1H substantially limiting multiorgan lesions in the recipient with major outcome improvement. This research continues to be translated into treatment programmes in many countries\textsuperscript{170-172}.
Additionally systematic studies have, over many years, demonstrated that there is no associated increase in leukaemia relapse at least as far as acute myeloblastic subtypes are concerned\textsuperscript{173,174}.

Careful characterisation of the skin, liver and the bowel have led to the description of the new \textit{forme fruste} of acute immunologically mediated disease. This variant is readily responsive to topical corticosteroids and remarkable for having no consequential chronic expression. Meticulous characterisation of infectious complications have also failed to demonstrate any increase in cytomegalovirus infections.

These impressive outcome data continue to be reported on regular international basis\textsuperscript{155,159,168,171,175,176}. 
Campath-1 for prevention of graft-versus-host disease and graft rejection.
Summary of results from a multi-centre study

G. Hale, H. Waldmann for CAMPATH users, Department of Pathology, University of
Cambridge, Tennis Court Road, Cambridge, UK

The rat IgM antibody CAMPATH-1H recognizes an abundant family of glycoproteins
present on virtually all human lymphocytes and monocytes (1). We have obtained
rat IgG1, IgG2a, IgG2b and IgG2c antibodies with the same specificity and they are
lytic with human complement to a greater or lesser extent. Since 1982
CAMPATH-1H has been widely used for removal of T cells from human bone marrow to
prevent graft-versus-host disease (GVHD) (2). In 1986 we reported the combined
experience of the CAMPATH users group and noted a substantial reduction in the
incidence and severity of GVHD but an increased risk of graft rejection (3).
Other effective techniques for T cell depletion have all given similar results
(4). Subsequently there have been several suggestions of an increased relapse
risk following T cell depletion and this has been most clearly demonstrated in
CGL (5). Here we summarise the results of T cell depletion with CAMPATH-1H up to
December 1987 and outline a new approach to prevention of graft rejection using
the IgG2b CAMPATH-1G to give extra immunosuppression to transplant recipients.

A total of 441 matched sibling transplants for patients with leukaemia were
reported by 20 centres. There was no special selection of patients, and other
aspects of their treatment remained largely unchanged except that the majority
received no post-transplant immunosuppression and some patients received
additional total lymphoid irradiation (TLI) in an attempt to reduce the risk of
graft rejection. The median age of patients was 29 and the distribution by
disease was: ALL 98, AML 128, CGL 188, others 27.

T cell depletion of marrow buffy coat cells was accomplished by a single
TREATMENT with CAMPATH-1H and 25% autologous serum as described before (2). This
reduced the fraction of E-rosette forming cells to 1% or less in 90% of the
patients. Further depletion can be achieved by an extra round of complement
lysis, but this has not yet been used clinically. The median number of nucleated
cells infused was 2.3 x 10^9/kg. Engraftment was obtained in 393 patients with a
median time to reach 0.5 x 10^9 neutrophils/l of 19 days.

| Graft-versus-host disease and graft failure in matched sibling transplants |
|--------------------|----------|--------|--------|----------------|----------------|
|                    | No of  | Acute GVHD | Chronic GVHD |               |               |
|                    | patients| 0 1 2 3/4 | 0 M S | complete partial |
| GVHD prophylaxis: |         |         |         |                |                |
| 180 CyA, 3 Mtx     | 181     | 93 35 13 9 | 98 28 3 | 20 3           |
| none               | 260     | 127 26 14 18 | 128 13 4 | 44 4           |
| Total              | 441     | 220 61 27 27 | 226 41 7 | 64 7           |

Patients are scored 0 for GVHD only if they survived 100 days (acute) or 120 days
(chronic) with durable engraftment.
The incidence of acute GVHD was 18% grade 1, 8% grade 2 and 8% grade 3-4. The percentages are calculated as fraction of the 335 patients who survived to day 100 with durable engraftment or suffered from GVHD but died before day 100. Acute GVHD was not significantly affected by the use of prophylactic CyA but correlated with the infusion of more than 4 x 10^6 T cells/kg (P<0.0001). The incidence of chronic GVHD was particularly low; 15% mild/moderate and 3% severe (calculated as a percentage of 274 patients who survived to day 120 with durable engraftment). Chronic GVHD was not significantly associated with T cell dose but, paradoxically, it did correlate with the use of prophylactic CyA (P=0.008).

The incidence of graft failure was 15% complete and 3% partial (reversed by immunosuppressive treatment). It is likely that most graft failure was due to host rejection of the marrow. However, no particular conditioning regime seemed to be able to prevent graft rejection despite some attempts at intensification. The most promising method tested appeared to be the addition of TLI; however there were still 12 cases (11%) of graft failure among 108 patients who received TLI compared with 59 cases (18%) among 333 patients who did not receive TLI.

The risk of haematologic relapse was assessed for patients with acute leukaemia transplanted in first remission and for patients with chronic granulocytic leukaemia transplanted in chronic phase. So far the results for acute leukaemia do not differ significantly from published registry results for unpurged transplants, but the results in CGL illustrate the increase in relapse risk following T cell depletion.

The following patients were excluded from analysis of the effect of GVHD and engraftment rate in CGL: 4 who died early, 11 who did not engraft and 2 where engraftment day was not reported. Inclusion of these patients did not affect the remission chances but of course overall survival was then slightly lower. Probability (P) values were calculated by the log-rank method.

There are at least two alternative hypotheses for a possible anti-leukaemic effect of the donor T cells (6). Either they may exert a direct cytotoxic action against the leukaemia cells or there might be an indirect effect mediated by the immune balance between donor and recipient T cells. A low level of host anti-graft activity might delay engraftment and allow a higher proportion of host (including leukaemic) stem cells to repopulate the marrow. On the first
hypothesis we expect relapse to correlate (roughly) with lack of GVHD; on the second, we think that relapse might correlate with slow engraftment.

Detailed analysis of relapse in ALL was impossible because of the small numbers of patients transplanted at any particular phase. For AML transplanted in first remission, Cox linear regression analysis revealed only age as a significant risk factor for relapse (P=0.04), but patients with no GVHD (acute or chronic) also suffered more relapse and this was just significant (P=0.05) after allowing for the higher risk of relapse of older patients. In CGL, there were three risk factors for haematological relapse: higher dose-rate radiation (P=0.02), slow engraftment (P=0.02) and lack of GVHD (P=0.01). The effect of radiation dose rate may not be reliable because of differences in measurement techniques between centres and it could easily have been confounded with other inter-centre variations. The independent correlation of relapse with both lack of GVHD and slow engraftment suggests that both mechanisms of graft-versus-host-leukaemia may be operating in this disease.

Graft rejection is the major problem following T cell depletion in transplants for non-malignant disease and, as we have suggested above, it may also be connected with some of the extra relapse in CGL. We have recently developed the rat IgG2b antibody CAMPATH-1G which has similar specificity to the original IgM, hoping that it would be a useful immunosuppressant for conditioning, by analogy with our successful use of monoclonal antibodies to prevent rejection in a mouse model (7). CAMPATH-1G is active both in complement fixation and antibody dependent cell-mediated killing (8). Three sets of clinical studies suggest that it can eliminate lymphocytes and be immunosuppressive in vivo.

Serotherapy of patients with leukaemia and lymphoma

A total of 16 patients with B cell leukaemias (8) or lymphomas (8) have been treated with CAMPATH-1G (25mg/day for 10 days). The majority had advanced disease which was unresponsive to chemotherapy. In contrast to previous experience with CAMPATH-1H and other antibodies, 13 patients showed tumour regression following antibody treatment. Blood lymphocytes were always cleared, splenomegaly (6 patients) was always improved and bone marrow infiltration (when measured, 7 patients) was always reduced and sometimes (3 patients) cleared of tumour cells. The effect on lymph nodes was not consistent; sometimes they were reduced in size (4 patients) but in others they were unaffected (4 patients) and CNS disease (3 patients) was unaffected. Blood lymphocytes remained low for weeks or months after treatment arguing for cell elimination rather than sequestration.

Treatment of kidney graft rejection

Six patients with acute kidney graft rejection were treated with CAMPATH-1G (5mg/day for 10 days). All had biopsy-proven cellular rejection; in addition four had some vascular changes (presumably antibody-mediated). Three had already received high-dose steroids but without response. In each case the cellular rejection was reversed (judged by biopsy and improved function) though two kidneys were subsequently lost with humoral rejection.

Treatment of graft-versus-host disease

A total of 28 patients with severe GVHD have been treated with CAMPATH-1G
(5mg/day for 10 days). This was a heterogeneous group and hard to analyze in detail. Most had acute GVHD which had not responded to conventional treatment. All showed a response to antibody treatment, judged by improvements in some or all clinical symptoms and biopsy. Some made a good response and became long-term survivors, others suffered recurrence of GVHD after stopping antibody therapy and several died of infectious complications.

Studies are now underway in several centers to assess whether CAMPATH-1G might be useful for prevention of marrow graft rejection. So far, most have concentrated on situations more difficult than transplants from matched siblings, e.g., unrelated donors, partly matched family members or retransplants after graft failure. Although we find the preliminary results encouraging, it is still too early to draw firm conclusions.

Acknowledgements

We thank the Medical Research Council UK for financial support and acknowledge the work of Peter Friend (Department of Surgery) and Martin Dyer (Department of Haematology) in the trials of CAMPATH-1G for treatment of kidney rejection and serotherapy of tumours. We are very grateful to many colleagues and their transplant teams at the following centers for sharing results of marrow transplants and treatment of GVHD. (The numbers of transplants evaluated from each center is shown in brackets.) Most of the data and ideas in this paper were discussed at a meeting of CAMPATH users in Cambridge in Jan 1988. SUMMARY
CAMPATH-1H is a rat IgM monoclonal antibody which binds to an antigen on all human lymphocytes and monocytes, but which is not present on marrow stem cells [1]. Lymphocytes can be efficiently killed in bone marrow buffy coat preparations using the antibody and donor human serum as a means to avoid graft versus host disease (GVHD) [2]. An analysis of 520 matched sibling bone marrow transplants (BMT) for leukemia demonstrates that T-cell depletion using CAMPATH-1H markedly reduces the incidence and severity of GVHD, but there is an increased risk of graft rejection. In the case of CGL in chronic phase there is also an associated extra risk of relapse, particularly in patients where engrafment may have been compromised [3]. A rat IgG2b antibody of the same specificity as CAMPATH-1H (CAMPATH-1G) was developed which is able to both fix human complement and opsonise lymphocytes in vivo [4]. Initial studies for the prophylaxis of bone marrow rejection in 55 mismatched and matched unrelated donor (MUD) BMHS suggest that CAMPATH-1G treatment of the recipient may reduce, but not eliminate, marrow graft rejection. The broad CAMPATH-1 specificity means that it is also ideal for purging a range of lymphoid malignancies prior to autologous BMT, or even for direct serotherapy of leukemic patients. However, there may be limitations of monoclonal antibody purging using complement or other natural effector mechanisms either in vivo or in vitro; in particular antigenic modulation and an anti-globulin response. Phase 1 studies of 'in vivo purging' with either recombinant antibody or in vitro purging were mostly unsuccessful, most interest has been focussed on ways of trying to improve antibodies by, for example, coupling them to cytotoxic agents. However, our approach has been instead to select monoclonal antibodies which most efficiently use the natural humoral (complement) and cell-mediated (K-cell) effector mechanisms. From a number of studies using rat antibodies against mouse or human lymphocytes, it is now clear that the ability to kill cells both in vitro and in vivo depends on two factors. First, only certain cell surface antigens seem to be effective targets for lysis [7], and second, the monoclonal antibody must be of an appropriate isotype [8]. For example, the CAMPATH-1 antigen (CD52; Fourth International Workshop on Human Leucocyte Differentiation Antigens, Vienna, 1989) is an antigen present on all human lymphocytes and monocytes, and represents a particularly good, non-modulating target antigen for lysis. The rat IgM antibody (CAMPATH-1H) to this antigen is very efficient at lysing cells in vitro with donor human serum as a source of complement, and is therefore our reagent of choice for purging lymphoid cells, including T cells, from bone marrow transplants [1]. However, a series of antibodies to the same antigen (rat IgM, IgG2a, IgG2b, and IgG2c), only the rat IgG2b (CAMPATH-1G) was effective at killing lymphoid cells [4] in vivo or via cell-mediated cytolysis (ADCC). This antibody therefore was the starting point for our attempts to use monoclonal antibodies in vivo for immunosuppression to avoid marrow rejection, and for 'in vivo' purging in lymphoid malignancies.

T-CELL PURGING WITH CAMPATH-1H FOR ALLOGENEIC BONE MARROW TRANSPLANTS

Graft versus host disease
Graft-versus-host disease is the major barrier to allogeneic bone marrow transplantation, but this can be avoided by eliminating T cells from the donor marrow [2]. Since 1983, a large number of centres around the world (for CAMPATH users see Table 1) have contributed to a study of GVHD prophylaxis using CAMPATH-1H and human serum complement for removing T cells [3]. The majority (520) of transplants were from matched sibling donors given to recipients with leukemias as listed in Table 2. Of these, the largest homogeneous group (156) were transplanted for chronic granulocytic leukaemia (CGL) in their first chronic phase (CP1). Donor marrows were depleted of T cells by adding CAMPATH-1H to 0.1mg/ml to buffy coat preparations in a volume of 250ml of balanced salt solution containing C52. Donor human serum was added to 20-25% (v/v) and incubated at 37°C for 30-45 mins. The mean number of residual T cells was then estimated by E-rosette to be 0.7%, with a variation between <0.1% to approximately 1%. As would be predicted, this led to a much reduced incidence and severity of GVHD (Table 3) compared with that expected without T-cell depletion, particularly as half of the patients received no other GVHD prophylaxis. Also encouraging is the very low incidence of chronic GVHD. There was no additional benefit in terms of GVHD for those patients who also received Cyclosporin A, although this group may show a marginally lower incidence of marrow rejection (not significant).

Narrow rejection
Rejection of the T-cell depleted bone marrow remains a major problem for approximately 15% of the transplants, even in this setting of matched sibling donors. It is clear that a solution is needed if unrelated or mismatched BMT are ever to be successful. To this end,
numbers of patients are still small and very heterogeneous in terms of their matching, disease and conditioning (many patients also received TLI), but it does seem that the CAMPATH-1G group as a whole show a much reduced incidence of graft failure (Table 5). However, both in this study, and the few matched sibling CAMPATH-1G patients (Table 3), the rate of rejection is still substantial. One possibility is that the administration of CAMPATH-1G is still not optimal, particularly in relation to all the other conditioning which may compromise some of the effector mechanisms by which the antibody works. Alternatively, it may be that we will need antibodies which are even more potent. With this in mind we have been looking at ways of trying to improve the effectiveness of monoclonal antibodies in vivo.

MONOVALENT ANTIBODIES FOR IN VITRO AND IN VIVO PURGING

Antibody and complement is potentially a very efficient way of killing cells, but there seems to be a number of mechanisms by which cells can protect themselves from such an attack. In particular, bivalent binding to cell surface antigen induces a resistant state and eventual capping and loss of antigen (antigenic modulation). For example, this effect is one of the factors that limit the effective period of GvMT administration [12]. It is possible to make and purify monoclonal antibodies which have one of their two arms inactivated by a light chain with an irrelevant variable region in the binding site [13]. We have shown that such an antibody to CD3 (Monovalent CAMPATH-3) has a greatly increased capacity to kill T-cells with complement in vitro compared to its bivalent parent. The antibody is also effective in vivo, as it was able to deplete the blast cells in a patient with T-cell lymphoma, without causing gross antigenic modulation [5]. It was also able to reverse acute, steroid-resistant cellular rejection episodes in kidney transplant patients [4]. However, two of these patients developed antoglobulin responses which once again would have limited further serotherapy, highlighting another important limitation to the use of rat or mouse monoclonal antibodies in man.

IN VIVO PURGING WITH CAMPATH-1H - TOWARDS THE ULTIMATE AUTOGRFT?

Recent advances in molecular biology have meant that it is now possible to redesign the genes encoding monoclonal antibodies. This led to the development of CAMPATH-1H [14], which is essentially a human IgG1 monoclonal antibody containing just the minimal binding site (the hypervariable loops or complementarity determining regions) from the rat CAMPATH-1G. The humanized antibody is equally, if not more, effective at lysing lymphocytes with human complement or by cell-mediated cytolysis (ADCC). Phase I studies in two patients with non-Hodgkin's lymphoma who had high circulating leukemic cells demonstrated that CAMPATH-1H is extremely potent in vivo (Figure 2), with both patients achieving a complete remission in the peripheral blood, bone marrow, spleen and lymph-nodes [6]. During treatment, bone
narrow function improved and in the patient with neutropenia this resolved. After cessation of treatment, normal oligoclonal B cells began to return in the blood. Neither patient made an antiglobulin response, and when one of the patients showed signs of relapse at approximately six months she was treated with CAMPATH-1H again with equally impressive results and remains well at a further six months. This suggests that humanized monoclonal antibodies are not only extremely effective in vivo, but can be used over extended periods with no loss in efficacy.

The ability of CAMPATH-1H to induce remission in such patients suggests a new approach to the autograft in leukaemia and lymphoma. Rather than to remove and then clean up the diseased bone marrow in vitro, it may be more effective to purge the whole patient, including the marrow, in vivo with monoclonal antibodies. As this treatment is non-toxic to both the patient and the marrow, a conventional autograft then allows cyto-reductive therapy of the patient to clean up any residual leukemic cells which may have escaped the antibody treatment. Such a scheme allows leukemic therapy to concentrate on the patient, where it seems that most relapses originate in current autografting protocols.

CONCLUSIONS

Monoclonal antibodies can utilise natural effector mechanisms such as complement and ADCC to kill cells both in vitro and in vivo, with the one great advantage of simplicity in use. This is effective in controlling both of the major barriers to allogeneic marrow transplantation: graft versus host disease and marrow rejection. In the future the development of even more potent, humanized monoclonal antibodies may lead to new approaches in the treatment of leukaemia and lymphoma, for example, by in vivo purging followed by autografting.

ACKNOWLEDGEMENTS

We are grateful to all the transplant teams at the centres listed in Table 1 for their participation in these studies. We also wish to thank Gilly Martin for preparing the clinical grade monoclonal antibodies. This work was supported by grants from the Medical Research Council and Wellcome Biotech Ltd. CAMPATH is a registered trade mark of Wellcome Foundation.

FIGURE LEGENDS

Figure 1
CGL-CPI patients with a slow rate of engraftment have an increased rate of relapse.

156 CGL patients in first chronic phase received CAMPATH-1H purged marrow from matched sibling donors. They were divided into two groups: those who grafted (>500 neutrophils/mm³) in less than 25 days (normal engraftment) and those who took 25 or more days to engraft (slow engraftment). The curves show that the probability of remaining in haematologic remission for the two groups at two years is 82% (normal group) vs 58% (slow group); P = 0.03 (Log-rank method).

Figure 2
Induction of remission with CAMPATH-1H in non-Hodgkin lymphoma

A patient with non-Hodgkin lymphoma in leukaemic phase, who was unresponsive to chemotherapy, was given doses of CAMPATH-1H from 1 mg to 20 mg per day (total 126 mg over 30 days). The lymphoma cells (closed triangles) were eliminated from the peripheral blood, while the neutrophils (open triangles), which had been absent at the start of treatment, returned to normal levels. The lymphocytes which appeared in the blood from day 42 were of normal morphological appearance, included both CD3 and CD19 positive cells.

Proposed abstract for discussion at workshop on "Prevention and treatment of GVHD"

CAMPATH-1 ANTIBODIES FOR PREVENTION OF GVHD AND GRAFT FAILURE

Geoffrey Hale and Herman Waldmann for CAMPATH users, Department of Pathology, University of Cambridge, Tennis Court Road, Cambridge, CB2 1QP, UK.

The advantages and drawbacks of T cell depletion are now well known. The use of CAMPATH-1M (IgM) with human complement for in vitro depletion has been one of the simplest and most effective methods, resulting in a low incidence of GVHD, but an increased risk of graft failure. An increased risk of relapse for patients with CGL is also well documented, but 5 year follow-up on patients with acute leukaemia fails to show extra relapse. It has been shown that graft failure is due to radioreistant host T cells so, in an effort to reduce it, we have introduced the IgG antibody CAMPATH-1G into conditioning regimes. This antibody is very effective at depleting lymphocytes in vivo and recent clinical studies show that this results in less graft failure in the context of T cell depletion. CAMPATH-1G alone can also reduce GVHD, either when added to the marrow infusion, or when administered to the patient at the time of transplantation. These findings lead to a new proposal for a simple protocol to avoid the immunological problems of marrow transplantation which we believe will be applicable to transplants from matched unrelated or mismatched donors as well as siblings.

Professor Peter Jacobs

Elimination of graft-versus-host disease by in-vitro depletion of alloreactive lymphocytes with a monoclonal rat anti-human lymphocyte antibody (CAMPATH-1).

A new monoclonal rat anti-human lymphocyte antibody (CAMPATH-1) which lyses cells with autologous human complement was used for depletion of T lymphocytes from human bone-marrow allografts in vitro before transplantation in 11 high-risk patients. HLA-matched siblings were used as marrow donors. T-cell depletion was substantial when measured by E-rosette formation (0-0.18% residual T cells) and immunofluorescence with a monoclonal anti-T-cell antibody (0-0.5%). No anti-graft-versus-host disease prophylaxis was given after transplantation. Rapid engraftment was reported in all patients, and the post-transplantation course was uneventful. No signs of graft-versus-host disease developed in any of the patients, who were observed for a maximum period of 12 months. The method might be suitable for larger-scale studies in high-risk patients. The late graft failure seen in 2 patients may reflect residual host resistance uncompromised by GVHD.

PMID: 6147548 [PubMed - indexed for MEDLINE]
Availability of Campath-1 antibodies for bone marrow transplantation

Recently you have published two papers from the Campath users group showing that Campath-1 antibodies can be successfully used to control graft-versus-host disease and graft rejection in particular situations. Since then we have received many requests from different centres wanting to know whether these antibodies could be made more widely available, so we are writing to explain the present situation.

The original rat CD52 antibodies Campath-1M and Campath-1G have been produced by us in the Therapeutic Antibody Centre for a number of physicians who requested them for clinical trials. Although we aim to provide material of a suitable quality for clinical use, our premises do not have a manufacturers licence nor do the antibodies have a product licence. Our understanding is that in the UK, at least, it is permissible for physicians to use unlicensed products under certain circumstances provided that they obtain approval from the Medicines Control Agency by means of a DDX (doctor's and dentist's exemption).

Until recently the Wellcome Foundation have been developing the humanised antibody Campath-1H for possible use in the treatment of non-Hodgkin's lymphoma and rheumatoid arthritis, and so this antibody might have become commercially available. However, on 27 September 1994 they announced that the development of Campath-1H had been halted because it seemed to have insufficient commercial potential. The possibility of another company taking on the project has not been ruled out.

Meanwhile, we have recently been awarded funding to rebuild and improve our production facilities and hope to open a new production centre in Oxford in 1995. While this work is going on, our ability to supply Campath-1 antibodies will be limited. Although we will continue to support the trials which have already been started, we regretfully have to decide that it is impossible to accept any new requests. We believe that careful scientific evaluation together with commercial development is the best way of ensuring that these reagents are available to the transplant community in the long run. We hope that those teams reading this letter with whom we have not had the pleasure of working will understand our present situation.

Summary:

Graft-versus-host disease (GVHD) is a major cause of mortality and morbidity after allogeneic bone marrow transplantation, but can be avoided by removing T lymphocytes from the donor bone marrow. However, T cell depletion increases the risk of graft rejection. In this study, two strategies are used to overcome rejection: (1) use of high doses of stem cells obtained from peripheral blood (PBSC). (2) admixture with a CD52 monoclonal antibody in order to deplete both donor and residual recipient lymphocytes. Two antibodies are compared: CAMPATH-1G (rat IgG2b) and its humanized equivalent CAMPATH-1H (human IgG1). A total of 187 consecutive patients at six centers received PBSC transplants from HLA-matched siblings between 1997 and 1999. A wide spectrum of diseases, both malignant and non-malignant, was included. The recovery of CD3⁺ cells after antibody treatment was close to 100%. The risk of acute GVHD (grade 2 to 4) was 11% in the CAMPATH-1G group and 4% in the CAMPATH-1H group (P = NS). The risk of chronic GVHD (any grade) was 11% in the CAMPATH-1G group and 24% in the CAMPATH-1H group (P = 0.03) but the risk of extensive chronic GVHD was only 2%. The overall risk of graft failure/rejection was 2%, not significantly different between the two antibodies. Antibody treatment was equally effective at concentrations between 10 µg/ml and 120 µg/ml and it made no significant difference to the outcome whether the patients received post-transplant immunosuppression or not (87% did not). Transplant-related mortality in this heterogeneous group of patients (including high-risk and advanced disease) was 22% at 12 months. It is proposed that treatment of peripheral blood stem cells with CAMPATH-1H is a simple and effective method for depleting T cells which may be applicable to both autologous and allogeneic transplants from related or unrelated donors. Special advantages of this approach are the simultaneous depletion of donor B cells (which reduces the risk of EBV-associated lymphoproliferative disease) and the concomitant infusion of CAMPATH-1H to deplete residual recipient T cells and thus prevent graft rejection. Bone Marrow Transplantation (2000) 26, 69-76.

Keywords: CAMPATH-1H; peripheral blood progenitor cells; GVHD; graft failure; HLA-identical sibling; T cell depletion

Transplantation of allogeneic stem cells is a curative therapy for patients with congenital or acquired deficits of hemopoiesis. Combined with high-dose chemotherapy and radiotherapy, it is also a very effective treatment for hematologic malignancies. In recent years, it has become possible to harvest large numbers of stem cells from peripheral blood following mobilization with growth factors, and this is likely to eliminate the need for aspiration of donor bone marrow. However, all forms of allogeneic stem cell transplantation suffer from adverse effects, the most serious being graft-versus-host disease (GVHD), caused by attack of the donor T cells on recipient tissue. Despite the best immunosuppressive therapy with combinations of cyclosporin and methotrexate, this remains a significant cause of morbidity and mortality. If it were not for side-effects such as GVHD, allogeneic stem cell transplantation might be considered for treatment of other conditions, such as autoimmune diseases and induction of tolerance to organ transplants.

GVHD can be prevented by depleting T lymphocytes from the donor stem cells and there are several methods to accomplish this. In 1983 we developed the monoclonal antibody CAMPATH-1M, a rat IgM antibody which recognizes the CD52 antigen. CD52 is abundantly expressed on all human lymphocytes and is an exceptionally good target for cell lysis by antibody with human complement. This provided a simple method for purging the donor T cells which was very effective and gave a significant reduction in GVHD. However, the benefit was offset by an
increased risk of graft rejection by residual host T cells. Animal models showed that this might be overcome by using monoclonal antibodies to deplete residual host T cells. A rat IgG2b CD52 antibody, CAMPATH-1G, effectively depletes human lymphocytes in vivo. Like CAMPATH-1M, it can activate human complement, although this is not sufficient for systemic T cell depletion. Rat IgG2b also binds human Fe receptors and engages cellular killing mechanisms (ADCC). The combination of CAMPATH-1M to T cell deplete donor bone marrow and the intraoperative injection of CAMPATH-1G to ablate residual host immunity overcomes both the problems of GVHD and graft rejection and results in a significantly decreased transplant-related mortality compared with conventional long-term immunosuppressive therapy.

However, a simpler strategy was to use a single dose of CAMPATH-1G added to donor bone marrow to accomplish both objectives at once. Some antibody binds to donor T cells, preventing them for subsequent clearance. The excess antibody is infused along with the bone marrow and gives sufficient depletion of residual host T cells to prevent rejection. We therefore wondered if the same simple method could be used with peripheral blood stem cells. In this case, the number of contaminating T cells is potentially larger and may be quite variable, according to the exact mobilization and collection protocols.

In 1988, a humanized version of CAMPATH-1G was described, namely CAMPATH-1H. This antibody is being developed for the treatment of CLL. CAMPATH-1H is a human IgG1, chosen for its optimal effector function and in principle it should be equally as effective as CAMPATH-1G for elimination of T cells in vivo. There is already a lot of data to support this concept from clinical trials with CAMPATH-1H in CLL, rheumatoid arthritis, multiple sclerosis and organ transplantation. Here, CAMPATH-1G and CAMPATH-1H are compared for use in allogeneic stem cell transplantation and by consideration of the heterogeneity of actual stem cell donations, the robustness of the treatment protocol is assessed.

Collection of peripheral blood stem cells
Donors were treated with G-CSF s.c. at between 5 and 20 μg/kg/24 h in order to achieve a white cell count between 20 and 50 × 10^9 per litre by day 5. Apheresis was started around 2 h after the last dose of G-CSF and continued for up to 6 h. The anticoagulant was ACD-A, typically one volume for every 10 volumes of blood. Based on the ideal body weight of the patient, the target cell dose was either 5 × 10^6 mononuclear cells/kg or 4–5 × 10^6 CD34+ cells/kg. This typically required the processing of 10 to 20 litres of blood. In the event that the target cell dose was not achieved, the apheresis procedure was repeated the following day subject always to the safety and tolerability of the procedure for the donor. No donors were subjected to more than two aphereses. Special procedures were established for donors <35 kg according to local requirements. The volume of each apheresis unit was measured and the concentration of mononuclear cells determined using a suitable automated differential cell counter.

Treatment with monoclonal antibody
CAMPATH-1G or CAMPATH-1H was added to the stem cell concentrate, gently mixed and kept for 30 min at room temperature (18–25°C). The target dose of antibody was either 10 μg or 20 μg according to local protocol, but additional antibody was sometimes added up to a maximum of 60 μg when the volume or number of cells was particularly high. In the event that two apheresis units were collected, standard procedure was to apportion the antibody dose between them. The entire cell suspension was then infused to the recipient over 30 to 60 min without further manipulation according to standard local procedures. Various premedications were used to ameliorate the expected flu-like symptoms due to cytokine release caused by the antibody, including paracetamol (acetaminophen) with either 100 mg hydrocortisone plus 12.5 mg phenergan (promethazine hydrochloride), or prednisone (2 mg/kg) given 1 h before the graft.

Measurement of cell subpopulations
Mononuclear cells were measured with electronic cell counters and calculated as the combination of lymphocytes plus monocytes from differential cell counts. CD34+ progenitors and CD3+ T cells were enumerated by flow cytometry both before and after the antibody treatment. CD34+ cells were measured according to the guidelines of the International Society for Hemotherapy and Graft Engineering using phycoerythrin-labelled CD34 antibody and FITC-labelled CD45 antibody.

Patients
Six transplant centers participated in the study: A-Z St Jan, Bruges; Groote Schuur Hospital, Cape Town; Constantinberg Medi-Clinic, Cape Town; Hopital Cantonal, Geneva; University Hospital, Leiden; Ulm University Hospital, Ulm. They are arbitrarily coded 1–6. Each center recruited consecutive patients provided that they gave informed con-
sent. Data were collected on all patients who received stem cell transplants treated in vitro with CAMPATH-1G or CAMPATH-HI up till May 1999 (a total of 217 patients).

For this analysis, 30 patients were excluded who received transplants from donors other than HLA-matched siblings or who also received CAMPATH-1 antibodies in vivo as part of the conditioning regimen. All categories of disease, conditioning regimens and post-transplant immunosuppression were included, representing the range of normal practice at each center.

**Statistical analysis**

Characteristics of the treatment groups and outcomes were compared using the chi-square test for categorical variables and the Mann Whitney U/Wilcoxon rank sum test for continuous variables. Time-dependent outcomes (engraftment, survival) were compared by the log-rank test. Multifactorial non-linear regression was used to analyze the possible relationship between GVHD and the following covariates: patient sex, patient age, donor sex, type of antibody, post-transplant immunosuppression, antibody dose, antibody concentration, cell dose. These tests were carried out using the ‘FIRST’ suite of statistical software (Serious Statistical Software, Lynwood, South Wirral, UK) or ‘LOGRANK’ software (SP Coblod, University of Oxford, Oxford, UK) running under the RISC operating system on an Acorn Archimedes computer.

**Results**

**Study centers, conditioning regimens and patient characteristics**

The purpose of this study was to test whether a simple single procedure for treatment of donor stem cells could be used with all types of patients. Therefore, consecutive patients were enrolled at each center with no selection according to type or stage of disease, and all other aspects of the transplant procedure (conditioning regimen, prophylactic antibiotics etc.) continued according to the usual local procedures adopted as clinically required according to the status of the patient. Most patients received standard conditioning with cyclophosphamide plus total body irradiation (TBI), but where TBI was not indicated, a combination of chemotherapeutic agents was used (Table 1). Two centers gave supplementary total lymphoid irradiation as anti-rejection prophylaxis. One center used only CAMPATH-1G for treatment of the stem cells, two used only CAMPATH-HI and three switched from the rat to the humanized antibody during the course of the study. Post-transplant immunosuppression with cyclosporin A (CyA) or a combination of CyA and methotrexate (MTX) was used routinely at only two centers. Three patients received donor leukocyte infusions post transplant for prevention or treatment of relapse. Other characteristics of the patient population are summarized in Table 2.

*Non-TBI regimens consisted of busulfan/cyclophosphamide, busulfan/methotrexate, cyclophosphamide/methotrexate, methotrexate/thiotepa or busulfan/methotrexate/thiotepa.

Protocols normally included standard-dose cyclophosphamide, sometimes with the addition of other anti-leukemia chemotherapies depending on the clinical indication.

Ten patients received additional conditioning with anti-lymphocyte globulin and five received radioimmunotherapy with a radiolabelled CD56 antibody.

*Refers only to T cells given at the time of transplant. Some centers gave donor leukocytes for treatment of relapse.

*Total lymphoid irradiation was given routinely by two centers in addition to TBI. This was increased to 1500 rad for three patients with aplastic anaemia who did not receive TBI.

The extreme range of the data is shown in brackets. Probabilities (P) are calculated by the chi-squared test or Mann Whitney-U/Wilcoxon rank sum test as appropriate. Diseases are classified as: early leukaemia, ALL-CRI, AML-CRI, CML-CP1; other malignant, more advanced leukaemia, lymphoma and myeloma; non-malignant, Fanconi's anaemia, aplastic anaemia and inborn errors.

**Recovery of cells from apheresis**

The yields anticipated a priori for an adult apheresis unit were: volume 200 to 500 ml, total number of mononuclear cells 100 to 300 x 10^6, CD34+ cells 100 to 300 x 10^6. The median actual yields were approximately double the original targets but there were no major differences between the two groups of patients (Table 3). There was a range of

Probabilities (P) were calculated by the Mann-Whitney-Wilcoxon rank sum test. Differences in the numbers of CD34⁺ cells remained significant even after excluding data from one center which reported lower CD34⁺ counts than others.

Cell recovery following antibody treatment

There were small differences between the two groups, but in both cases the recovery of CD34⁺ cells was very good (Table 3). The median recovery of mononuclear cells was 70% (95% CI 44-99%) and the total number infused was 6.7 x 10⁶ per kg (95% CI 3.5-14 x 10⁶ per kg), which was a little higher than the target of 5 x 10⁶ per kg. The median recovery of CD34⁺ cells was 99% (95% CI 35-666%) and the total number infused was 6.3 x 10⁶ per kg (95% CI 19 x 10⁶ per kg), i.e. close to 1% of the mononuclear cells. The median recovery of CD3³ cells was 26% (90% CI 5-65%). It was not expected that all the T cells would be lysed in vivo.

Engraftment and graft failure

Univariate analyses of outcome are shown in Table 4. Recovery of neutrophils was rapid, as expected for peripheral blood stem cell transplants. The median day to reach 500 neutrophils/µl was day 13 (range 10-44) for the CAMPATH-1G group and day 12 (range 8-30) for the CAMPATH-1H group. There was one case of early graft failure (never reached 500 neutrophils/µl) and one case of late graft failure in each group.

Graft-versus-host disease

The incidence of both acute and chronic GvHD was higher in the CAMPATH-1H group compared with the CAMPATH-1G group, almost entirely as a result of a higher frequency of grade 1 acute GvHD or mild/moderate chronic GvHD (Table 4). However, neither the antibody dose nor the final antibody concentration had a significant effect on the incidence of GvHD. This is exemplified in...

The outcome is reported, together with the 95% confidence interval. Probabilities were calculated by the chi-squared test (GVHD) or the univariate log-rank test (other outcomes). They do not take into account any potential covariates.

Figure 1, where the mean GVHD grade is plotted against antibody concentration. Similar results (not shown) were obtained when mean grades for acute or chronic GVHD were plotted against total antibody dose or total cell dose. Furthermore, the use of post-transplant immunosuppression had no significant impact on the frequency of GVHD. The influences of potential covariates was examined by multivariate linear regression with acute GVHD as the dependent variable and the following independent variables: patient sex, patient age, donor sex, type of antibody, post-transplant immunosuppression, antibody dose, antibody concentration, cell dose. The only factor found to be correlated with acute GVHD was the patients age – not surprisingly, there was an increasing risk of GVHD in older patients.

Mortality

Transplant-related mortality is defined as death from any cause other than relapse of the original disease. There was no significant difference between the groups (Table 4). Because of the relatively short follow-up and the disparate diseases treated, there was no attempt to analyze relapse, overall survival or leukemia-free survival. The causes of death are listed in Table 5. There was one death from EBV-associated lymphoproliferative disease. There were more deaths from infection in the CAMPATH-1H group (13%) than the CAMPATH-1G group (6%), although the difference is not statistically significant due to the relatively small numbers. As expected, there were relatively fewer deaths among the patients transplanted for early leukemia, but with the small numbers and short follow-up of this study, the differences were not statistically significant.

Comparison with reference groups of patients

No large reports are available from the transplant registries or other sources with which to compare these data. We selected three comparison groups of transplants from HLA-identical siblings in order to put the results into a clinical context. (1) Bone marrow transplants treated with CAMPATH-1G ex vivo according to the present protocol. The patients are described in Refs 3, 4, 11 but the most recently updated data (previously unpublished) have been used. (2)
PBSC transplants where GVHD prophylaxis consisted of either cyclosporin or tacrolimus combined with either methotrexate or prednisolone. Data from eight separate single-center studies were combined as described by Besinger and Buckner. The follow-up was short and so there are uncertainties in the calculation of chronic GVHD and transplant-related mortality. (3) PBSC transplants which had been T cell-depleted by positive selection of CD34+ cells by either an immunoadsorption or an immunomagnetic technique. The comparative data are presented in Table 6.

Discussion

Treatment of bone marrow with CAMPATH-1G has been established for some years as an effective method for depletion of donor T cells to prevent GVHD, without incurring a high risk of graft rejection. In principle, grafting is expected to be faster and more reliable from peripheral blood stem cells. However, it was not obvious whether the larger numbers of contaminating T cells could be dealt with as effectively by the antibody treatment. Furthermore, we wanted to test whether CAMPATH-1G could be replaced by the humanized version, CAMPATH-3H. This prospective analysis of PBSC transplants at the participating centers was carried out to compare the outcomes according to the type of antibody used. Although certain aspects of the antibody treatment protocol were standardized in advance (eg, time and temperature of treatment), other potentially important parameters were not so tightly controlled because of the varying logistical requirements of different patients. This provided an opportunity to determine the importance of factors such as antibody dose, concentration and post-transplant immunosuppression; in effect, a natural experiment to test the robustness of the procedure.

Outcomes according to alternative transplant protocols are compared with the outcomes in this study, (1) Bone marrow transplants treated with CAMPATH-1G ex vivo. (2) PBSC transplants with drug-based GVHD prophylaxis. Data marked * are incomplete due to short follow-up or limited reporting. (3) PBSC transplant T cell-depleted by positive selection of CD34+ cells.

tant antibody concentration in the apheresis bag varied from 6 to 240 µg/ml (median 56 µg/ml, 90% CI 10–120 µg/ml). The concentration of CAMPATH-1G or CAMPATH-3H required for 90% saturation of the CD52 antigen is approximately 10–20 µg/ml. However, maximal cell-mediated killing (ADCC) can be achieved with as little as 0.1 µg/ml. Therefore, in theory, even the lowest concentrations of antibody should have been adequate to opsonize the donor T cells for lysis in vivo.

Recoveries of mononuclear cells and CD34+ cells were consistently good with this procedure, which is not surprising, considering the simplicity of the manipulations. It is well documented that CAMPATH-1 antibodies spare hematopoietic colony-forming cells. However, there is a subpopulation of CD34+ cells in bone marrow which is also CD52- and CD34+, most probably lymphoid progenitors.

Treatment of bone marrow with CAMPATH-1G or CAMPATH-3H can result in depletion of this subpopulation, but in peripheral blood CD34+ cells a similar CD52-CD34+ subpopulation was not detected. In an experimental study, the concentrations of cells and antibody were systematically varied over a range corresponding to that achieved in clinical practice, but without effect on the depletion of lymphocytes or recovery of CD34+ cells.

It was not expected that treatment with CAMPATH-1G or CAMPATH-3H would result in extensive depletion of T cells prior to infusion into the patient. Although both antibodies can activate human complement, the conditions were not optimized for complement-mediated lysis. Some degree of depletion did occur in vivo, but the extent was highly variable (13–99%), probably because the amount of residual plasma was not specifically controlled. We believe that the main depleting effect occurs in vivo by antibody-dependent cellular effector mechanisms, after the mixture of antibody and cells has been infused.

GVHD was well controlled in the majority of patients, irrespective of the antibody concentration or the use of post-transplant immunosuppression. The overall incidence of acute and chronic GVHD was significantly lower than expected when CAMPATH-1 antibodies were used in previous studies for T cell depletion of bone marrow transplants and is also similar to that seen using other effective methods for depleting donor T cells. However, there was a higher incidence of grade I acute GVHD and of mild/moderate chronic GVHD in patients who received CAMPATH-3H, despite the fact that the average antibody dose was slightly higher. The reason for this is not known, although it is notable that the starting concentration of T cells in the CAMPATH-3H group was significantly higher. Limited GVHD has not been a major clinical problem; in fact, there is some reason to believe that it may provide a desirable graft-versus-leukemia effect.

The incidence of graft failure or graft rejection in this series of patients was low. Engraftment is probably facilitated by the larger number of stem cells available from peripheral blood compared with bone marrow. In addition, the surplus CAMPATH-1 antibody infused with the transplant probably contributes by depleting any residual host lymphocytes which have been spared by the conditioning regimen. In this regard, the present approach is superior to
those methods which rely purely on in vitro means, such as
magnetic beads, for removing donor T cells. As with most clinical studies of stem cell transplantation,
there are never sufficient patients to allow prospective ran-
domized trials for comparing different treatments. Instead,
we are obliged to rely on historical comparisons and a
registry style of statistical analysis to elucidate significant
trends. Only the most obvious conclusions can be drawn
from the type of comparison presented in Table 6, since we
have to acknowledge that the groups of patients are not
necessarily equivalent in terms of prognostic factors. How-
ever, each group involved consecutive patients treated in
at least six different centers, so the data should be representa-
tive of typical clinical experience. The average number of
CD34+ cells infused in this study was similar to that for
unmanipulated PBSB and about twice that for CD34+ selec-
ted PBSB where the recovery is typically about 50%.
Clearly, T cell depletion results in a significant reduction
in the risks of acute and chronic GVHD, and this is most
striking in the CAMPATH groups because little or no post-
transplant immunosuppression was used, whereas all of
the patients in the CD34+ selected group also received post-
transplant CyA. The risk of graft failure is lower for T cell
depleted PBSB transplants compared with T cell-depleted
bone marrow transplants, probably because of the larger
dose of stem cells, which also results in significantly faster
engraftment. However, the use of CAMPATH-1G or CAM-
PATH-H in PBSB transplants has not been associated with
a reduction in transplant-related mortality. Whereas
deaths from complications of GVHD are greatly reduced
by T cell-depletion, it appears that there is still a risk from
infectious complications.

Thus the two outstanding problems are leukemia relapse
and immune reconstitution. An increased risk of relapse is
likely for patients with CML who received T cell-depleted
allogeneic transplants compared with recipients of T cell
replete transplant. In future, this might be overcome by
controlled infusion of donor leukocytes, but this needs to
be done without risking severe GVHD. Any increase in
relapse risk for patients with acute leukemia is modest, and
probably compensated by the reduction in GVHD. In
previous studies we observed that patients who received T
cell-depleted bone marrow transplants were at risk from
infections mainly during the first year post transplant.
After that the 10 year actuarial risk of death from infection
was only 3.5% (CH and CAMPATH users, unpublished work,
1998). Nevertheless, immune reconstitution after T cell-
depleted PBSB transplants is an issue of concern and needs
to be studied in much more detail over a long term. Such
a study has been carried out on 20 T cell-depleted bone
marrow transplants by one of the present centers. Immu

References

5. Bunjes D, Heit W, Arnold R et al. Evidence for the involvement of host-derived OKT3-positive T cells in the rejection of EBV and consequent lymphoproliferative disease (BLPD), possibly leading to fatal lymphoma. There was one such case in this series of 187 patients. In a published study of 2582 bone marrow transplants T cell-depleted with CAMPATH-1 antibodies, the risk of BLPD was only 1.3%, hardly different from results for T cell replete transplants, but in stark contrast to the high incidences reported following
some other forms of T cell depletion. The difference may be due to the fact that CAMPATH-1 antibodies target donor B cells equally as well as T cells thus reducing the virus load or the virus target or both.

Treatment with CAMPATH-1H is a simple and reliable
method for prevention of GVHD and graft failure following
allogeneic peripheral blood stem cell transplantation. The
procedure results in a good yield of CD34+ cells and effec-
tive control of GVHD under a wide range of conditions. It
may be suitable not only for allogeneic transplants but also
for depletion of T cells in autologous transplant procedures
for autoimmune diseases. During the period of this study
there were very few PBSB transplants from volunteer unre-
lated donors. However, CAMPATH-1 antibodies have
proved to be effective in controlling GVHD following unre-
lated donor marrow transplantation so we hope that the
present approach may also be useful if and when donations
of blood stem cells from unrelated donors become more
widely used. The important issue of immune reconstitution
needs to be addressed and the possibility of using donor
lymphocyte infusions should be considered especially if
methods can be developed to manipulate them to
selectively remove alloreactivity.

Summary:

Twenty-two patients (16 male, six female; median age 34 years, range 16–49) with acute myeloid leukemia (1st complete remission (CR), n=9), acute lymphocytic leukemia (1st CR, n=5), chronic myeloid leukemia (chronic phase n=5, accelerated phase n=1), malignant lymphoma (n=1) and myeloma (n=1) were transplanted with unmanipulated donor bone marrow after standard conditioning including the monoclonal antibody Campath-1G daily from day -4 to day 0. No further graft-versus-host disease (GVHD) prophylaxis was given. All patients engrafted and neither graft failure nor rejection were observed. Acute GVHD grade I (skin) was seen in 12 out of 21 patients at risk. Acute GVHD grade II (skin) occurred in two patients. Severe GVHD (grade III, IV) of the gut, liver and skin developed in two patients. The overall incidence of severe acute GVHD (II-IV) was 19% of the patients at risk. Chronic GVHD (skin only) was seen in eight patients (42%) (six of extensive severity). A total of 14 patients died, the causes being relapse (four), direct cytotoxic drug toxicity (one), aGVHD (two), disseminated varicella zoster (one), systemic tuberculosis (one), interstitial pneumonitis (three) and veno-occlusive disease (two). These results indicate that the intravenous administration of Campath-1G may have reduced the incidence of severe acute GVHD without the occurrence of graft failure. However, the incidence of chronic GVHD does not appear to have decreased.

In the past decade ex vivo depletion of mature T lymphocytes from a bone marrow graft was been successful in preventing acute graft-versus-host disease (GVHD) after allogeneic bone marrow transplantation (BMT).¹ The incidence of acute GVHD (grade II-IV) decreased from at least 80% for patients receiving no prophylactic treatment at all to 10–25% when T cells were depleted from the bone marrow.² A variety of physical and immunological techniques have been used to deplete the marrow of T cells.³–⁵ The most widely used monoclonal antibody is the rat IgM monoclonal antibody Campath-1M which recognizes a heterogeneous 23–30 kDa glycoprotein expressed by all lymphocytes and monocytes.⁶ In the presence of human complement it may effectively deplete T cells from bone marrow grafts in vitro,⁷ resulting in less than 20% acute GVHD among patients at risk.

However, although in vitro T cell depletion prevents aGVHD, it has resulted in an increased incidence of early and late marrow graft failure and leukemic relapses. Depending on the degree of compatibility between donor and recipient the incidence varies from 10% to more than 30%.⁸,⁹ Alternative approaches, including more intensive immunosuppression as a means of conditioning, increasing the number of marrow cells in the graft, and less complete removal of T cells, have been explored. Attempts to apply more intensive conditioning regimens have caused increased toxicity, which counteracted the positive effects on engraftment and relapse rates, whereas leaving more T cells in the graft resulted in more severe GVHD.⁹

In mice, Cobbold et al.¹⁰ showed that engraftment of in vitro T cell-depleted donor bone marrow may be promoted by the systemic administration of anti-T lymphocyte antibodies to the recipient prior to BMT, presumably as a result of in vivo depletion of recipient lymphocytes capable of rejecting the graft. Thierfelder et al.¹¹ showed that a single injection of the rat monoclonal antibody anti-Thy-1 of the IgG2b isotype after irradiation but before marrow infusion prevented GVHD mortality and suppressed host-versus-graft reactivity so that the radiation dose necessary after engraftment of mismatched donor cells could be reduced.

Clinical data on the effective depletion of lymphocytes in vivo by monoclonal antibodies are scarce.¹²–¹⁶ One of the most lytic of the rodent antihuman lymphocyte antibodies so far is the recombinant IgG2b anti pan-lymphocyte antibody (Campath-1G).²,¹¹ It can be given intravenously and produces a profound depletion of lymphocytes from blood, spleen and bone marrow. It has been applied successfully in the treatment of patients with progressive lymphoma and chronic lymphocytic leukemia without major complications.¹⁷

We report the results of a study on the intravenous administration of Campath-1G to patients undergoing
transplantation of an unmodified matched sibling donor bone marrow graft. The aim of this study was to prevent acute GVHD by in vivo elimination of donor T cells from the graft and simultaneously to prevent rejection by elimination of residual antidonor reactive T cells from the recipient.

Patients and methods

Study group

To investigate the effect of Campath-1G on the number of circulating lymphocytes and to study the pharmacokinetics of the antibody, 12 patients who underwent allogenic BMT between September 1987 and February 1988 received intravenous Campath-1G just before the conditioning regimen was started. Subsequently, between February 1988 and April 1990, a further 22 patients who required a bone marrow graft from an HLA-matched sibling donor entered a phase II study to assess whether Campath-1G could be used during the conditioning phase for depletion of immunocompetent recipient lymphocytes and to determine whether any effect on GVHD incidence, graft rejection and infection pattern could be detected. Clinical features such as age, sex and viral status of donor and recipient, diagnosis and stage of the disease and interval between diagnosis and BMT are presented in Tables I and III. The group comprised 16 male and six female patients with a median age of 34 year (range 16–49). The median age of the donors was 30 years (range 14–48), 14 of them were sex-matched with the recipient. The protocol was approved by the Leiden Internal Review Board. All patients entering the study had given informed consent.

Study protocol

The preparatory regimen consisted of intravenous cyclophosphamide (60 mg/kg/body weight per day on days -6 and -5) and single-dose total body irradiation (9 Gy, 25 cGy/min on day -1) for 18 patients. Because of extensive prior radiotherapy four patients followed a conditioning regimen consisting of oral busulfan at a daily dose of 1 mg/kg body weight four times daily on days -9 to -6, and intravenous cyclophosphamide at a daily dose of 50 mg/kg body weight on days -5 and -4. In both cases Campath-1G at a daily dose of 5 mg in 500 ml 5% glucose was given as a 2–6 h infusion on days -4, -3, -2, -1 and 0. Unmodified bone marrow cells (mean cell number 2.1 × 10^10/kg body weight) were infused within 4 h of the last Campath-1G infusion. Intravenous methylprednisolone (250 mg daily) was given to suppress severe side-effects during the administration of cyclophosphamide and Campath-1G. All patients were nursed in high-efficiency particulate air (HEPA)-filtered isolation units, received a diet with a very low bacterial content, underwent prophylactic selective antibiotic decontamination of the digestive tract and had a central venous catheter. Continuous monitoring of the bacterial, fungal and viral status of the recipient was performed. Supportive treatment included broad-spectrum antibiotics, fungostatic or virostatic agents.

*Interval between diagnosis and bone marrow transplantation in months
for documented infection and fever, leukocyte-free platelet and red blood cell transfusions to maintain the platelet count above 10 × 10⁹/l and the hemoglobin concentration above 5–6 mmol/l. All blood products were screened for cytomegalovirus (CMV) and were irradiated (20 Gy). Patients of CMV-negative recipient-donor combinations received transfusions of CMV-negative blood products. No additional GVHD prophylaxis was given.

Engraftment was measured by peripheral blood counts and marrow examinations. IgG-class antibodies against herpes simplex virus (HSV) and varicella-zoster virus (VZV) and the capsid antigens of Epstein-Barr virus (EBV) were assessed using an indirect immunofluorescence assay. IgM class antibodies against HSV were detected using an indirect immunofluorescence technique. IgG and IgM class antibodies against cytomegalovirus (CMV) late antigen were assessed with an enzyme-linked immunosorbent assay (ELISA). The diagnosis of active HSV or VZV infection was based on clinical symptoms and, in most cases, confirmed by virus isolation. Active CMV infection was diagnosed on the basis of characteristic symptoms and appearance of the immediate early antigen (IEA) in the blood.

Acute GVHD was assessed according to the Seattle grading system. In case of symptoms of acute GVHD, methylprednisolone was started at a total daily dose of 10 mg/kg body weight. Chronic GVHD was treated with cyclosporin, methotrexate, total lymphoid irradiation or PUVA therapy alone or in combination.

Serum levels of Campath-1G were determined using an immunofluorescence assay. Serum samples were incubated with K422 cells (a B cell line which expresses high levels of the Campath-1 antigen) in the presence of 5 mM EDTA (to prevent complement activation). Bound antibody was detected with FITC-anti-(rat Ig). A standard curve was constructed using known dilutions of Campath-1G in normal human serum and the relationship between mean fluorescence intensity and antibody concentration was determined so that the antibody concentration in the test samples could be calculated.

Results

Pharmacokinetics and toxicity of intravenous Campath-1G

In the preliminary study, 12 patients received Campath-1G intravenously as a 4–6 h infusion for 5 days before the start of the conditioning regimen. Complete blood cell counts and the levels of Campath-1G were determined in daily blood samples. All blood lymphocytes had disappeared within 24 h (data not shown). The levels of Campath-1G were derived from measurements in 12 patients. In 10 patients samples were available from prior to Campath-1G infusion. At various time points during Campath-1G infusion or after Campath-1G infusion, samples were collected, i.e. at each time point, 2–4 samples were available, originating from different patients. All concentrations in Figure 1 represent means of multiple measurements derived from different patients. No kinetic studies in single patients have been performed. Levels of Campath-1G increased to a maximum on the fifth day of infusion. Detectable levels were present up to 24 h after discontinuation of the infusion. Except for fever and chills in a few patients on the first day of administration no side effects were observed. This might be due to the concomitant administration of methylprednisolone.

Effect of Campath-1G on engraftment and GVHD

Effect of Campath-1G on incidence of infection

The rate of reactivation of herpes virus infections is shown in Table III. None of the patients exhibited a clinical reactivation of the EBV virus infection. HSV reactivation within the first weeks after BMT was seen in eight patients, two of whom were seronegative before transplantation and received bone marrow from a seropositive donor. The overall incidence was 40% of the patients at risk. All patients were treated successfully with intravenous acyclovir. CMV reactivation, as measured by the appearance of the immediate early
antigen in the blood in addition to clinical symptoms compatible with a CMV infection, was diagnosed in seven of 15 patients (47%) who had a positive serology or were seronegative but received marrow from a seropositive donor. They were treated with ganciclovir (DHPG). Only one of the seven died, due to CMV pneumonia. Four patients experienced a generalized varicella zoster infection, which in spite of treatment with high-dose acyclovir was fatal in one case. One patient was seronegative before BMT but received marrow from a seropositive donor and acquired a VZV infection.

*Clinical and serological evidence of reactivation of viral disease after bone marrow transplantation

Cause of death (Table IV)

Four patients died due to leukemic relapse, two to acute GVHD, one to direct cardiopulmonary toxicity of the conditioning regimen, five to opportunistic infections which were related to chronic GVHD in three patients, and two to a clinical picture compatible with veno-occlusive disease. Thus, after a minimum follow-up of 1 year, eight patients survived. The quality of life for seven is good. One patient still suffers debilitating chronic GVHD.

Discussion

The present study provides evidence that intravenous administration of the rat monoclonal IgG2b antibody (Campath-1G) without additional immuno-

suppression after BMT permits engraftment and is associated with a low incidence of severe acute GVHD. The protocol was designed such that at the time of bone marrow infusion plasma levels of Campath-1G in the recipient were detectable so that effective elimination of donor lymphocytes was feasible. Since recipient lymphocytes disappeared within 24 h of the first Campath-1G administration, residual recipient cells that have been shown to be capable of surviving the conditioning regimen – thus leading to rejection of the graft,25 were likely to have been depleted from the recipient.

Acute GVHD can be prevented by in vitro depletion of T cells in donor bone marrow or administration of immunosuppressive drugs to the recipient after BMT.1 The extent of T cell depletion probably determines the incidence and severity of acute GVHD, 1 log depletion of T cells being associated with a considerably higher rate of acute GVHD than a 2 log depletion.26 In studies in which 2-3 log depletion was achieved there was approximately a 10% incidence of clinically significant acute GVHD, even when post-transplant immunosuppression was not administered. Relatively little information is available on the effect of T cell depletion on chronic GVHD, although the incidence

![Figure 1](image_url)  Concentration of Campath-1G in serum before conditioning and transplantation. Data are presented as means of measurements for 12 patients.
appears to be reduced in most studies. T cell depletion is complicated by an increased incidence of graft failure. From pooled data, it appears that the incidence of irreversible complete graft failure may be in the range of 10% for HLA-matched family donor transplantation. The most extensive experience with in vitro T cell depletion involves the rat IgM monoclonal antibody Campath-1M. A recent update of the results for several hundred allogeneic BMTs performed in the 'Campath-user groups' revealed an incidence of acute GVHD grade II-IV of 16% of the patients. Complete graft failure was observed in 15%.2,27

Severe acute GVHD (grade II-IV) was observed in only four of 21 evaluable patients (19%). This percentage is similar to that obtained with in vitro Campath-1M depletion but may be somewhat higher than the incidence reported for other in vivo T cell depletion procedures.1,28 The incidence of acute GVHD is also similar to that which can be achieved in BMT with post-transplant immunosuppression only.29 It is possible that the degree of T cell depletion in our patients was less than that achieved with some in vitro techniques resulting in a 2-3 log depletion.28 Thus, it is possible that the incidence of acute GVHD can be further decreased by prolongation of the Campath-1G infusion post-BMT or by increasing the dose.

In most reported series of patients who received HLA-identical sibling marrow grafts, the incidence of chronic GVHD was between 25 and 50%.30 For patients who had evidence of prior acute GVHD the probability of developing subsequent chronic GVHD was significantly higher than for those without or with only mild acute GVHD. In line with these data is the observation that patients who received T cell-depleted marrow developed chronic GVHD less frequently.31 Chronic GVHD is seen in only 18% of the patients who received a bone marrow graft that was depleted in vitro by Campath-1M.27 In our series the incidence of aGVHD does not appear to have been reduced (42%, 8/19 of the evaluable patients). In most cases, it was transient and responded to intensive treatment.

Immunological incompetence with the risk of opportunistic infections is apparent after BMT during the first 6-12 months. T cell function, as measured by proliferative response to phytohemagglutinin and normal IgG production, normalized 4-8 months after conventional BMT and 11-15 months after transplantation of T cell-depleted bone marrow.32-34 Grataua et al.21 reported reactivation of HSV infection in 45% and CMV infections in 47% of the patients after BMT. In our current series reactivation of viral diseases was observed in 19 episodes. This includes HSV reactivation in 40% and CMV reactivation in 47% of the patients at risk. Five patients died due to opportunistic viral, bacterial or fungal infections. It is conceivable that both the additional immunoincompetence caused by in vivo depletion of recipient and donor lymphocytes and the high incidence of chronic GVHD might be responsible for a number of these opportunistic infections. In this phase II study, however, the incidence of viral infections was not increased compared to the experience in previous years when systemic anti-lymphocytic antibodies were not used. The overall long-term survival for this group of patients was not particularly good, however, it has to be taken into account that a large proportion of these patients had recognized high risk features. No conclusion can be drawn regarding a specific diagnosis due to the small numbers.

In conclusion, in vivo depletion of recipient and donor lymphocytes with Campath-1G results in a relatively low incidence of acute GVHD without a concomitant increase in graft failure or relapse rate but with a relatively high incidence of chronic GVHD. A further decrease in the incidence of GVHD may be achievable by alteration of the infusion schedule or dose.

CAMPATH-1 Monoclonal Antibodies in Bone Marrow Transplantation

GEOFF HALE and HERMAN WALDMANN for CAMPATH USERS

ABSTRACT
CAMPATH-1 (CDw52) antibodies recognize a very small lipid-anchored glycoprotein that is expressed on the surface of human lymphocytes. They are remarkably lytic with human complement. In addition, CAMPATH-1G (rat IgG2a) and CAMPATH-1H (human IgG1) bind to human Fc receptors and are very effective for cell lysis in vivo. CAMPATH-1M (rat IgM) and CAMPATH-1G have been used to control GVHD and graft rejection in bone marrow transplantation by depletion of the T cells of the donor and recipient. Depletion of donor T cells alone gave excellent control of GVHD but up to 20% of the patients transplanted from HLA-matched siblings, and 51% of those transplanted from nonsibling donors, experienced graft failure caused by immunological rejection. Graft rejection could be partly overcome by additional immunosuppression either with CsA or total lymphoid irradiation (TLI). More effective was the use of CAMPATH-1G in vivo to deplete residual host lymphocytes. Preliminary results from current protocols of antibody depletion give two year actuarial leukemia-free survival as good as or better than similar studies with conventional GVHD prophylaxis, as well as a decreased morbidity from chronic GVHD, although engraftment was delayed by about 5 days. We propose that prophylactic T cell depletion with CAMPATH-1 antibodies is a simple and valid alternative to drug-based immunosuppression that may be particularly applicable to patients with acute leukemia or nonmalignant diseases transplanted from HLA-matched siblings as well as any patients transplanted from unrelated donors. Future developments of antibody-based immunosuppression may allow the extension of marrow transplantation for tolerance induction to organ transplants or in autoimmune diseases.

INTRODUCTION
Bone marrow transplantation can be used in the management of several different kinds of disease. It gives a remarkably powerful effect against some types of leukemia (notably CML) and would often be the treatment of choice for inborn or acquired defects of the hemopoietic system. In theory, it could be used to create tolerance to other organs and as a radical treatment for severe autoimmune diseases. The biggest problem is the two-way immune recognition of donor and recipient that leads to the major complications of graft-versus-host disease (GVHD) or graft rejection. With powerful immunosuppressive drugs, these can be controlled to some extent, yet GVHD still remains a significant cause of morbidity even when the donor and recipient are HLA-matched siblings. When the donor and recipient are less well matched, or unrelated, GVHD and graft rejection are major problems and this currently limits the use of marrow transplantation to only the most severe diseases. The key players in the generation of immune responses are T lymphocytes, and it has been shown that they are the prime mediators of

Department of Pathology, University of Cambridge, Tennis Court Road, Cambridge, CB2 1QF, UK.
GVHD and rejection. If T cell alloreactivity could be more effectively controlled, then the immunological complications could be overcome and marrow transplantation could be more widely applied.

Several years ago it was shown in animal models that removal of mature T cells from the donor bone marrow would prevent GVHD (1–4). However, ablation of recipient T cell function has not been so straightforward. Even after total body irradiation some recipient T cells remain and, in the absence of donor T cells, they can gain the upper hand and reject the marrow (5–7). The methods that were originally developed for depleting the donor T cells (e.g., agglutination with soybean lectin, E-rosette, density gradient centrifugation) were mostly not applicable to depletion of the same cells in vivo, so it was difficult to tackle this side of the problem with any specificity. The one type of agent that could be used both in vitro and in vivo was antilymphocyte globulin, and this was shown to be immunosuppressive and capable of preventing GVHD (8). The problem with antilymphocyte globulin is that it is a heterogeneous mixture of antibodies directed against different cell antigens, only a minority of which are T cell specific. It was therefore difficult to obtain samples that were reproducibly active and nontoxic.

When monoclonal antibodies became available, one of the first clinical applications was for purging marrow of donor T cells. However, most monoclonal antibodies were singly very inefficient at killing target cells because they did not activate human effector mechanisms (complement and/or Fc-receptor-dependent cell-mediated killing). Early efforts were therefore not very successful (9,10) and this led many investigators to search for different ways of using the antibodies for cell depletion. One method was to couple the antibody to a toxin (e.g., ricin) (11); others have used magnetic particles (12) or immunoadsorption (13). However, we continued to look for antibodies that could exploit natural human effector functions, with the prospect that these could eventually be used in vivo as well. Thus finding a lytic antibody for T cell depletion of bone marrow was not just an end in itself, but also a way to test reagents that might later find wider applications for immunosuppression.

THE CAMPATH-1 ANTIGEN

From a fusion of rat spleen cells with a rat myeloma cell line, we selected a set of antibodies that was unusually lytic for human lymphocytes using autologous complement (14–16). It turned out that all of them recognized the same antigen, which we now know to be a glycoprotein that is attached to the cell membrane by a lipid (glycosphingolipid) anchor that has a conventional structure similar to other mammalian GPI anchors. The N-linked carbohydrate, and indeed the 9 N-terminal amino acid residues, can be removed without destroying the antigenicity or sensitivity to complement lysis. The CAMPATH-1 antibodies therefore seem to recognize an epitope which includes the three or four C-terminal amino acids and possibly part of the GPI anchor. This implies that they bind very close to the cell membrane, which

surface antigens isolated from the same fusion, which were almost exclusively IgG\(_2a\), or IgG\(_{2b}\). The CAMPATH-1 antibodies recognized virtually all human lymphocytes, both T cells and B cells as well as monocytes and macrophages, although the latter seemed to be less sensitive to complement-mediated lysis. Tests on panels of fresh leukemia and lymphoma cells and cell lines showed that they recognized most cases of lymphoid malignancy, but only a small minority of myeloid leukemias (17,19). In the fourth leukocyte workshop the CAMPATH-1 antibodies were assigned to the cluster CDw52 (20). Little or no reactivity with colony-forming cells could be detected either by complement-mediated lysis, or by cell sorting (14,15). This important result was confirmed in numerous laboratories (21–24), although one group has reported only approx. 40% recovery of colony forming cells (25). Valentin and co-workers (26), using a different CDw52 antibody, which is known to have a broader reactivity than CAMPATH-1M, also found a significant depletion of CFU-GM. In these cases, we cannot be sure that the colony-forming cells did not require growth factors from the lymphocytes since the appropriate controls were not included. However, a recent comprehensive study of CAMPATH-1H found no evidence for reactivity with the cells that give rise to colony-forming cells during long-term culture (27).

CAMPATH-1 antibodies were found to recognize lymphocytes from old world monkeys, but not other species (15,23). At this time we also found that red cells were recognized in some of the monkeys. Antigen expression on the red cells seems to be under the control of a single autosomal gene, whereas expression on lymphocytes is constitutive (28). It has been reported that some CAMPATH-1 antibodies can recognize an antigen on human red cells (26), but despite extensive studies with large panels of cells using numerous techniques, we have never been able to detect such reactivity (15) (V. Taylor and G. Hace, unpublished observations).

Structure of the antigen

Recent work indicates that the antigen is a remarkably small glycoprotein, having only 12 amino acids, with a single N-linked carbohydrate on Asn-3, which is comparatively large and complex (Fig. 1) (18,29,30). At the C-terminus the peptide is attached to a glycosphingolipidinositol anchor that has a conventional structure similar to other mammalian GPI anchors. The N-linked carbohydrate, and indeed the 9 N-terminal amino acid residues, can be removed without destroying the antigenicity or sensitivity to complement lysis. The CAMPATH-1 antibodies therefore seem to recognize an epitope which includes the three or four C-terminal amino acids and possibly part of the GPI anchor. This implies that they bind very close to the cell membrane, which
Expression of antigen on spermatozoa

There is very little information about the physiological function of the CAMPATH-1 antigen. Like virtually all other GPI-anchored glycoproteins, there is some evidence that cells can be activated by CAMPATH-1 antibodies under suitable conditions (17,26,43). However, an intriguing observation was the discovery of the same antigen on mature human sperm (44–47). It actually seems to be synthesized by the epithelial cells of the epididymis, secreted into the seminal plasma (probably in the form of membrane-bound vesicles) from where it is taken up by the sperm as they pass through. Mature sperm are therefore sensitive to complement attack in the presence of CAMPATH-1 antibodies, but this is not thought to be a major problem in the context of therapy because only minute amounts of antibody would be expected to reach the seminal fluid and there the sperm would be protected by the large excess of vesicular antigen (47).

A homologous epididymal antigen has recently been identified in monkeys (48). It has a mature protein sequence of only 11 amino acids, which is very similar to the human antigen. It is likely that this is the same antigen that we detected on monkey lymphocytes. In mice, a related antigen has also been described that is expressed on lymphocytes and epididymis (49,50). Although the mature peptide (approx. 20 amino acids) does not closely match the human antigen, it contains a similar N-glycosylation site and the untranslated portions of the cDNA are significantly similar. We expect that these homologues will provide good targets for experiments to elucidate the antigen function. Meanwhile, they will also provide models for studying the therapeutic applications of CAMPATH-1 antibodies, which are by now well advanced in humans.

APPLICATIONS OF CAMPATH-1 ANTIBODIES IN BONE MARROW TRANSPLANTATION

CAMPATH-1M for T cell depletion

CAMPATH-1M was selected because it gave the highest titre of cell lysis with no effect on colony-forming cells. Studies in cynomolgus monkeys and in patients with end-stage lymphocytic leukemia showed no unexpected toxicity (51) and experiments in monkeys also showed no delay in the engraftment of autologous bone marrow treated with CAMPATH-1M and complement in vitro (52). On the basis of these studies, colleagues at the Hammersmith Hospital, London, the Hadassah University Hospital, Jerusalem, and the University Hospital, Ulm, started to use CAMPATH-1M with complement from donor serum for T cell depletion of donor bone.
marrow for allogeneic transplants. A series of 11 patients transplanted for advanced leukemia from HLA-matched siblings demonstrated that this was a very effective method of preventing GVHD, even when no posttransplant immunosuppression was used (21). Nevertheless, even in this small series, three cases of graft failure were observed, which we now know is the almost inevitable corollary of extensive T cell depletion.

Several lines of evidence suggest that the graft failure was mainly due to immunological rejection of the donor bone marrow, rather than, for example, an adverse effect of the antibody treatment on stem cells or their ability to repopulate the recipient (53). First, only one case of graft failure has been seen in more than 60 patients who received autologous bone marrow purged by the same method (to remove residual leukemia cells). Second, the incidence of graft failure was higher when bone marrow from unrelated or mismatched donors was used. Third, there were several cases in which host-derived cytotoxic T cells could be detected immediately preceding graft failure and some of them were shown to be specific for donor cells (54–56).

Since 1983, more than 500 transplants have been performed by 23 transplant centers throughout Europe and the Middle East, using this method of preventing GVHD in HLA-matched siblings (22,57–63) (Protocol 01, Fig. 2). Various modifications to the regime were made in an effort to reduce the risk of graft rejection. Some patients received posttransplant CsA. Others received intensified conditioning regimes, including additional radiotherapy, drugs, or total lymphoid irradiation.

A recent analysis (64) in patients transplanted for malignant diseases showed that the incidence of either severe or chronic GVHD was substantially reduced compared with other types of therapy. Overall, the frequency of acute GVHD > grade 1 in patients at risk was 17% and the frequency of severe acute GVHD (grade 3–4) was only 7%. The frequency of chronic GVHD was 19% and of severe chronic GVHD, 2%. The incidence of graft failure was lower in those patients who received CsA or TLI (12–13%) compared with those who did not (19–21% graft failure). The use of CsA (though not TLI) was also associated with a significant reduction in transplant-related mortality. Only a small number of patients (n = 24) received both TLI and CsA, but they fared particularly well with only 4% graft failure.

Prevention of rejection with Campath-1G

The partial success in prevention of graft failure by immunosuppressive reagents led us to believe that better control might be achieved with more selective and potent immunosuppressants. Experiments in animals showed that treatment of the recipient with depleting anti-T cell antibodies could abolish rejection of T cell-depleted bone marrow, even with reduced irradiation or when the donor and recipient differed across major histocompatibility barriers (7,65). We therefore looked for monoclonal antibodies that could produce a similar effect in humans. Antibodies that could deplete lymphocytes in vivo were important in these experimental studies and so again we turned to the Campath-1 antibodies since they were the most effective reagents available at the time (66).

The original IgM antibody Campath-1M, although extremely lytic with complement, gave only transient depletion of lymphocytes in vivo in patients with CLL or lymphoma (51). However, from another CDw52 clone that secreted an IgG2a antibody, we were able to isolate a spontaneous class-switch variant, the rat IgG2b antibody Campath-1G (62). The IgG2b subclass is not only the best rat IgG for activating complement but is also optimal for binding to human Fc receptors and activating cell-mediated killing (67–69). Campath-1G proved to be very efficient at depleting lymphocytes in vivo in several patients with lymphoid malignancies and in patients

FIG. 2. Illustration of the different antibody protocols studied by the Campath users group. The dose of Campath-1M was typically 25 mg for in vitro purging, whereas the dose of Campath-1G was usually 5–10 mg for in vitro purging or 5–10 days at 5–10 mg/day for in vivo treatment.
suffering steroid-resistant kidney graft rejection (70,71). In both studies, the treatment with CAMPATH-1G gave a beneficial clinical response in many of the patients.

The first objective was to see whether treatment with CAMPATH-1G would decrease the risk of graft rejection in the context of "standard" T cell depletion. This was not easy to test because the actual incidence was comparatively low, and so quite a large number of patients was needed to demonstrate an effect. Initially we did not know whether the recipient's effector mechanisms would be compromised by the conditioning regime, so it was possible that administration of antibody at the time of the transplant might not be effective. Therefore the CAMPATH-1G was given at 5–10 mg/day for 5 days before the start of chemoradiotherapy (Protocol 02). Although this had the slight disadvantage that extra inpatient time was required, the protocol had several advantages: (a) the degree of lymphocytopenia produced by CAMPATH-1G could be measured, uncomplicated by other treatments, (b) adverse effects of the antibody could likewise be assessed, and (c) most of the antibody would be cleared by the time of the transplant and so be unlikely to contribute to extra depletion of the donor T cells. T cell depletion with CAMPATH-1M and other elements of the conditioning regime were kept the same as in historical control groups. No other prophylactic agents to prevent GVHD or graft rejection (e.g., CsA, TLI) were given. The plan is to enroll 100 patients with acute leukemia in first remission, which will provide a homogeneous group where the effect of the antibody protocol on relapse can also be observed.

To date about 75 such patients have been enrolled by three transplant teams (Royal Free, London; University Hospital, Ulm; King Faisal Hospital, Riyadh). The interim results are very satisfactory and a detailed report will be published when the study is complete. Meanwhile we have analyzed these study patients as part of a larger group of patients, including CML and advanced disease, who all received the same antibody protocol (Table 1). Out of 144 patients there has been only 2% severe acute GVHD, no case of severe chronic GVHD, and 9% graft failure. The risk of death at 2 years from all causes other than relapse is 21 ± 8%, which is significantly lower than that seen with the original protocol (28 ± 3%). Furthermore, the leukaemia-free survival at 2 years is also significantly better (Fig. 3A). Although graft failure has not been totally eliminated, there is a possibility that in the future, the addition of a short course of CsA might make the risk still lower.

The degree of lymphocyte clearance induced by CAMPATH-1G in vivo has been measured by a sensitive limiting dilution analysis and found to be similar to that achieved with busulphan/cyclophosphamide or total body irradiation (72). Antibody therapy was as effective as the conventional treatments at depletion of cytotoxic T cell precursors (> 99%) but far more effective at eliminating helper T cells that were relatively resistant to chemotherapy or radiotherapy.

The use of CAMPATH-1G for prevention of GVHD

The successful use of CAMPATH-1G to eliminate cells in vivo suggested that it could be used in a similar way to remove the donor T cells in order to prevent GVHD. In principle, this could be done either by addition of the antibody to the donor bone marrow to opsonize the cells for subsequent clearance in vivo (protocol 03), or by administration to the patient at or around the time of the transplant (protocols 04–06). In both cases, the antibody should also help to remove residual host lymphocytes though its effect on the donor T cells would presumably be greater when it was admixed with the bone marrow. The advantage of these procedures is that no additional complement or processing of the bone marrow would be required. Both approaches have been tried by different transplant centers and the results prove that sufficient depletion of donor T cells to avoid GVHD can be achieved by either method (Table 1).

Teams at the Hadassah Hospital, Jerusalem and the University Hospital, Cape Town have used CAMPATH-1G in vitro (Protocol 03) (73–75). Most patients (24/26) received additional total lymphoid irradiation to prevent graft rejection, but no posttransplant immunosuppression. The incidence of either severe GVHD or graft failure was very low, but as the number of patients so far treated is small, this is not yet significantly different from the results with the original protocol. However, the 2 year transplant-related mortality of this group of patients is already significantly better than those treated on the original protocol and so is the leukemia-free survival (Fig. 3B).

These results provide convincing evidence that mere opsonization with CAMPATH-1G is sufficient to deplete the donor T cells. We know that CAMPATH-1G can bind to human Fc receptors as well as activating human complement, but we cannot say which mechanism is more important. If the donor bone marrow was not washed free of plasma, significant lysis of T cells was obtained within 30 min of addition of CAMPATH-1G, even though no extra complement was added (W. Fibbe and R. Willemze, University Hospital, Leiden and E. Yousaf and D. Pamphilon, Blood Transfusion Service, Bristol, unpublished observations). However, the procedure seemed to be equally as successful with bone marrow separated on Ficoll and washed free from plasma, so presumably the necessary effector mechanisms are sufficiently intact in the recipient despite the chemoradiotherapy.

An alternative way of using CAMPATH-1G to prevent GVHD has been tested by teams at the University Hospi-

*The fraction who suffered graft failure or GVHD is calculated as a percentage of the patients at risk. Patients were considered not evaluable for engraftment if they died before day 20 without engraftment, and not evaluable for GVHD if they suffered graft failure or died before day 100 without GVHD (day 120 for chronic GVHD). Results in each protocol were compared with the original protocol (01) by the χ² test. Those that are significantly better are in boldface and those that are worse are in italics. Note: Leukemia-free survival means freedom from hematologic disease. Cytogenetic relapse in CML was not included.*
PATH-1M \textit{in vitro}. However, an observation that may be relevant is that all of the patients who have received CAMPATH-1G \textit{in vivo} had slower engraftment than normal, with a median time to reach 500 neutrophils of about 24 days compared with a median of about 19 days for patients who had only \textit{in vitro} T cell depletion (64). This delay in engraftment was more marked when the CAMPATH-1G was given close to or around the time of the transplant. We do not think there was a direct toxic effect on bone marrow stem cells because no delay was seen with CAMPATH-1G \textit{in vitro}. Possibly, a small number of lymphocytes, either donor or host, play a role in engraftment, perhaps by secreting cytokines that promote the growth of progenitor cells.

\textbf{Leukemia relapse}

One of the potential risks of T cell depletion for patients with leukemia is the loss of a beneficial graft-versus-leukemia effect. In 1979 the Seattle transplant team showed that patients with advanced acute leukemia who suffered from GVHD were at lower risk of relapse, compared with those who did not develop GVHD (78). Subsequent analysis of large collections of data has confirmed this finding in all the major categories of leukemia treated by marrow transplantation (79). There has been considerable speculation as to whether the beneficial graft-versus-leukemia effect can be separated from GVHD, perhaps by selective manipulation of the donor T cells, and there have been several experimental studies in animals which suggest that this may be possible (80–83). However, there are very considerable practical difficulties in applying these principles to human therapy. At present, we can only examine whether the trade-off between decreased transplant-related mortality and increased relapse is favorable or not.

The risk of relapse for all patients with early leukemia who received T cell-depleted transplants is shown in Fig. 4. Results of both \textit{in vitro} and \textit{in vivo} depletion are included, but patients who received any form of T cell addback are excluded. With up to 10 years follow-up, the risk of relapse in ALL and AML shows a plateau at approx. 30%, with most cases occurring in the first year. In CML, the risk of hematologic relapse continues to rise for at least 5 years, reaching an apparent plateau of about 60% by 7 years. It has been clear for some time that T cell depletion results in a significant increase in relapse risk for patients with CML transplanted from matched siblings (59,61,62,84,85), though it was initially surprising to find that the risk of relapse of T-depleted patients is much greater than for conventionally treated patients who do not suffer from GVHD (79). This is perhaps the best evidence yet in humans that the antileukemic effect of the marrow transplant might be distinct from clinical GVHD.
In contrast, the results in acute leukemia do not show such a distinction, since the effect of T cell depletion can be accounted for in terms of the improved control of GVHD. The relapse rates we see are a little greater than reported using conventional therapy with MTX/CsA (86,87) and this results in a slightly lower leukemia-free survival when we consider the CAMPATH-1-treated patients as a whole. However, the overall control of transplant-related complications is so much better with the recent protocols, particularly 02 and 03, that this should compensate for the slightly increased risk of relapse. Currently the leukemia-free survival at 2 years for patients with acute leukemia treated according to protocol 02 or 03 is 56%, which is almost exactly what would be expected using MTX/CsA. However, the improved control of GVHD, particularly chronic GVHD, with antibody therapy is likely to be a significant advantage.

Transplants for nonmalignant diseases

If antibodies could be routinely used to control GVHD and rejection, one of their most useful applications would be in transplants for nonmalignant diseases, such as severe aplastic anemia and eventually thalassemia or sickle cell anemia. These situations are not complicated by the potential graft-versus-leukemia effect of donor T cells. Irradiation is also undesirable and so there would be significant long-term advantages in obtaining a powerful but nontoxic immunosuppressive conditioning regimen.

To date the CAMPATH-1 users group have carried out 116 such transplants from HLA-matched siblings (80 aplastic anemia, 22 thalassemia, 9 Fanconi’s anemia, 5 other inborn errors). A diversity of conditioning regimens and antibody treatment protocols has been tested as in the patients with malignant diseases. However, the numbers of patients treated according to each individual protocol are small. Two main groups of patients can be identified according to the antibody treatment (Table 2). The first group received T cell depletion in vitro, either with CAMPATH-1M (31 patients, protocol 01) or CAMPATH-1G (16 patients, 17 transplants, protocol 03). The second group received CAMPATH-1G in vivo either with

\[ \text{Percentages} \]
T cell depletion in vitro (11 patients, protocols 02, 07) or without (9 patients, protocol 06). Three of the transplants in the second group were retransplants after graft rejection of patients in the first group (75). In every case the control of GVHD has been excellent. There were only two cases of acute GVHD > grade 1 and only one case of chronic GVHD (not severe). In the group who received only in vitro T cell depletion, the incidence of graft failure was 45%, but in the group who received in vivo T cell depletion it was only 5% (p < 0.01, χ² test). The actuarial survival at 1 year for the in vitro group was 74% and for the in vivo group 100% (p < 0.03, log-rank test). Unlike the situation in transplants for leukemia, the use of CAMPATH-1G in vivo was not associated with any delay in engraftment. The median day to reach 500 neutrophils for the in vitro group was day 19 and for the in vivo group was day 14 (excluding patients who did not engraft). Unlike the patients with leukemia, most of these patients did not receive TBI. Possibly their bone marrow microenvironment was therefore more conducive to rapid regeneration.

Transplants from donors other than HLA-identical siblings

Only a minority of patients who might benefit from a marrow transplant have a suitable HLA-identical sibling. Patients who receive transplants from HLA nonidentical family members or from "HLA-matched" unrelated donors are at significantly higher risk of GVHD and other severe transplant complications. Therefore much attention has been given to the use of T cell depletion in these situations. CAMPATH-1 antibodies have been particularly used in transplants from parents for immune deficiencies and other inborn errors (88–92) and in unrelated donor transplants (93–95).

A summary of the results to date is given in Table 3. T cell depletion in vitro gave good control of GVHD with only 25 cases of severe acute GVHD out of 180 patients evaluable (14%). However, the incidence of graft failure was substantial (51%) in those patients who did not receive additional therapy with CAMPATH-1G in vivo. This is despite the fact that many of them received various other treatments designed to reduce the risk of graft rejection, such as additional irradiation or CsA or other antibodies, including LFA-1 and CD2 (92). Patients who received in vitro T cell depletion combined with in vivo treatment with CAMPATH-1G had a significantly lower incidence of graft failure (24%), though it was still a substantial problem. The use of in vivo antibody alone combined with conventional GVHD prophylaxis using MTX/CsA gave a similar rate of graft failure and GVHD.

Because these results included all categories of patients with early or advanced leukemia or nonmalignant disease, it would be uninformative to compare the survival curves. The largest subset is the patients transplanted for CML in chronic phase from unrelated donors (94). They are of particular interest in view of the high incidence of relapse that was seen following T cell depletion in HLA-matched sibling transplants. The patients are divided into two groups (Table 4). Thirty patients received in vivo CAMPATH-1G combined with in vitro T cell depletion (Protocol 02) and 60 received only in vivo CAMPATH-1G with conventional GVHD prophylaxis (Protocol 05/06). There were no significant differences between the incidences of graft failure and GVHD in the two groups although, as expected, the trend was toward less GVHD but more graft failure with in vitro T cell depletion. However, in both cases the incidence of relapse seemed to be much lower than in comparable transplants from HLA-matched siblings (Fig. 5). Two-year survival was significantly better in the group who received only in vivo antibody, and the

</table>
leukemia-free survival in this group \((53 \pm 15\%)\) was as good as that obtained in matched sibling transplants and superior to published results for unrelated donor transplants using conventional GVHD prophylaxis \((96)\).

**Lymphoproliferative disease, immune reconstitution, and infections posttransplant**

Unlike some other trials of T cell depletion \((97-100)\) lymphoproliferative disease was rare. Out of 1529 transplants, 10 cases of lymphoproliferative syndrome or secondary lymphoma have been reported \((101)\). This represents an actuarial risk at 5 years of 1% in transplants from siblings \((5/1067)\) and 2.3% from mismatched or unrelated donors \((n = 5/462)\). CAMPATH-1 antibodies recognize B cells as well as T cells and it is possible that bone marrow purging with CAMPATH-1M or CAMPATH-1G helps to reduce the potential target for EBV-driven oligoclonal proliferation of B cells in the early posttransplant period, which can lead to fatal malignant lymphomas if uncontrolled.

The CAMPATH users group have not centrally collected data on the recovery of lymphocyte subsets or the incidence of nonfetal infections because of the huge amount of complex reporting and analysis this would have entailed. The number of fatal infections late after transplant did not seem to be more than seen with conventional GVHD prophylaxis, since transplant-related mortality did not increase much after the first 9 months. However, individual centers have observed relatively slow T cell regeneration following lymphocyte depletion with CAMPATH-1M \((102,103)\) and some have found a high incidence of CMV viremia \((A\ Bacigalupo, Genoa, and D. Bunjes, Ulm, unpublished observations)\). Since the normalizations of T cell numbers may not occur for a year or more after a bone marrow transplant even with conventional GVHD prophylaxis, it is not easy to assess the impact of T cell depletion on this parameter. Furthermore, we do not know how well the T cell phenotype really reflects the immune status of an individual. Probably functional assays of T cells are more relevant although they are more laborious to carry out.

**CONCLUSION**

T cell depletion is certainly the most effective method of preventing graft-versus-host disease. We have developed simple procedures to accomplish this using the patient's own immune effector mechanisms. CAMPATH-1 monoclonal antibodies are particularly effective, possibly because of the unique properties of their target antigen. Furthermore, there is the possibility that in vivo antibody treatment may contribute to elimination of residual leukaemia in some cases \((70)\).

Better control of GVHD is a prerequisite before bone marrow transplantation can be fully used in the treatment of a wide range of diseases. Unfortunately, T cell depletion is associated with increases in the risks of graft rejection and leukemia relapse. Substantial progress has been made toward overcoming the problem of graft rejection by giving increased immunosuppression to the recipient, either with CsA or TLI, or most successfully by in vivo treatment with CAMPATH-1G. Eventually we believe that a combined strategy should permit successful engraftment in virtually all HLA-matched sibling transplants and the great majority of others. This should mean that bone marrow transplants can be used for nonmalignant hematological diseases with less fear of procedure-related mortality and it might open the way to the use of marrow transplantation for tolerance induction in organ transplantation and autoimmune disease.

The risks of leukemia relapse associated with extensive T cell depletion have now been well defined, at least in patients with early disease. In acute leukemia the increase in risk is modest compared with current results using drug-based GVHD prophylaxis. The extra mortality from relapse is likely to be offset by a reduction in transplant-related complications. In CML, T cell depletion has a significant adverse effect, at least in patients transplanted from HLA-matched siblings. We do not know why a similar increase in relapse was not seen in patients transplanted from unrelated donors. It may be relevant that most of the latter group receive higher doses of radiotherapy \((95)\), but it is also possible that there is a stronger allogegenic effect that is not completely abrogated by the antibody depletion.

Some groups have tried to add back small numbers of lymphocytes to the depleted bone marrow or after the transplant in order to preserve a graft-versus-leukemia effect \((74,104,105)\). The effect has been to increase the risk of GVHD and decrease the risk of leukemia relapse.
HALE AND WALDMANN

(64) and, overall, the results are similar to those obtained without T cell depletion. In other cases donor T cell infusions have been used to effectively treat relapse (106, 107), but this procedure is not always effective and carries a high risk of fatal GVHD. Ideally, T cell addback could be administered 2–4 months after the transplant when the patient had recovered from the effects of the conditioning regime but before hematological relapse is likely to have occurred. If a sensitive assay were available to indicate the amount of residual disease at that stage (108), this immunotherapy could then be reserved for only those patients who were likely to relapse and had not suffered any GVHD. However, whatever refinements are made in the timing, dose, or cellular content of lymphocyte therapy, it is unlikely that its potential for producing severe GVHD will be eliminated. The biological effect will largely be dictated by the immune repertoire of the lymphocytes and the genetic disparity between donor and recipient. The alternative strategy is to seek for new drug treatments for residual leukemia, or more effective combinations of existing ones. For example, the drug thiotalpa is reported to be myelosuppressive and may be useful for treatment of CML in the context of T cell depletion (109, 110). So far the clinical results are very early, and longer follow-up is needed to be sure whether this treatment will give improved results.

Bone marrow transplantation will continue to be an important arena for the testing of new types of biological therapy. As the clinical results gradually improve and the range of potential new treatments becomes broader, it will be more and more difficult to design prospective trials that have a good chance of showing significant improvements. We believe that the best use can be made of these limited opportunities if we test therapies that, like CAMPATH-1, potentially have a very broad application. Although we have not described here the wider range of clinical applications where CAMPATH-1 antibodies are being used, such as for treatment of leukemia, control of organ transplant rejection, and treatment of autoimmune diseases (70, 71, 111–114), nevertheless, the results obtained from the studies in bone marrow transplantation have helped to make those possible.

Received 2 June 1994; accepted for publication 9 November 1994

Summary. One hundred and forty-six patients with acute leukaemia (81 with ANL and 65 with ALL) received allogeneic bone marrow transplantation from their fully matched siblings. 121 patients underwent T-cell depletion (TCD) using Campath 1 monoclonal rat anti-human lymphocyte (CDw52) antibodies; 67 with Campath 1M and 54 with Campath 1G isotypes. Patients were conditioned for transplant using either total body irradiation combined with chemotherapy (125 patients) or busulfan and cyclophosphamide (21 patients). 112 recipients of T-cell depleted allografts received in addition total lymphoid irradiation (TLI) for prevention of rejection. Engraftment of neutrophils (>0.5 × 10⁹/l) and platelets (>25 × 10⁹/l) occurred on days 15 and 18, and on days 18 and 20 in recipients of Campath 1M and Campath 1G treated marrows respectively. Rejection was documented in 6-8% of T-cell depleted transplants. Leukaemia relapse-free survival at 2 years was 83% for patients transplanted in first CR, 76% in second CR (P² = 0.34) and 42% in advanced leukaemia (P² = 0.009).

81 marrow recipients, 38 with Campath 1M and 43 with Campath 1G treated marrow, received post-transplant graded increments of donor’s peripheral blood lymphocytes (PBL) to induce graft-versus-leukaemia (GVL) effects. Administration of donor’s PBL was associated with clinically significant GVHD and with decreased relapse rate especially in patients with ALL. Our data suggest that in patients receiving marrow allografts depleted of T cells by Campath 1 monoclonal antibodies, rejection can be reduced by adequate pregrafting immunosuppression. In patients with advanced disease, post-transplant cell-mediated immunotherapy (CMI) using donor’s PBL may be beneficial; however, further studies are needed to define the optimal schedule of CMI for safe and effective prevention of relapse following TCD bone marrow transplantation in malignant haematological diseases.

Keywords: allogeneic BMT, T-cell depletion, donor lymphocytes.

Acute and chronic graft-versus-host disease (GVHD) is the primary complication of allogeneic BMT affecting one-third to a half of HLA-matched bone marrow transplant recipients with potentially severe multisystemic complications which may lead to poor quality of life with occasional serious or even fatal outcome (Sullivan, 1986; Gale et al. 1987; Atkinson et al. 1990).

The most successful prophylaxis against GVHD consists of combined administration of ciclosporin A and methotrexate (Storb et al. 1986, 1988; Deeg & Henslee-Downey, 1990), a combination associated with delayed engraftment and increased rate of leukaemic relapse (Storb et al. 1989; Sullivan et al. 1989a). Alternatively, effective prevention of GVHD may be accomplished by pretransplant depletion of...
Donor PBL for Prevention of Relapse in T-cell-depleted BMT

Donor immuno-competent T cells (T-cell depletion, TCD) (Waldmann et al. 1984; Martin et al. 1985; Slavin et al. 1985; Frame et al. 1989; Antin et al. 1991). T-cell depleted marrow allografts are, however, susceptible to rejection (Keroan et al. 1989; Bordignon et al. 1989), which may be prevented by more intense immunosuppression of the host during the pre-transplant conditioning (Slavin et al. 1986). Moreover, effective depletion of lymphocytes from the marrow prevents the immune-mediated interaction of donor T cells against residual host tumour cells – the graft-versus-leukaemia (GVL) phenomenon (Sullivan et al. 1989a; b; Martin et al. 1985; Gale & Reimer, 1986; Weiden et al. 1979, 1981; Horowitz et al. 1990). Therefore the relapse rate in chronic myeloid leukaemia, and to a lesser extent in acute leukaemia, is significantly higher following TCD when compared with non-T-cell depleted allografts (MacKinnon et al. 1990; Truitt & Atasoy, 1991; Goldman et al. 1988). Because it has been shown consistently that GVHD induced by T cells is associated with GVL effects, it would therefore seem desirable to retain their antileukaemic effects and at the same time prevent or control the GVHD associated with their administration. We have shown in an experimental animal model of murine B cell leukaemia/lymphoma (BCL1) that delayed administration of allogeneic immunocompetent T cells after TCD transplant can effectively induce GVL without GVHD (Weiss et al. 1992; Slavin et al. 1978, 1992). Similar observations were recently reported in patients relapsing after BMT (Drebycki et al. 1992; Kohl et al. 1990; Porter et al. 1994). We have therefore chosen to use a similar approach by gradual transfer of controlled increments of donor's peripheral blood T lymphocytes (PBL) in order to reduce the risk of leukaemic relapse in recipients of TCD marrow allografts (Slavin et al. 1988).

Data presented in this report summarizes our initial results in allogeneic BMT for acute leukaemia, using Campath (monoclonal rat and human CD52) antibodies for TCD and post-transplant cell-mediated immunotherapy (CMI) with donor PBLs.

MATERIALS AND METHODS

Patients. Between 1981 and 1991, 146 patients with acute leukaemia were referred to the Bone Marrow Transplantation Centre at the Hadassah Hospital in Jerusalem for allogeneic BMT. All had HLA-identical, MLC non-responding sibling donors. Patients were eligible for transplantation irrespective of the stage of leukaemia if there was no life-threatening associated disease or organ impairment. Patient stratification into types of leukaemia and stage of disease is summarized in Table 1. Patients in third or subsequent remission, non-responsive or resistant relapse, or patients with extramedullary disease, were categorized as advanced stage.

All the treatment protocols were approved by the Hadassah Hospital IRB and the Ministry of Health Human Experimentation Committee. Written informed consent was obtained from all adult patients and donors, and court permission was obtained in each case of a minor donor.

Pretransplant conditioning. All patients with ALL were treated with total body irradiation (TBI) and chemotherapy, whereas patients with ANLL were treated either with busulfan and cyclophosphamide (BU-CY) or with combined

1 Busulfan 50 mg/kg/d x 4 and cyclophosphamide 50 mg/kg/d x 4.
2 Patients received in addition total lymphoid irradiation (TLI).
3 TBI 200 cGy x 6 and cyclophosphamide 60 mg/kg/d x 2.
4 Same as 3 but with addition of melphalan 60 mg/m² x 1 or cytosar 500 mg/m² x 4.
5 TBI 200 cGy x 6, cyclophosphamide 50 mg/kg, melphalan 60 mg/m², and VP-16 1500 mg/m².
chemoradiotherapy (Table I). Since July 1984, 114 patients receiving TCD allografts were given additional total lymphoid irradiation (TLI) for further immunosuppression and prevention of rejection (Slavin et al., 1986).

**Chemotherapy.** 21 patients were treated with BU-CY (busulfan 4 mg/kg/d for 4 d and cyclophosphamide at 50 mg/kg/d for 4 d). 117 patients were conditioned with TBI and chemotherapy. Over the years, three different regimens were used: during 1981–85 a single drug, consisting of cyclophosphamide 60 mg/kg/d for 2 d (38 patients), during 1986 a two-drug combination consisting of similar doses of cyclophosphamide and melphalan (60 mg/m² × 1) or cytosar (500 mg/m² × 4) (13 patients), and since 1987 a triple chemotherapeutic combination consisting of etoposide (VP-16) 1500 mg/m² × 1, cyclophosphamide 60 mg/kg × 1 and melphalan 60 mg/m² × 1 (66 patients). The remaining eight patients were treated with modified conditioning regimens according to individual needs. Unless contraindicated, all patients received two intrathecal doses of methotrexate and cytosar before the transplant.

**Irradiation.** TBI was administered in six fractions of 200 cGy each every 12 h, at 20 cGy/min over 3 d to a total of 1200 cGy. Partial lung shielding was accomplished by half value leaf shield after 600 cGy. TLI was administered at 80–120 cGy/min in four fractions of 150 cGy each over 2 d to a total of 600 cGy for patients scheduled for TBI, and five daily fractions of 200 cGy to a total of 1000 cGy for patients scheduled for BU-CY. Whenever indicated, patients with ALL received supplemental cranial and testicular irradiation.

**Bone marrow transplantation and T-cell depletion (TCD).** Bone marrow was harvested under epidural (adult donors) or general (minor donors) anaesthesia. 15 patients received unmanipulated marrow allograft (13 of them underwent BM transplant during 1981) and received standard GVHD prophylaxis consisting of methotrexate alone.

One hundred and thirty-one patients received TCD marrow allografts: 10 patients using the sheep red blood cell rosette (E rosette) separation technique with or without soybean agglutination (SBA) (Reimer et al., 1984), and, since July 1983, using monoclonal rat anti human CDw52 (Campath-1) antibodies as previously described (Hale et al., 1983; Waldman et al., 1984; Slavin et al., 1985).

**TCD using Campath-1 mAb. Campath 1M (IgM kappa).** Marrow buffy coat fraction was prepared by sedimentation with hetastarch (0-66%). Cells were resuspended in Hanks balanced salt solution at a concentration of 70-100 × 10⁶ cells/ml, and Campath 1M added at 0-1 mg/10⁶ cells for 30 min at room temperature. Fresh donor serum (20%) was then added as a source of complement for 30 min at 37°C. Cell clumps were carefully removed and the marrow was washed and infused (Hale et al., 1983; Cobbold et al., 1986).

**Campath 1G (IgG2b kappa).** Campath 1G was added directly into the marrow bag at three different concentrations: 0-3 (17 patients), 1 (30 patients) and 3 mg/10⁶ nucleated marrow cells (7 patients). Marrow cells were infused following 30 min incubation at room temperature and gentle agitation (Naparstek et al., 1989). In ABO mismatched transplants, RBC were first removed by sedimentation with hetastarch and Campath 1G was added into the buffy coat.

Residual T lymphocytes in marrow treated with Campath 1M were estimated consistently through the years by E-rosettes.

**Engraftment and chimerism.** The day of marrow infusion was designated as day 0. Engraftment was defined as an ANC of >0-5 × 10⁹/l for three consecutive days and unsupported platelets >25 × 10⁹/l. Engraftment was confirmed whenever possible by donor's cytogenetic markers and by red blood cell antigens and isoenzymes.

**Post-transplant cell-mediated immunotherapy (CMI) using donor peripheral blood lymphocytes (PBL).** 81 patients received fresh unirradiated donor's PBLs at weekly intervals for induction of graft-versus-leukemia (GVL) activity. The lymphocytes were collected by venipuncture or by continuous-flow apheresis using Barter's CS 3000 plus. Cell dose was calculated as the equivalent proportion of T cells/kg.

Two regimens for graded post-transplant T-cell repletion (TCR) were applied: (1) patients transplanted with Campath 1M treated marrow and patients receiving marrow treated with high concentrations (3 mg/10⁶ cells) of Campath 1G received donor's T cells early, beginning on day 1+1 with 10⁴ or 10⁵ T cells/kg, followed by a general schedule of weekly 1 log increment for a total of up to four doses (10⁴, 10⁵, 10⁶, and 10⁷ T cells/kg on days 1+1, +6, +14, and +21 or +28 respectively); (2) patients transplanted with marrow treated with low concentration of Campath 1G received donor's T cells only if no signs of acute GVHD developed by day 28; thereafter they received donor's PBL at an equivalent proportions of 10⁵, 10⁶, 10⁷ T cells/kg on days +28, +56 and +84, respectively. Subsequent administration of donor's PBL was discontinued as soon as signs or symptoms suggestive of acute GVHD appeared.

**Statistical evaluation.** Results were analysed as of August 1991. The follow-up period extended from 10 years to 1-5 months for the most recent patient included in the study, with median potential follow-up of 3-7 years.

Event-free survival (either death in remission or relapse) and relapse-free survival were computed from the date of transplant until date of death or relapse, or were censored at appropriate dates if these events had not occurred. Patients who died without relapse were considered as censored observations in relapse-free survival analyses, whereas the first event experienced by a patient (relapse or death without relapse) was considered a failure for event-free survival. The Kaplan-Meier method was used to calculate the probability of event-free survival or relapse-free survival as a function of time (Kaplan & Meier, 1958). The significance of the differences between pairs of Kaplan-Meier curves was determined by the Mantel-Haenszel technique (Mantel, 1966). Cox proportional hazards modelling (Cox, 1972) was used to identify whether any factors are jointly predictive of the probability of event-free or relapse-free survival. Patient characteristics considered for evaluation in the models included type of leukaemia and stage of disease at the time of transplantation, age, pretransplant conditioning, method of T-cell depletion, presence of acute or chronic GVHD and T-cell repletion. All P values are two-sided and denoted by P².
RESULTS

Patient characteristics and pretransplant condition
One hundred and forty-six consecutive patients with acute leukaemia, 82 with ANLL (among them 11 patients with MDS and four with secondary leukaemia) and 64 with ALL (among them three patients with leukaemic relapse of lymphoma), received marrow allografts from fully matched sibling donors. Table I summarizes the patients characteristics at the time of transplantation. The majority of patients with ANLL (61%) were in first CR, whereas 73% of patients with ALL were in second or subsequent remission. Overall, 29% of the patients in both disease categories were transplanted in advanced disease, among them 19 in second or unresponsive relapse. The median age of patients transplanted for ALL was significantly lower than that of ANLL patients (17 and 24 years, p = 0.00312), particularly among those transplanted in advanced stage. 122 patients received TBI combined with single, double or triple chemotherapy, whereas 21 patients, mostly children (median age 13 years) were conditioned with BU-CY, all of them with ANLL 17 in first CR.

Bone marrow transplantation, T-cell depletion and engraftment
Table II presents data on the methods of T-cell depletion employed. Similar numbers of patients in each disease category received marrow treated with either Campath 1M or Campath 1G. The number of bone marrow cells infused varied according to the method of purging and in vitro manipulation. In 32 patients receiving marrow treated with Campath 1M, residual T lymphocytes could not be detected, and in the remaining patients the mean percentage of T cells infused was 0.08%. In Campath 1G treated marrow, estimation of the number of infused T lymphocytes is somewhat more difficult, because T-cell depletion is expected to occur in vivo, most likely through antibody-dependent cell-mediated cytotoxicity (ADCC).

Uneventful engraftment occurred in 126 patients; two additional patients had prolonged pancytopenia, received a top-up marrow and reached satisfactory blood counts with documented donor type cells. The median day to attain ANC > 0.5 x 10^9/L was 15.5 d and to reach unsupported platelets > 25 x 10^9/L was 16 d for Campath 1M treated marrow recipients and 18 and 20 d respectively for those receiving marrow treated with Campath 1G.

Nine patients (6%) died within the first 18 d (median 14 d) before attaining sustained engraftment. Causes of death were infection, hepatic failure, ARDS and bleeding.

Rejection and graft failure
Nine recipients of T-depleted marrow (Table II) rejected their allografts (6-8%). Initial engraftment was documented only in four patients with subsequent rejection, whereas the remaining five patients never attained sustained haemopoiesis. Rejection occurred in 6/67 (9%) patients transplanted with Campath 1M treated marrow: 2/54 (4%) with Campath 1G treated marrow and 1/10 patients transplanted with marrow treated with E-rosettes. Seven had ANLL and three were in advanced stage. The median age was 30 and only two patients were below age 24. An attempted second allograft failed in eight and was successful in only one patient who later died of interstitial pneumonitis.

CMi by T-cell repletion using donor’s PBL
Of 67 patients transplanted with Campath 1M treated marrow, 38 received early CMi with donor’s PBL (Table III). 16 patients were able to complete the scheduled T-cell repletion, but in 12 patients CMi was discontinued due to GVHD. Of the 54 patients transplanted with Campath 1G treated marrow scheduled to receive donor T cells, 11 were excluded: nine because of acute GVHD which appeared before day +28 and therefore they were not eligible for further therapy, and two others due to donor’s intercurrent infection. In 16/43 patients treated CMi was discontinued due to GVHD.

Acute GVHD
Overall, 50 recipients of Campath 1 treated marrow (41-3%)

</table>

\* Seven patients were excluded from late TCR, in nine because GVHD developed before day +28.
\* Probability of remaining in remission at 2 years.
\¶ \( p \) value determined by Mantel-Haenszel test.
\$ Rejection, four patients; relapse, three patients; early death, four patients; minor donor, one patient.
\¶ \( p \) value determined by Fisher test.

Developed acute GVHD, most of them after receiving donor’s PBL. Patients receiving donor’s T cells had significantly higher risk to develop GVHD than patients not receiving donor’s T cells \((p^2 < 0.0001)\), irrespective of the type of antibody used. The incidence of GVHD was significantly higher in patients transplanted with Campath 1G treated marrow (63%) than with Campath 1M treated marrow (24%, \( p^2 < 0.0001 \)).

The probability of developing acute GVHD was similar in patients conditioned with TBI or BU-CY only, but among those receiving TBI, administration of more aggressive chemotherapy was associated with higher incidence of GVHD \((p < 0.001)\). There was no difference in the overall incidence of acute GVHD among the two types of leukaemia irrespective of the stage of disease, and no statistically significant differences between the various age groups with respect to the risk of GVHD.

Among 67 patients transplanted with marrow purged with Campath 1M (Table III), no acute GVHD was observed unless donor’s T lymphocytes were administered \((p^2 = 0.0001)\). Among those receiving donor cells, 16 patients developed acute GVHD of which three were severe. Among Campath 1G treated allograft recipients, nine patients whose marrows were treated with low concentration of antibody developed acute GVHD before any T cells were administered. Among the remaining 43 patients who received donor lymphocytes, acute GVHD occurred in 23.

**Chronic GVHD**

Chronic GVHD occurred in 28 recipients of Campath 1 treated marrows, 21 of whom received donor’s PBL (Table III). In 10 patients chronic GVHD represented the initial manifestation of the disease, whereas in others it was a progression of acute GVHD. The incidence of chronic GVHD among patients treated with donor’s PBL was higher in recipients of Campath 1G when compared with Campath 1M treated marrow.

There was no difference in the overall incidence of chronic GVHD among patients with ALL and ANLL and no difference between the various age groups. The incidence of chronic GVHD was similar in patients conditioned with TBI containing regimen and BU-CY only, and in the case of acute GVHD, chronic GVHD occurred predominantly in patients receiving TBI with triple chemotherapy as compared with patients receiving single or double chemotherapy \((p^2 = 0.0002)\).

**Event-free survival**

The overall event-free survival at 2 years of patients transplanted in first CR was 48%. In second CR 40% \((p^2 = 0.77)\) for first versus second CR), and in advanced disease 24% \((p^2 = 0.032\) for second CR versus advanced stage). There were no differences in event-free survival of patients transplanted in first or second remission in either type of leukaemia, but in both ALL and ANLL patients in advanced stage had significantly worse survival when compared with the two earlier stages combined: 19% vs 45%, respectively at 2 years in ALL \((p^2 = 0.018)\) and 30% vs 50%, respectively at 2 years in ANLL \((p^2 = 0.05)\). Among the variables analysed, age was the only other factor associated with improved survival: patients below 20 years of age had significantly better outcome compared to older patients \((p^2 = 0.038)\). Conditioning regimen, type of antibody, donor T-cells repletion and occurrence of GVHD had no effect on the overall event-free survival.
Cox proportional hazards model analysis demonstrated that factors associated with significantly worse favourable outcome were advanced stage of disease with relative risk of 2·68 compared to earlier stages \( (P^2 = 0·004) \), and age older than 10 years compared to younger patients (relative risk = 1·86, \( P^2 = 0·037 \)). Patients who developed chronic GVHD showed reduced risk of developing a relapse or dying compared with those who did not (relative risk = 0·54, \( P^2 = 0·0009 \)).

The probability of remaining in remission
The probability of remaining in remission by 2 years for patients receiving TCD allografts was 83% and 76% for first and second CR respectively \( (P^2 = 0·34) \) and 42% in advanced stage \( (P^2 = 0·009) \) (Fig 1). For ANLL patients transplanted in first or second CR the probability was 86% by 2 years compared with 51% for patients in advance stage \( (P^2 = 0·0012) \) (Fig 2). ALL patients transplanted in first or second remission had similarly higher 2-year probability of remaining in remission (72%) than patients transplanted in advanced stage (33%, \( P^2 = 0·0036 \)) (Fig 3).

For the 121 recipients of CamPATH 1 treated marrow the probability of remission was similar: for ANLL patients in first and second remission 84% by 2 years compared with
52% in advanced disease ($P^2 = 0.0065$), and for all patients 80% by 2 years for first and second remission and 29% for advanced disease ($P^2 = 0.001$).

The effect of donor’s T cell administration. The administration of donor T cells to 81 patients receiving T-cell-depleted marrow allografts using any Campath antibody had no significant benefits on their overall probability of relapse compared to 40 patients transplanted with T-cell-depleted marrow without T-cell repletion. The 2-year probability of relapse in patients treated with donor T cells was 25% compared with 32% without T-cell repletion ($P^2 = 0.64$). Among recipients of Campath 1M treated marrow, the probability of remaining in remission was higher among those receiving donor T lymphocytes (78% at 2 years) than without addition of donor T cells (60% at 2 years), although this difference was not significant ($P^2 = 0.20$, Fig 4).

Patients in first CR treated with donor T cells were more likely to remain in remission when compared to those untreated (90% vs 74% at 2 years respectively), regardless of whether or not they develop GVHD, but this difference is not significant. For the stage of leukaemia, all patients who received donor T cells and developed GVHD had only a 14% chance of relapse by 2 years, compared with 61% for patients who received T cells but had no GVHD ($P^2 = 0.013$), and 56% for patients who had neither T cells nor GVHD ($P^2 = 0.021$). No such difference was noticed in patients with ANLL.

The effect of GVHD. Patients in all disease categories had higher probability of remaining in remission if they developed any form of GVHD (84% at 2 years) compared with patients without any sign of GVHD (63%, $P^2 = 0.046$). Acute GVHD did not increase the probability of remaining in remission in any stage category; however, patients with ALL who developed GVHD seemed to have improved leukaemia-free survival than those without ($P^2 = 0.08$). Chronic GVHD had a general beneficial effect on the probability of remaining in remission ($P^2 = 0.068$), but it was significant only when patients were transplanted in first and second remission ($P^2 = 0.04$).

A multivariate Cox proportional hazards analysis was performed to determine factors associated with improved relapse-free survival. The risk factors studied included age, stage of leukaemia, conditioning protocol, type of T-cell depletion, CMV by donor’s PBL and GVHD. Age, type of antibody used for TCD, conditioning regimen, T-cell repletion by donor’s PBL and acute GVHD had no effect on leukaemia relapse-free survival. Stage of disease was found to be a significant factor with relative risk of 5.3 for developing relapse with more advanced stage compared with less advanced stage, along with chronic GVHD which had a relative low risk of 0.52 of developing leukaemic relapse.

Transplant-related mortality
Eighty-two patients died, 24 (29%) as result of leukaemic relapse. Six patients treated with donor T cells died of GVHD. Another 14 died of GVHD-associated CMV infection and liver failure, nine of whom were treated with donor T cells. Nine patients died as a result of graft failure, four treated with donor’s PBL. 15 other patients died as a result of organ failure attributed to the toxicity of the conditioning therapy, and nine from CMV and IP, irrespective of type of Campath used or donor T cell administration. In five other patients the cause of death was not determined.

DISCUSSION
The present report summarizes our results in a non-homogenous cohort of patients with acute leukaemia receiving T-cell-depleted allogeneic bone marrow transplant using Campath 1 antibodies and CMF using donors’ PBL to induce GVHD effect. Our preliminary data suggest that donors’ T lymphocytes mediate their antileukaemic activity in parallel with clinically evident GVHD, and that this effect is observed predominantly in ALL.

We have previously shown that Campath 1M is a safe, technically simple, and effective method for in vitro removal of lymphocytes from the bone marrow prior to transplantation. Campath 1M and more recently Campath 1G, have been widely used now in over 15 transplant centres (Hale et al, 1988; Hale & Wakhmann, 1988). We report here 121 leukaemia patients who received Campath 1 treated marrow, which also comprises the largest single-centre study using this antibody.

Campath 1 antibodies recognize CDw52, expressed abundantly on T and B cells and weakly on macrophages and NK cells (Hale et al, 1983; Cobbold et al, 1986). The IgM isotype is a potent lytic antibody which, in the presence of donor’s serum as a source of complement, effectively lyses T
cells in vitro. The major advantage of the IgG2b isotype, introduced in 1987, is the simplicity of using it. We have developed a simple 'Campath 1G in the bag' method (Naparstek et al., 1989), which requires only adding the antibody to the marrow bag without further in vitro manipulations. This antibody, when infused into the recipient with the marrow, has the capacity to kill both donor and host lymphocytes, most likely by antibody-dependent-cell-mediated cytotoxicity, thereby preventing GVHD as well as graft rejection by residual host lymphocytes (Slavin et al., 1986; Cobb et al., 1986; Hale et al., 1988). The use of Campath 1M historically preceded 1G, therefore the patients were not randomized, and no comparison of these two antibodies is possible. Nevertheless, regardless of the isotype used, the survival and the incidence of leukaemia relapse were similar.

Eight recipients of Campath 1 treated marrows (6-6%) rejected their graft: six received their marrow treated with Campath 1M and two with Campath 1G. This rejection rate is significantly less than in previously published reports on TCD BMT (Kerman et al., 1989; Bordignon et al., 1989; Patterson et al., 1986). Because residual immunocompetent host cells are believed to be responsible for graft rejection, the escalation of immunosuppression by addition of TIL to our conditioning regimen has resulted in improved rates of sustained engraftment (Slavin et al., 1984, 1986). This approach has been successfully employed by us in aplastic anaemia and also in genetic diseases (Slavin et al., 1982; Or et al., 1986).

Patients transplanted in advanced stage of disease show relatively high probability of remaining leukaemia free at 2 years: 42% (P = 0.009 compared to earlier stages). When analysed separately for AML and ALL, the probability of remaining in remission was 86% and 72% respectively for transplants conducted in first and second remission, and 51% and 33% in patients transplanted in advanced leukaemia. This improved relapse-free survival in high-risk patients may be attributed in part to post-transplant immunotherapy with donor T lymphocytes, more aggressive pretransplant antileukaemia conditioning, or a combination of these. Multivariate Cox proportional hazards analysis revealed that among the many factors analysed, stage of leukaemia and chronic GVHD were the only factors significantly associated with improved relapse-free survival.

Prevention of leukaemic relapse is a major aim in allogeneic BMT. It may be achieved either by intensifying the pretransplant chemoradiotherapy which has been shown to augment organ toxicity and predispose to early transplant-related death, or by intensifying the immunemediated interaction of donor's immunocompetent lymphocytes against residual tumour cells, i.e. the GVL effect. Previous attempts to use donor's buffy coat in recipients of non-TCD marrow allografts in patients treated with conventional GVHD prophylaxis did not result in any appreciable benefits (Sullivan et al., 1989c, Verdonck et al., 1990), most likely due to procedure-related toxicity, particularly GVHD in a significant proportion of patients (82% and 60% respectively).

Over the past few years cumulative clinical data from the International Bone Marrow Transplant Registry suggest that GVL can occur independently of GVHD (Horowitz et al., 1990). Studies in animal models also suggest that under certain experimental conditions GVL may be induced with no overt GVHD (Trott et al., 1987; Weiss et al., 1990; Kornfeld & Sprent, 1987; Slavin et al., 1990). Our results in experimental B-cell leukaemia/lymphoma in BALB/c mice have shown that GVL may be accomplished without GVHD in tolerant GVHD-free chimeras by delayed post-transplant administration of donor-type lymphocytes, thus establishing our rationale for post-transplant CMI (Slavin et al., 1981, 1992; Weiss et al., 1992).

In our non-prospectively randomized heterogeneous group of patients, only recipients of Campath 1M treated marrow were partially informative for the role of cell-mediated immunotherapy using donor's PBL for prevention of relapse. Of 67 patients, only 38 were scheduled to receive CML, therefore the remaining 29 patients serve as historical controls. Due to the strong lytic activity of Campath 1M in vitro, resulting in 3–4 log depletion of T cells, the incidence of GVHD was extremely low in this group (Table III). Post-transplant administration of donor's PBL resulted in clinically evident GVHD in 42%, but was associated with higher probability of remaining in remission as noted predominantly in high-risk patients and in patients with ALL. Therefore, under the experimental conditions investigated, donor T lymphocytes seem to modulate antileukaemic activity when accompanied by clinically evident GVHD. GVHD could be controlled in most patients by withholding subsequent doses of immunocompetent lymphocytes. However, patient variability unfortunately does not permit accurate prediction of the individual threshold of the cell dose that leads to GVH or GVL effect, and indeed, GVHD was fatal in three patients. Effective GVL independent of GVHD was therefore not demonstrated.

The interpretation of the higher occurrence of GVHD in patients transplanted with Campath 1G treated marrow is less conclusive. The T-lymphocyte depletion using 1G antibody 'in the bag', depends largely upon the efficacy of the in vivo effector mechanisms (ADCC), the activity of the reticuloendothelial system of the recipient, and antibody concentration. Because we noticed that low antibody concentration (0.3 mg/10^6 cells) is insufficient to completely prevent GVHD, early T-cell repletion in this group of patients may have accelerated ongoing subclinical donor-versus-host responses, and GVHD was indeed observed in a substantial proportion. Smaller doses of T cells and/or delayed TCR might have resulted in more effective CMI without severe GVHD. Further prospective studies using different concentrations of Campath 1G 'in the bag' are required to confirm the optimal conditions for prevention of GVHD using this simplified method for TCD.

The onset and the intensity of GVHD in TCD allograft recipients seem related to the timing as well as to the proportion of T cells administered in relation to BMT (Slavin et al., 1978). We intend to improve the CMI by optimizing the schedule of administration of donor's T cells to be given, in an attempt to further intensify the graft-versus-
leukemia effect without augmenting GVHD. In future, CMI could be further improved by administration of well-defined lymphocyte subsets or possibly by in vitro and/or in vivo activation of antileukemia effector cells of T and possibly NK lineages.

The encouraging preliminary results, and the recent observations suggesting that donor's PBL are useful in eradication of leukemic cells in patients relapsing after allogeneic BMT, suggest that cell therapy may represent a novel and effective approach not only for treatment but for prevention of relapse in malignant haematological diseases.

Meeting report

Recent results using CAMPATH-1 antibodies to control GVHD and graft rejection

G Hale and H Waldmann for CAMPATH users

Department of Pathology, University of Cambridge; Dunn School of Pathology, University of Oxford, UK

Summary:

Recent data from the CAMPATH users group are reported. Different protocols have been tested using CD52 antibodies CAMPATH-1M and CAMPATH-1G for prevention of GVHD and graft rejection in allogeneic transplants from both sibling and volunteer unrelated donors. Leukaemia relapse remains a significant problem for patients with CML, but in other diseases the recent results using T cell depletion appear to be as good as, or better than, published data with conventional GVHD prophylaxis. In addition, the morbidity and mortality associated with chronic GVHD are substantially reduced. Future collaborative studies to consolidate these findings include a randomised trial of the humanised antibody CAMPATH-1H organised under the auspices of the EBMT. There are also plans to carry out experimental studies using CAMPATH-1 antibodies to deplete T cells from peripheral blood stem cell harvests.

Keywords: CAMPATH; GVHD; graft rejection

The merits and drawbacks of T cell depletion in allogeneic marrow transplantation have been debated for the last 10 years without consensus. It is clear that removal of donor T cells, by whatever means, is the most effective way of preventing graft-versus-host disease, but there is a potential penalty of graft rejection and loss of a beneficial graft-versus-leukaemia effect. The largest studies have been carried out using CAMPATH-1 (CD52) monoclonal antibodies for T cell depletion and a co-operative group consisting of 40-50 bone marrow transplant centres has been working and meeting together since 1986 to evaluate different ways of using CAMPATH-1 antibodies to the best advantage. On 7 January 1995 the CAMPATH users group met in Cambridge, UK to review the recent results. To date CAMPATH-1 antibodies have been used in over 2000 bone marrow transplants for the prevention of graft-versus-host disease and graft rejection. The clinical data vindicate the concept that these complications can most effectively be prevented by depletion of T lymphocytes from both donor and recipient. However, they also show that donor lymphocytes can, under some circumstances, contribute an anti-leukaemia effect and that lymphocyte depletion can lead to subtle changes in the speed of engraftment and of viral reactivation. Thus there is a fine balance between GVH, HVG, relapse and infection. Various protocols of lymphocyte depletion have been tested, using either CAMPATH-1M (IgM) plus complement or CAMPATH-1G (IgG2b) to treat the donor bone marrow ex vivo and CAMPATH-1G in vivo to treat the recipient (Figure 1, Table 1).

For transplants from HLA-identical siblings, the best results reported by the CAMPATH users have been obtained with either of two protocols:

02 CAMPATH-1M plus complement for T cell depletion combined with CAMPATH-1G in vivo (day -10 to day -6) to prevent graft rejection (Royal Free Hospital, London, UK, University Hospital, Ulm, Germany and King Faisal Hospital, Riyadh, Saudi Arabia).

03 CAMPATH-1G in the bag to deplete donor T cells and possibly contribute to host immunosuppression. Pre-transplant conditioning also included total nodal irradiation in order to reduce the risk of graft rejection (Hadassah University Hospital, Jerusalem, Israel and University Hospital, Cape Town, South Africa).

In both, the transplant complications have been very low (less than 10% combined risk of graft failure or severe grade 3-4 GVHD) and leukaemia-free survival has been good (approximately 60% at 2 years for patients with acute leukaemia transplanted in first remission). These results are significantly better than with depletion of donor T cells alone (Figure 2) and compare favourably with published data using CsA/MTX for GVHD prophylaxis since chronic GVHD was virtually eliminated.

Other teams (University Hospital, Leiden, The Netherlands and Addenbrookes Hospital, Cambridge, UK) have tested the combination of CAMPATH-1G in the bag for T cell depletion plus CAMPATH-1G in vivo (instead of TLI) to prevent rejection (Protocol 07). Unexpectedly, this resulted in significantly delayed engraftment and a high incidence (approximately 20%) of graft failure. Since CAMPATH-1 antibodies did not appear to be directly toxic to stem cells in any of the other clinical studies, this result was hard to explain. One hypothesis previously suggested was that
Figure 1. Protocols of antibody treatment for prevention of GVHD and graft rejection. The approximate timing of in vivo antibody treatment with Campath-1G is shown. The dose was usually 5-10 mg/day.

Results are compared with the first group (Protocol 01). Those which are significantly better are highlighted in bold script, those which are worse are in italic script. In each case the P value is also given. Although the data presented in this table are of only patients who received no post-transplant immunosuppression, essentially identical results were obtained when all patients were analysed irrespective of post-transplant immunosuppression. M = moderate; S = severe.
Figure 2 Leukaemia-free survival for patients with malignant disease transplanted from HLA-matched siblings. (a) Comparison of Protocol 02 and Protocol 01; (b) comparison of Protocol 03 and Protocol 01.

there may be a low, but important contribution from lymphocyte activation (either donor or recipient) towards stimulation of haemopoiesis during the immediate post-transplant period.1

Some complications of antibody therapy were not seen uniformly at all centres. For example, delayed engraftment was observed by most groups using Campath-1G in vivo for treating matched siblings, but this was not the case in many of the transplants from unrelated donors. One centre (Ulm) reported an increase in the frequency and speed of CMV reactivation following therapy with Campath-1G. In most patients the infection was controlled, possibly as a result of activation of donor NK cells. These cells may also have contributed to the low rate of relapse reported at that centre. However, this reactivation of CMV did not seem to be a universal phenomenon since other groups found it to be quite rare. An understanding of the reasons for these differences might give us useful insights into the biology.

In patients transplanted for CML from matched siblings, T cell depletion results in a substantially increased risk of relapse and therefore it is now rarely used in this setting. In contrast, there is only a modest increase in relapse risk for patients with acute leukaemia.1,10 Some teams (notably Hadassah Hospital, Jerusalem) have tried to induce a beneficial graft-versus-leukaemia effect by graded infusion of donor lymphocytes following the transplant11,12 and others have added back small numbers of lymphocytes or unfractionated marrow after T cell depletion. Combined analysis of all these studies shows that the addition of donor T cells does give a small, but significant reduction in the risk of relapse (from about 38% to 26% at 2 years) when data for all patients transplanted for acute leukaemia are pooled. However, the addition of T cells is also associated with an increase in acute and chronic GVHD and an increase in transplant-related mortality so the overall leukaemia-free survival is virtually identical. Although this approach does not yet seem to give an overall benefit, the hope is that it may be more tolerable and effective to give donor T cells once the graft is well established.

In recent years a major application of Campath-1 antibodies has been in treating patients transplanted from volunteer unrelated donors.2,13 Children (mostly with ALL in CR2 or more advanced) have largely been treated with Campath-1G in vivo plus Campath-1M ex vivo (Protocol 02) and this has proved to be quite successful (Royal Hospital for Sick Children, Bristol, UK, Royal Free Hospital, London, UK). In Bristol, the incidence of graft failure was 12%, of severe GVHD 13%, and of relapse (at 2 years) 23%. Survival (at 2 years) was approximately 48%. So far there are few published data using conventional GVHD prophylaxis with which to compare the results but they compare favourably with transplants from HLA-matched siblings.

Adults receiving VUD transplants have mostly been treated with just Campath-1G in vivo both before and after the transplant (Protocol 06). The donor marrow has not been manipulated but conventional GVHD prophylaxis of CSA and MTX has been given. This protocol, rather than the more radical one was adopted for two reasons. First, the preliminary results indicated a trend towards better leukaemia-free survival, and second the majority of the patients suffered from CML and it was feared that T cell depletion would incur an unacceptable risk of relapse. For patients transplanted for CML in first chronic phase the incidence of graft failure was 16%, of severe GVHD 25%, and of relapse (at 2 years) 23%. Leukaemia-free survival (at 2 years) was 46%, which is similar to that reported for VUD transplants using conventional GVHD prophylaxis.14 As expected, the incidence of severe GVHD is lower and relapse is higher following the in vivo T cell depletion. The net impact on morbidity and mortality in the longer term is hard to gauge. A randomised trial of this protocol compared with standard treatment has been initiated by the Hammersmith team for the Chronic Leukaemia Working Party of the EBMT. This study will use the humoral antibody Campath-1H, for which there is a prospect of commercial production in the long run. All centres who are members of the EBMT are invited to enrol patients in this study.

Currently there is a great deal of interest in transplantation using peripheral blood stem cells. It has already been shown that Campath-1H is effective for depletion of T cells15 in this setting and studies are now planned to test the IgG antibodies, particularly Campath-1H for this application. It seems reasonable to suppose that in vitro depletion would be the best way of preventing GVHD after allogeneic transplantation of PBSC and this approach may eventually be preferable to the use of bone marrow.

Graft-versus-host disease is still a potentially horrendous
complication of BMT and, particularly in its chronic form, leads to severe morbidity and a poor quality of life for many patients. This is what motivates so many teams to persevere with T cell depletion, despite the potential disadvantages. With new developments in the techniques for monitoring residual disease it is hoped that patients might be spared the major risks associated with immune reactions during the immediate post-transplant period, and perhaps be treated with more selective immunotherapy using donor leukocytes only in the event of impending clinical relapse.

Acknowledgements

We are grateful to the staff of the TAC, Jenny Phillips, Annamarie Drumm, Patrick Harrison, Donna Stock, Angela Shaw and Jeremy Hoigate, for their work producing Campath-1 antibodies.

We also gratefully acknowledge the efforts of the many members of the following bone marrow transplant teams who contributed to the clinical care, analytical measurements and data collection: Birmingham Children’s Hospital, Birmingham, UK; Queen Elizabeth Medical Centre, Birmingham, UK; Institute of Haematology Seragolli, Bologna, Italy; Royal Bournemouth Hospital, Bournemouth, UK; Royal Hospital for Sick Children, Bristol, UK; Jules Bordet Hospital, Brussels, Belgium; Addenbrooke's Hospital, Cambridge, UK; University of Cape Town Leukaemia Centre and Department of Haematology, Groote Schuur Hospital, Cape Town, South Africa; University of Wales Medical School, Cardiff, UK; Royal Devon and Exeter Hospital (Wonford), Exeter, UK; Hospital Cantonal, Geneva, Switzerland; San Martino Hospital, Genoa, Italy; Department of Paediatrics, University of Gothenburg, Gothenburg, Sweden; Hadassah University Hospital, Jerusalem, Israel; Royal Free Hospital, London, UK; St George’s Hospital, London, UK; Hammersmith Hospital, London, UK; Institute of Child Health, London, UK; The London Clinic, London, UK; Royal Marsden Hospital, London, UK; University College Hospital, London, UK; Westminster Hospital, London, UK; St. James University Hospital, Leeds, UK; Royal Infirmary, Leicester, UK; Departments of Haematology and Paediatrics, University Hospital, Leiden, The Netherlands; Royal Infirmary, Liverpool, UK; Mainz Children’s Hospital, Mainz, Germany; Royal Manchester Children’s Hospital, Manchester, UK; Christie Hospital, Manchester, UK; Manchester Royal Infirmary, Manchester, UK; Ludwig-Maximilians University Hospital, Munich, Germany; Newcastle General Hospital, Newcastle, UK; City Hospital, Nottingham, UK; John Radcliffe Hospital, Oxford, UK; Hospital Necker, Paris, France; Policlinico S Matteo, Pavia, Italy; Royal Perth Hospital, Perth, Australia; King Faisal Hospital, Riyadh, Saudi Arabia; University degli Studi La Sapienza, Rome, Italy; Medico Marques de Valdecilla, Santander, Spain; St Vincent’s Hospital, Sydney, Australia; University of Ulm, Ulm, Germany.

Campath-1G in vivo confers a low incidence of graft-versus-host disease associated with a high incidence of mixed chimaerism after bone marrow transplantation for severe aplastic anaemia using HLA-identical sibling donors.

Department of Haematology and Child Health, St George's Hospital, London, UK.

We have evaluated the effect of in vivo Campath-1G on engraftment and GVHD in 23 patients with severe aplastic anaemia transplanted from HLA-identical sibling donors. In 14 patients Campath 1G was given pre-transplant for up to 9 days in an attempt to overcome graft rejection (group 1). In nine patients Campath-1G was given pre-transplant, but also continued post-transplant until day +5 to reduce GVHD (group 2). There were three patients with late graft failure in group I following initial neutrophil engraftment, and four cases of grade II+ GVHD. In group II, two patients had early graft failure (no take), and there were no cases of acute GVHD out of seven evaluable patients. One patient in group I developed chronic GVHD of the liver, and two patients (one in each group) had transient localised chronic GVHD. PCR of short tandem repeats was used to evaluate chimaeric status in 13 patients. Of 11 patients with initial neutrophil engraftment, only one had 100% donor haemopoiesis at all times. The remaining patients had either transient mixed chimaerism or persistence of recipient (< 20%) cells. We conclude that in vivo Campath-1G is associated with a high incidence of mixed chimaerism which tips the balance away from GVHD but towards graft rejection.

T cell depletion

Excessive T cell depletion of peripheral blood stem cells has an adverse effect upon outcome following allogeneic stem cell transplantation

R Chakraverty¹, S Robinson¹, K Peggs¹, PD Kottaridis¹, MJ Watts¹, SJ Ings¹, G Hale², H Waldmann², DC Linch¹, AH Goldstone¹ and S Mackinnon¹

¹Department of Haematology, University College London, London, UK; and ²Sir William Dunn School of Pathology, University of Oxford, UK

Summary:

We evaluated the outcome of two modes of T cell depletion for HLA-identical sibling stem cell transplants in 34 consecutive adult patients: group A (n = 11) received PBSCT post ClinIMACS immuno-magnetic enrichment of CD34⁺ cells and group B (n = 23) received bone marrow following in vitro incubation with CAMPATH-1M and complement. All patients received an identical conditioning regimen which consisted of in vivo CAMPATH-1H 20 mg over 5 days, thiopeta 10 mg/kg, cyclophosphamide 120 mg/kg and 14.4 Gy TBI. No additional graft-versus-host disease prophylaxis was given. The mean T cell dose administered was 0.02 ± 0.05 x 10⁹/kg for group A and 2.8 ± 2.8 x 10⁹/kg for group B (P < 0.001). With a median follow-up of 28 months overall survival was 36.4% for group A at 12 months compared to 73.3% for group B (P = 0.001). Transplant-related mortality in group A at 12 months was 63.6% as compared to 18.0% in group B (P = 0.003). Most of the procedure-related deaths in group A occurred secondary to infection. These results suggest that extensive in vitro T cell depletion of peripheral blood stem cells in combination with in vivo T cell depletion may have profound effects upon the incidence of infections following allogeneic stem cell transplantation and this may adversely affect transplant-related mortality. Bone Marrow Transplantation (2001) 28, 827–834.

Keywords: CD34 selection; allogeneic transplantation; T cell depletion

T cell depletion (TCD) is an effective means of reducing the incidence and severity of acute or chronic graft-versus-host disease (GVHD) following allogeneic stem cell transplantation (SCT).¹,² A number of different methods for TCD have been developed over the last two decades that include counter-flow elutriation,³ lectin agglutination,⁴ monoclonal antibodies directed at T cell antigens with narrow⁵ or broad specificity⁶ or depletion through positive selection of CD34⁺ stem cells.⁷ The clinical benefit of TCD allogeneic SCT is controversial since this approach may be compromised by increased rates of graft rejection⁸ and a higher rate of relapse.⁹ To overcome the risk of graft rejection additional approaches have been adopted that include increasing pre-transplant immunosuppression,¹⁰ 'partial' TCD¹¹ or increasing the number of stem cells administered by using peripheral blood stem cells (PBSCs).¹²,¹³ The optimal T cell content of a graft that maintains a significant graft-versus-leukaemia (GVL) effect has not yet been defined. Although TCD is used widely by many different transplant centres, few studies have assessed directly how different modes of TCD affect clinical outcome.

One area of potential concern is the significant delay in immune reconstitution that occurs following TCD allogeneic SCT. This is particularly the case in adults, where the initial T cell repertoire is dependent upon peripheral expansion of mature T cells in the graft.¹⁴–¹⁶ Delayed recovery of CD4⁺, CD4⁺CD45RA⁺ and TCRγδ T cells with a concomitant reduction in TCR diversity are typical features of the early post-transplant period following TCD allogeneic SCT.¹⁶–¹⁸ T cell purging may thus exacerbate post-transplant immunodeficiency and be complicated by an increased incidence of opportunistic infections, particularly CMV re-activation.²⁰

In this report, we highlight the major impact on clinical outcome of two approaches to in vitro TCD, using either positive selection of CD34⁺ cells from PBSCT or CAMPATH 1M treatment of bone marrow, as part of a protocol that employed additional in vivo TCD. Patients who received donor PBSCT heavily depleted of T cells (5 log) by immuno-magnetic selection of CD34⁺ cells had a substantially higher procedure-related mortality than recipients of CAMPATH 1M-treated bone marrow. The higher number of procedure-related deaths was caused by a marked increase in the number of opportunistic infections within the TCD PBSCT group. This study suggests that following HLA-identical sibling SCT in adults, extensive in vitro TCD of PBSCT in combination with in vivo TCD is compli-
cuted by a profound immunodeficiency that outweighs any benefit in terms of reduction of GVHD.

Patients and methods

A total of 34 consecutive adult patients who received a TCD HLA-identical sibling donor stem cell transplant at University College Hospital London, UK between January 1997 and October 1999, were included in the analysis. During this period, the method of in vitro TCD was changed due to an insufficient supply of CAMPATH 1M. The protocols were approved by the local institutional review committees and all patients gave informed consent. Two groups of patients were defined according to the mode of T cell depletion employed: ‘group A’ consisting of 11 patients who received PBSC following ClinIMACS immuno-magnetic enrichment of CD34+ cells and ‘group B’ comprising 23 who received bone marrow following in vitro incubation with CAMPATH 1M and complement.

Patient characteristics

The patient characteristics for each group are shown in Table 1. Patients were considered to be ‘standard risk’ in the case of acute myeloid leukaemia (AML) in complete remission (CR) or chronic myeloid leukaemia (CML) in first chronic phase. All other diagnoses were considered high risk. There were no significant differences between the groups in terms of sex, performance status at the time of transplant, time to transplant or those at risk of CMV disease (Table 1). However, only one patient in group A was considered to be high risk as compared to 11 of 23 patients in group B (P = 0.05). This reflected, in part, the lack of patients with lymphoproliferative disorders in group A. Three patients in group B had received a previous SCT and none in group A.

Antibodies

CAMPATH-1H is a humanized IgG1 monoclonal antibody against the CD52 antigen. It was prepared from the culture supernatant of Chinese hamster ovary cell transfectants cultured in a hollow fibre fermenter. It was purified by affinity chromatography on Protein A sepharose and size exclusion chromatography on Superdex 200 and formulated in phosphate-buffered saline. The half-life of CAMPATH-1H in humans is dependent on the amount of target CD52 antigen in the patient. Based on work in progress, there is persistence of CAMPATH-1H in vivo past day 0 sufficient to cause T cell lysis by ADCC. CAMPATH-1M is a rat IgM antibody that recognises the same antigen. It was prepared from hybrid myeloma cells using stimulated ferments, purified by fractionation with ammonium sulphate and reconstituted in phosphate-buffered saline.

Conditioning regimen

All patients received the same conditioning regimen which consisted of in vivo CAMPATH-1H 20 mg on days 9 to 12, thiopenta 5 mg/kg on days 1 and 2, cyclophosphamide 60 mg/kg on days 5 and 6 and 14.4 Gy total body irradiation, with partial lung shielding, in eight fractions over 4 days.

For stem cell collection for group A patients, sibling donors received G-CSF at 10 μg/kg subcutaneously once daily on day 4 to day 0. Leukaphereses were performed on day 0 + 1 using conventional techniques for PBSC. TCD was performed by positive immuno-magnetic selection of CD34+ cells using a ClinIMACS, (Miltenyi Biotec, Bergisch Gladbach, Germany) cell separation system.

For group B patients, donor bone marrow was aspirated under general anaesthesia and TCD performed in vitro upon the derived buffy coats by incubation with 25 mg CAMPATH 1M at room temperature for 10 min followed by incubation with 10-30% autologous plasma at 37°C for 45 min.

For both protocols, the level of TCD was monitored by flow cytometric analysis of CD3 staining.

Supportive care

Patients were managed in reverse isolation in conventional or laminar air flow rooms. All patients received prophylaxis with cotrimoxazole or pentamidine against Pneumocystis carinii infection. Azithromycin and trimethoprim prophylaxis were routinely used. Blood products were irradiated to 25 Gy. Red cell and platelet transfusions were given to maintain the Hb >9 g/dl and platelet count >10 x 10^9/L. Patients who were CMV seronegative received only blood products from CMV seronegative donors; seropositive patients received blood products from donors unscreened for CMV. Fibricle neutropenic patients received intravenous piperazobactam and gentamicin as first line antibiotic therapy. Patients received G-CSF at 5 μg/kg/day from day 4+6 until

MDS = myelodysplastic syndrome; MM = multiple myeloma; HD = Hodgkin's disease; HG-NHL = non-Hodgkin's lymphoma; 1st cp = first chronic phase; ap = accelerated phase; P = patient; D = donor.
the ANC was at least $1.0 \times 10^9/l$ for 2 consecutive days. CMV seropositive patients were monitored weekly from transplantation until at least day 120 by qualitative PCR of CMV DNA from peripheral blood. Pre-emptive ganciclovir therapy (5 mg/kg twice daily intravenously or adjusted according to renal function) was given following two consecutive positive PCR results and discontinued after 2 weeks if a negative PCR was obtained.23 In the event of continued PCR positivity, fosarnet was substituted for ganciclovir and the drugs alternated every 2 weeks according to the PCR results. A single patient (UPN5) received cidofovir as initial pre-emptive therapy for PCR detection of CMV re-activation.

**GVHD prophylaxis and grading**

No additional GVHD prophylaxis was given. Patients who survived 100 days or longer were evaluated for chronic GVHD. Both acute GVHD and chronic GVHD were graded according to the consensus criteria.25-26

**Evaluation of infective complications**

An infectious complication was defined as any infection occurring post day 21 which required continued or new hospital admission/referral. CMV re-activation was defined as two consecutive peripheral blood PCR positive results. CMV disease was diagnosed on the basis of an inflammatory process due to CMV confirmed by the presence of typical cytopathic and immuno-fluorescent features in histological preparations or positive detection of early antigen fluorescent foci (DEAFF) and/or CMV culture from relevant material such as washings from broncho-alveolar lavage (BAL). Pulmonary fungal infection was diagnosed either by histological confirmation or characteristic high resolution CT appearances (halo sign) plus positive cultures from a BAL. Fungal infection at other sites was identified from post-mortem histological analysis of affected organs. RSV, parainfluenza I and II or influenza B infection were defined as pulmonary signs plus direct immuno-fluorescence and/or culture for the relevant viruses from nasso-pharyngeal aspirate or BAL. Confirmation of Legionnaire's disease was made by the presence of urinary Legionella antigen on two consecutive occasions and confirmed by post mortem histological examination of lung. Adenovirus, RSV and measles infection were confirmed by histological examination of the relevant organs postmortem. Pneumonia was defined as fever, associated with signs of lung consolidation and new infiltrates identified on chest X-ray or high resolution CT.

**Statistical analysis**

Overall survival (OS) was measured from transplantation until death from any cause. Patients still alive at the time of the analysis were censored at the last follow-up date. Transplant-related mortality (TRM) was determined from the date of transplantation until death related to transplantation. Patients who died from other causes were censored at the time of death. OS and TRM were estimated by the Kaplan-Meier method and the significance of differences between the curves was estimated by the log rank test. Patient characteristics in the two groups were compared by Fisher's exact test or the Mann-Whitney test, whichever was appropriate.

**Results**

**T cell depletion**

Patients in group A received approximately 2 log less T cells than group B patients (Table 2). The mean T cell dose was $0.02 \pm 0.05 \times 10^9/kg$ for group A recipients and $2.8 \pm 2.8 \times 10^9/kg$ for group B patients ($P < 0.001$). Three patients in group A had "add-back" of donor T cells following the transplant (Table 2). Two of these patients, UPN6 and UPN8, received $1 \times 10^9/kg$ T cells at 4 and 5 months.

*109 cell/kg recipient weight.

*Patients had donor lymphocyte infusions at following doses x 109 CD3 cells/kg recipient weight (time post transplant in months): UPN3 18; UPN5, 11; UPN6, 1; UPN7, 3; and UPN20, 22 (12+). MDS = myelodysplastic syndrome; RA = refractory anemia; RAEB = refractory anemia with excess blasts; MM = multiple myeloma; HD = Hodgkin's disease; HG-NHL = non-Hodgkin's lymphoma; 1st cp = first chronic phase; ap = accelerated phase; Rel = relapse; PR = partial response; ND = not done.
respectively, because of progressive pulmonary infections. UPN3 was given 3 × 10^9/kg T cells for cytogenetic relapse of CML at 10 months. Two patients in group B received donor T cells. UPN17 received 3 × 10^9/kg T cells at 11 months for relapsed AML and UPN20 received 2 × 10^9/kg T cells for treatment of relapsed multiple myeloma.

**Engraftment**

The mean CD34+ cell dose per patient was 4.4 ± 1.8 × 10^9/kg in group A and 1.7 ± 1.0 × 10^9/kg in group B (P < 0.001). Neutrophil engraftment occurred more rapidly in group A, with neutrophils >0.5 × 10^9 on day 12.0 ± 2.1 compared to day 17.2 ± 4.0 for group B (P < 0.001). One patient in group B failed to engraft and died on day +74. All patients in group A engrafted. No cases of secondary graft failure occurred in either group. No differences were observed between the groups in terms of transfusional independence by day 100 (four of seven evaluable patients in group A as compared to 15 of 22 evaluable patients in group B were transfusion independent).

**GVHD**

The incidence of acute GVHD was low in both groups (Table 3). No patients in group A developed acute GVHD of greater than grade 1 as compared to two of 23 patients in group B. For patients who survived day 100 no difference in either the incidence or extent of chronic GVHD was observed. Thus, three of seven evaluable patients in group A developed chronic GVHD (extensive in all cases) as compared to 11 of 22 patients in group B (extensive in three patients and limited in the remaining eight patients).

In both groups, patients who received T cell add-back post SCT were at high risk for the development of extensive chronic GVHD. Thus, four of five patients who received a donor T cell infusion following the transplant subsequently developed extensive chronic GVHD. One patient (UPN3) died of progressive GVHD at 12 months following SCT and 2 months following infusion of 3 × 10^9/kg donor T cells for relapsed CML. The remaining patients have all required prolonged treatment with prednisolone and cyclosporine.

**Infective complications**

Most of the deaths in group A occurred secondary to infection (Table 3). Thus, at 12 months six of 11 patients in group A died secondary to infection (CMV disease n = 2, invasive pulmonary aspergillosis (IPA) n = 1, RSV/measles pneumonia n = 1, Legionella n = 1, E. coli sepsis n = 1) compared to only one of 23 patients (adenovirus) in group B (P = 0.002).

The propensity to infection in group A is also highlighted by the greater number of documented serious infections post day 21 in group A than in group B (Table 4). Thus, with a median follow-up of 28 months, four of 11 patients in group A had three or more significant infections as compared to one of 23 in group B (P = 0.03). Furthermore, patients in group A were more likely to have co-existent infections, with six of 11 patients in group A having two or more simultaneous infections as compared to only two of 23 patients in group B (P = 0.005). In a number of patients from group A, infection progressed despite the appropriate anti-microbial therapy. Patients UPN2 and UPN6 both developed IPA which failed to respond to conventional, and then liposomal amphotericin therapy. Patient UPN2 also developed a large, deep skin ulcer secondary to HSV II (proven on culture and biopsy), which failed to respond to aciclovir, foscarnet or cidofovir. Patient UPN3 developed CMV colitis and pneumonitis despite preemptive therapy with foscarnet and cidofovir and subsequent therapy with ganciclovir and intravenous immunoglobulin.

There were no significant differences between the two groups in terms of the frequency of CMV reactivation in that five of six CMV seropositive individuals in group A and 11 of 19 in group B met the criteria for preemptive treatment for CMV reactivation or CMV disease. The median total duration of anti-CMV therapy administered was 98 days (range 8-127 days) in group A and 33 days in group B (range 13-129 days). Two patients from group A died from CMV disease in group A and none from group B.

**Immune reconstitution**

Group A patients showed a significant delay in the recovery of the absolute lymphocyte count following transplant. Thus, at 2 months post transplant the absolute lymphocyte count was >1.0 × 10^9/l in none of nine evaluable patients in group A but 10 of 21 patients in group B (P = 0.01). Absolute lymphocyte numbers for the first 5 months for both groups are shown in Figure 1. Analysis of T cell subsets at our centre is usually performed at 2 monthly intervals post transplant. The poor outcome of patients in group A meant that the majority were not evaluated and thus an evaluation of T cell subset reconstitution was not possible.

**Overall survival and transplant-related mortality**

With a median follow-up of 28 months the overall survival (OS) and TRM for all 36 patients at 12 months were 64.7% and 33.0%, respectively. However, there was a major difference in OS between the groups (Figure 2). Thus, at 12 months OS was 36.4% for group A and 78.8% for group B (P = 0.001). This difference was accounted for to a great extent by the high number of procedure-related deaths in group A (Figure 3). At 12 months the TRM was 63.6% in group A and 18.0% in group B (P = 0.003). The causes of procedure-related deaths for the whole group are shown in Table 3. The median time for procedure-related death in group A was 87 days (range 28-221 days) and in group B was 148.5 days (range 74-287 days). All but one of the procedure-related deaths in group A were secondary to infection.

**Discussion**

This report highlights important differences in the outcome of HLA-identical sibling SCT following two approaches to

*Infections post day 21.

L = limited; E = extensive; Pn = pneumonitis; IP = idiopathic pneumonitis; IPA = invasive pulmonary aspergillosis; CMV = cytomegalovirus; RSV = respiratory syncytial virus; ARDS = adult respiratory distress syndrome; EBV-LPD = Epstein–Barr virus-associated lymphoproliferative disorder; NE = not evaluable.

In vitro TCD, using either positive selection of CD34+ cells from PBSC or CAMPATH 1M treatment of bone marrow. Patients in both treatment groups received additional in vivo TCD, identical conditioning and no post-transplant immunosuppression. We found that allogeneic SCT using PBSC heavily depleted of T cells by immuno-magnetic selection of CD34+ cells, was associated with prolonged lymphocytopenia and an extremely high number of opportunistic infections leading to a high rate of procedure-related deaths. In contrast, allogeneic SCT using in vitro CAMPATH 1M treatment of bone marrow was associated with a lesser depletion of T cells, fewer infections and more rapid immune reconstitution. Both strategies were effective at preventing acute GVHD, and excluding those patients who received donor lymphocytes post transplant, at preventing extensive chronic GVHD. There was a low risk of graft rejection in both groups. Since the follow-up is relatively short and there are too few long-term survivors in group A, no conclusions can be made regarding the risk of relapse.

It seems likely that the overall determinant of clinical outcome in this report was degree of T cell depletion. There are five important qualifications to this statement. First, the type of graft differed in each group, such that patients in group A received PBSC and patients in group B received bone marrow. Thus, there may have been both qualitative (eg the number of CD34+ cells or CD34+CD38− lymphocyte progenitors)27 and qualitative differences (eg the balance between Th1 or Th2 T cells)28 that could have conceivably affected outcome. However, to our knowledge, there are no substantive clinical data to support the contention that these differences could account for such a poor outcome in the PBSC arm. Second, exact comparison of the degree of TCD for the two methods is difficult since following CD34+ cell selection nearly all the remaining T cells will be viable whereas this may not be the case following in vitro treatment with CAMPATH 1M.29 Indeed, antibody coated T cells may undergo further lysis when they encounter fresh complement following infusion. Furthermore, pre-transplant in vivo CAMPATH 1-H treatment could have resulted

*aInfections post day 21.
MRSA = methicillin-resistant Staphylococcus aureus; VZV = varicella zoster virus; HSV = herpes simplex virus; PF = para-influenza; IPA = invasive pulmonary aspergillosis.

Figure 1  Absolute lymphocyte counts post-transplant. Mean ± s.e.m.
absolute lymphocyte counts (%IOPF) post transplant are given for group
A (clear bars) and B (stipped bars). The number of patients in each group
for each time point are as follows: 1 month - A 4, B 22; 2 months - A 8, B 20; 3 months - A 6, B 19; 4 months - A 5, B 15. Significant differences between group A and B were observed at 2
months (P = 0.005), 3 months (P = 0.007) and 4 months (P < 0.05).

Figure 2  Overall survival. Group A shown as dotted line and group B
as solid line.

in further destruction of donor T cells in the recipient and
it is conceivable that there are differences between the two
modes of TCD in terms of the sensitivity of the remaining
T cells to in vivo lysis. It seems unlikely, however, that
these factors could account for the >2 log difference in T
cell dose observed. Third, although CD3 4 cell selection
removes most other cell types. CAMPATH 1M may be less
efficient at removing certain cells such as NK cells (our
unpublished observations) that could be of benefit in the
patient post transplant. However, there are few clinical data
available that clearly define the effect of changing the num-
ber of NK cells or other non-T cells in the graft upon the
post-transplant course. Fourth, this was not a randomised
study and 'clusters' can arise due to local or seasonal fac-
tors, which make an assessment of the reasons for dif-
fences between the two groups problematic. Finally, the
patients in the two groups may have differed in certain
characteristics that biased our evaluation of outcome.
Although there were some differences between the groups
in terms of the spectrum of diseases treated, group B had
more high risk patients and included three patients who had
received a previous transplant, suggesting any bias was
likely to favour the null hypothesis that there was no dif-
fence in outcome between the groups.

All of the above factors may have had the potential to
influence outcome, but one of the key differences between
the groups was the measured number of T cells adminis-
tered with the graft. A 'safe' threshold could be defined as
the minimum T cell dose that permits high rates of engraft-
ment, low rates of GVHD and low rates of serious infec-
tion. Any such level will be heavily influenced by patient
factors such as age or status, donor characteristics
including the degree of HLA disparity or CD3 4 cell dose,
and by other transplant factors such as the use of in vivo
TCD or post-transplant immunosuppression. For example,
there is abundant evidence that 'safe' T cell doses as
defined for TCD HLA-identical sibling SCTs are less safe
in the context of unrelated or mismatched transplants with
resulting high rates of graft failure or infection.12,30,31

Using this protocol, our data suggest that extensive TCD
of PBSC was associated with a very low risk of GVHD, high
rates of engraftment but severely compromised
immune reconstitution. There is little consistent infor-
mation regarding the 'safe' T cell threshold in terms of
immune competence of the recipient following HLA-identi-

cal sibling SCT. Recent studies indicate that infections
cause death in less than 10% of patients following standard T cell-replete SCT, with no difference between recipients of peripheral blood stem cells or bone marrow. In an early study of 31 patients, intensive TCD of bone marrow by an E-rosette technique and administration of a fixed T cell dose of 0.1 x 10^6 T cells/kg was associated with only three infective deaths. Low rates of infection were also observed in a recent study of 14 patients who received CD34+ enriched bone marrow cells and a mean T cell dose of 0.09 x 10^9/kg. For the most part, other studies in the HLA-identical sibling transplant setting suggest that lesser degrees of TCD (T cell dose > 0.1 x 10^6 T cells/kg) are associated with no major increase in the risk of opportunistic infection, although there are exceptions to this. The effect of additional in vivo TCD is unclear. In a retrospective analysis of two approaches, the addition of in vivo CAMPATH 1G to a protocol using in vitro TCD of the graft using CAMPATH 1H was not associated with higher rates of serious infection. Our report suggests that in adults, depletion of PBSC to 0.02 x 10^9 T cells/kg cells in combination with in vivo TCD using CAMPATH 1H results in prohibitively high rates of opportunistic infection following HLA-identical sibling SCT, that offsets any benefit in terms of GVHD reduction. Patients suffered considerable morbidity with more infections, more simultaneous infections and sub-optimal responses to antimicrobial therapy. Since initial immune reconstitution in adults is primarily dependent upon thymus-independent expansion of peripheral memory T cells from the graft, a major reduction in their number results in the loss of certain pathogen-specific immune responses. Excessive TCD, as reported here, appears to reduce the peripheral mature T cell pool below a critical threshold that ensures adequate resistance of the recipient to infection. Although, thymic output of naive T cells may eventually increase the T cell repertoire, its contribution is age-dependent and is likely to be delayed in adult patients. Thus, it is possible that younger patients may tolerate greater degrees of TCD without an unacceptable risk of infection.

One potential strategy to overcome the disadvantages of extensive TCD is the 'add-back' of T cells at a fixed dose at the time of transplant. It is possible that T cell doses lower than 1 x 10^6/kg could be administered safely following transplant if in vivo TCD using sequestration was omitted from the conditioning regimen. However, the optimal timing and dose of T-cell add-back post transplant are unknown at present but will be influenced by the anticipated risks of GVHD or relapse at any one point post transplant. Other patients who may benefit from early add-back of T cells are those at risk of CMV reactivation or those who have persistent uncontrolled infections. It is possible that specific markers of immune reconstitution, such as thymic output of naive T cells, may provide a better guide to patients who are most likely to benefit from such a strategy. An alternative approach might be to use in vitro TCD of PBSC using CAMPATH 1H, which is reported to be effective in permitting engraftment and preventing GVHD. In conclusion, we have reported the adverse effect of extensive in vitro TCD of PBSC upon TRM following HLA-identical sibling SCT. There was an unacceptably high risk of opportunistic infection in adult patients receiving CD34+ selected cells from peripheral blood and a mean T cell dose of 0.02 x 10^9 T cells/kg which resulted in a considerable morbidity and which was responsible for 85% of procedure-related deaths. It is possible that the use of additional in vivo TCD with CAMPATH 1H further reduced the effective T cell dose. These results suggest that consideration should be given to fixed dose donor T cell add-back in patients who have received PBSC grafts which are extensively (>5 log) T cell depleted or that measures taken to achieve in vivo TCD are omitted.

Acknowledgements

We would like to thank Nikki McKaig, Judith Stuart and Brenda Miller for help in the collection and analysis of data. We would also like to thank Professor Paul Moss and Dr Charlie Craddock for their helpful criticisms regarding the manuscript.

Summary. We studied the outcome of 24 peripheral blood stem cell (PBSC) graft recipients, who were T-cell depleted (TCD) with either 20 mg (n = 14) or 10 mg (n = 10) Campath-1H in vitro, in comparison with a retrospective cohort of 23 unmanipulated (UM) PBSC recipients. While the neutrophil engraftment was similar, the platelet engraftment occurred earlier in the TCD group (d 11 vs 14). The incidence of acute and chronic graft-versus-host disease (GVHD) was 8-7% and 4-4% in the TCD group, respectively, compared with 47-7% and 56-3% in UM group (P < 0.001). In the TCD group, 5/6 chronic myeloid leukaemia (CML) and 4/18 non-CML patients relapsed (vs 0/6 and 3/17 in UM group, P = 0.06). All four molecular or cytogenetic relapses of CML were disease-free survivors following donor lymphocyte infusion. There was no difference in the incidence of serious infection between the TCD and UM groups and the lymphocyte recovery at 100 d was comparable. In the TCD cohort, the lymphocyte recovery was quicker in the 10 mg Campath-1H group. The non-relapse mortality (19.1% vs 66.3%) and 3 year survival (73.1 vs 19.2) were improved in the TCD group (P = 0.05). Thus elimination of late mortalities related to chronic GVHD and a rapid immune reconstitution, limiting either infection or relapse related deaths, contributed to an improved outcome following T-cell depletion with Campath-1H ‘in the bag’.

Keywords: Campath-1H, T-cell depletion, peripheral blood stem cell transplantation.

A major development in the field of allogeneic transplantation has been the use of growth-factor-mobilized peripheral blood stem cells (PBSC). The most consistent finding from studies on PBSC allografts has been a faster engraftment of both neutrophils and platelets, compared with bone marrow (BM) grafts (Blaise et al. 2000; Champlin et al. 2000; Bensinger et al. 2001; Korbling & Anderlini, 2001; Schmitz et al. 2002). Although this does not seem to improve the survival in standard-risk leukaemia (Schmitz et al. 2002) following sibling allogeneic stem cell transplantation (allo-SCT), there is a demonstrable impact on both survival and relapse in advanced leukaemias (Bensinger et al. 2001; Guardiola et al. 2002). However, these advantages of using a PBSC graft are negated by the increased incidence of graft-versus-host disease (GVHD). The incidence of chronic GVHD following PBSC allografts has varied between 46% and 67% in randomized studies, and a recent meta-analysis showed that the relative risk of developing extensive GVHD was significantly increased following PBSC (Cutler et al. 2001). The same meta-analysis also suggested an increase in the severity of acute GVHD with PBSC grafts, although this has been a less consistent finding in both randomized and non-randomized studies.

The challenge, therefore, lies in exploiting the engraftment and the antileukaemic potential of PBSC grafts and yet reducing the incidence and severity of GVHD. PBSC grafts

contain about 10 times more lymphocytes than BM grafts (Ottinger et al., 1996; Steren et al., 2001). Some studies have attributed the increased incidence of GVHD to the higher number of T cells infused with PBSC grafts (Cutler et al., 2001), while others have correlated it with a high CD34+ cell count (Przepiorka et al., 2001; Zaucha et al., 2001).

T-cell depletion (TCD) has been the most effective method for the prevention of GVHD to date. However, following TCD of BM grafts, there has been an increased incidence of graft-failure, infections as a result of a delay in immune reconstitution and an increase in the incidence of relapse (Hale et al., 1998; Lowdell et al., 1998; Papadopoulos et al., 1998; Small et al., 1999). Few studies have explored the outcome of TCD-PBSC grafts, particularly in terms of immune reconstitution (Martinez et al., 1999; Hale et al., 2000; Barbe et al., 2001).

The method of T-cell depletion has been widely variable, ranging from physical methods (Papadopoulos et al., 1998) and the use of monoclonal antibodies (Hale et al., 1998) to column-based immunomagnetic selection of specific cell populations (Martinez et al., 1999). Campath antibodies have long been used both in vivo and in vitro for T-cell depletion. Campath-1M in vitro resulted in graft failure in 16% of patients, but this risk was reduced by the use of Campath-1G in vivo as a part of conditioning treatment (Hale et al., 1998). In vitro Campath-1G has been used alone for PBSC grafts and patients have shown an improved survival at 6 months (Barbe et al., 2001), when compared with unmanipulated graft patients. Campath-1H is the humanized form of this antibody, which has recently been licensed by the Food and Drugs Administration (FDA) for use in chronic lymphocytic leukaemia.

Our centre was one of the first to adopt PBSC as the stem cell source in matched related transplantation. We observed both rapid engraftment and a low incidence of relapse. However, owing to a high incidence of late chronic GVHD observed in these patients, in June 1998 we elected to T-cell deplete PBSC grafts using Campath-1H in vitro. We report the outcome following T-cell depletion of PBSC grafts from matched related donors using Campath-1H antibody in vitro and compare this with a retrospective cohort of patients receiving unmanipulated (UM) PBSC grafts.

PATIENTS AND METHODS

We evaluated 47 consecutive allograft recipients who were treated in the Bone Marrow Transplant (BMT) Unit at Birmingham Heartlands Hospital between June 1996 and September 2001. Twenty-four patients received a T cell-depleted PBSC graft (TCD) from July 1998 to September 2001 and were compared with a retrospective cohort of 23 patients who received an unmanipulated PBSC graft (UM) from June 1996 to June 1998. All were transplanted for haematological malignancies.

Conditioning treatment

Conditioning regimens consisted of either cyclophosphamide 60 mg/kg for 2 d (n = 32) or etoposide 60 mg/kg single dose [for patients with acute lymphocytic leukaemia (ALL) only, n = 12] and fractionated total body irradiation (TBI) at 1440 cGy in eight doses. Patients not receiving TBI received cyclophosphamide at the above dose and busulphan 16 mg/kg over 4 d in four daily divided doses (n = 3).

PBSC mobilization and apheresis. All the donors were fully matched for both human leucocyte antigens (HLA) class I (A, B, Cw) and class II (DRB1, DP and DQ) using the polymerase chain reaction with sequence-specific primers (PCR-SSP). The donors were treated with lenograstim (Chugai pharmaceuticals, UK) at a dose of 10 μg/kg subcutaneously in the afternoon for 4 d. The stem cell apheresis was carried out using a Baxter CS 3000 continuous-flow automated cell separator from d 5 onwards for a maximum of 3 d. The donors received lenograstim at the same dose in the evening each day after completion of the apheresis. The procedure was carried out using peripheral venous access, and a femoral catheter was used in donors with poor peripheral access. For the TCD group, the target CD34+ cell dose was 5 × 10^6/kg of patient body weight. The excess amount, if any, was stored as CD3+ cell aliquots for future use as donor lymphocyte infusions (DLI).

T-cell depletion

T-cell depletion was carried out with Campath-1H in vitro. The apheresis products were stored for a maximum of 48 h and were pooled to a maximum volume of 500 ml. Campath-1H 20 mg (n = 14) or 10 mg (n = 10) was added to the final product. These were then incubated at 25°C in an agitator for 30 min. The cells were immediately infused to the patient over 30–60 min following premedication with intravenous methylprednisolone 1 mg/kg, paracetamol and chlorpheniramine 1 h before the infusion. Samples from pooled apheresis products were obtained both prior to and following incubation with Campath-1H. These were evaluated for CD34+ and CD3+ cell counts. Assays were carried out using a Becton Dickinson FACSCalibur flow cytometer. CD34 analysis was performed using a dual platform technique according to the International Society for Hemotherapy and Graft Engineering (ISHAGE) protocol using anti-CD34 and anti-CD45 antibodies (Sutherland et al., 1996). CD3+ T-cell analysis recorded CD3 events staining with anti-CD3 as a proportion of total nucleated cells staining with anti-CD45. All the monoclonal antibodies were obtained from Becton Dickinson (Oxford, UK).

GVHD prophylaxis

Patients transplanted with TCD-PBSC received intravenous cyclosporin A at 3 mg/kg in two divided doses from d −1 until they were able to tolerate oral cyclosporine. Oral cyclosporine was intended to continue to d + 180 post transplantation in the original protocol, with subsequent tapering. However, this was modified after the first five patients to continue to d + 100 only. Cyclosporine was continued beyond this period only in patients with GVHD. The dose of cyclosporin A was titrated to maintain plasma levels between 150 and 250 ng/l.
In the group of patients receiving UM-PBSC, cyclosporin A was continued at an identical dosage schedule for 6 months and short-course methotrexate was added at 15 mg/m^2 on d 1 and 10 mg/m^2 on d 3, 6 and 11 post transplantation.

Donor lymphocyte infusion
DLI was used following TCD-PBSC transplants for molecular, cytogenetic or haematological relapse of chronic myeloid leukaemia (CML) in an escalating dose schedule. The initial CD3⁺ cell dose was 1 × 10⁸/kg and this was followed by an increment of half a log every 3–4 months until cytogenetic and/or molecular remission was documented. The maximum dose used was 1 × 10⁹/kg CD3⁺ cells.

Disease status was evaluated on BM aspirate specimens at 3 months on all patients. Peripheral blood samples of patients transplanted for CML were obtained every 6 weeks for cytogenetic and molecular evaluations. Cytogenetic relapse was defined as sustained presence of t(9:22) on two separate occasions 4 weeks apart. Molecular relapse was defined as the demonstration of bcr-abl fusion mRNA transcripts on two separate occasions 4 weeks apart in the absence of cytogenetic or haematological evidence of CML. Once evident in peripheral blood, these were confirmed on BM samples.

Supportive care
All the patients were nursed in single rooms with high-efficiency particulate air (HEPA) filters. Anti-microbial prophylaxis consisted of oral fluconazole, ciprofloxacin and oral aciclovir from the beginning of conditioning treatment until engraftment. Oral cotrimoxazole was initiated when the neutrophil count was greater than 1 × 10⁹/L. Metronidazole 400 mg thrice daily, was started between the day of transplant to engraftment for anaerobic decontamination as a part of GVHD prophylaxis from January 1998.

Cytomegalovirus (CMV) sero-positive recipients or those receiving grafts from CMV sero-positive donors were screened for CMV reactivation by a non-nested polymerase chain reaction (PCR)-based assay (Ampliprime; Roche, Lewes, East Sussex, UK) on whole blood collected in ethylenediamine tetra-acetic acid (EDTA) (Chakrabarti et al, 2002a). The patients were screened every week from transplantation to 100 d post transplantation. Generally those patients who had CMV infection before 100 d or had GVHD were screened for 180 d or more. The patients received antiviral therapy if two consecutive PCR assay results were positive. CMV sero-negative patients receiving grafts from CMV sero-negative donors received CMV-negative blood products. Surveillance for other viruses was carried out on stool, urine and throat samples to 180 d post transplant.

Chimaerism. For TCD-PBSC recipients, chimaerism was analysed at 30, 90 and 120 d post transplantation and every 3 months thereafter for the first 2 years. This was carried out by fluorescent in-situ hybridization (FISH) with Y chromosome probes for sex-mismatched transplants. For sex-matched transplants, the peripheral blood and BM were assessed for donor chimaerism using microsatellite markers (Chakrabarti et al, 2001a). For the UM-PBSC cohort, chimaerism data were available for patients transplanted after 1997, at least once in the first year after transplantation.

Immune reconstitution
The absolute lymphocyte count (ALC) was noted at least once every 4 weeks following discharge for the first 6 months. The CD4¹ and CD8¹ T-cell counts (from August 1999) were measured every 6–8 weeks post transplant as previously described (Chakrabarti et al, 2002b).

Definitions and statistical methods. Disease status was defined as advanced if: acute leukaemia was beyond complete remission (CR)-1 or refractory, CML was beyond chronic phase (CP1), myeloma was beyond first plateau or poorly responsive to first-line therapy, myelodysplastic syndrome (MDS) was of the subtype refractory anaemia with excess of blasts (RAEB) or refractory anaemia with excess of blasts in transformation (RAEB-t) by the French–American–British (FAB) classification, or if adverse cytogenetics were detected at diagnosis in patients in CR1. Engraftment was defined as neutrophil recovery to more than 0·5 × 10⁹/L and unsupported platelet count of 20 × 10⁹/L. Acute and chronic GVHD were defined according to standard criteria (Glucksberg et al, 1974; Shulman et al, 1980). Acute GVHD could be evaluated in all patients beyond d 0 up to d 100 and chronic GVHD in survivors beyond 100 d. Non-relapse mortality (NRM) was defined as death from any cause in patients in remission.

Univariate P-values and odds ratios were calculated from 2 × 2 contingency tables using Fisher's exact test where appropriate. The continuous variables were compared using Mann–Whitney's non-parametric method. Cumulative probabilities of engraftment, acute and chronic GVHD, relapse, overall survival, and non-relapse mortality were analysed with censuring for competing risk factors as appropriate, and the difference between the groups was compared using the log rank χ² test. The Kaplan–Meier method was used for estimating overall survival. The effect of the variables on GVHD, relapse and NRM were tested in a Cox-regression model. The variables examined were age, donor sex, disease type (standard vs advanced), CMV sero-status, graft composition (CD34⁺ cells) and graft manipulation (TCD vs UM). The variables were analysed in a univariate model and the variables with P-value less than 0·10 were entered in the multivariate model.

RESULTS
Patient characteristics
The patient characteristics are detailed in Table I. Twenty-three patients received an UM graft and 24 received a TCD graft. There was no difference in the age, sex or underlying disease between the groups. There was a slight preponderance of advanced disease and female donors in the UM-PBSC group.

Graft composition
The CD34⁺ cell dose in the TCD-PBSC group was 5.2 × 10⁶/kg. This was similar to the UM-PBSC group. The median CD3 dose for the TCD group was 292 × 10⁶/kg (range 37–519). The depletion of CD34⁺ cells achieved after incubation with Campath-1H was less than one log in all cases, varying between 0.1 and 0.8 log. There was no difference in the in vitro depletion between the use of 10 mg or 20 mg Campath-1H.

Engraftment
The neutrophil engraftment occurred at a median of 14 d [95% confidence interval (CI): 12.6–15.4] in the TCD group and 13 d (95% CI 11.8–14.2) in the UM group (P = 0.8, Fig 1A). One patient in the UM group succumbed to a fulminating infection before engraftment. However, the platelet engraftment was faster in the TCD group (median 11 d [95% CI 9.8–12.2] vs 14 d [95% CI 13.1–14.9] in UM-PBSC, P = 0.00040 [Fig 1B]).

There was no secondary graft failure in the UM group and there was one late graft failure in the TCD group. This 33-year-old woman was transplanted for ALL in the first remission and had a prompt engraftment and an uneventful course until d 95. The patient’s blood counts declined progressively over the next 2 weeks with reversal of chimaerism to recipient type as measured by FISH technique. The BM was aplastic and there was no evidence of leukemia. She failed to engraft following conditioning with antithymocyte globulin and received further conditioning with fludarabine and melphalan. Although there was evidence of engraftment at d + 12, she succumbed to viral pneumonitis.

Acute GVHD
Ten UM-PBSC recipients developed acute GVHD of grade 2–4. Five of them had grade 3–4 GVHD. On the other hand, only two patients in the TCD group developed grade 2 GVHD, which was limited to the skin. Three other patients developed a mild non-specific rash in the extremities between 10 and 20 d post transplantation that resolved without treatment. The cumulative probability of grade 2–4 GVHD was significantly lower in the TCD group (8.7%, 95% CI 0–20) when compared with the UM group (47.7%, 95% CI 26–69) (P = 0.003, Fig 2A).

Chronic GVHD
Ten of the 18 patients who could be evaluated beyond 100 d developed chronic GVHD in the UM group, six of whom had extensive chronic GVHD. Only one of the 23 patients who could be evaluated developed mild oral chronic GVHD in the TCD group. The cumulative probability of chronic GVHD was 4.2% (95% CI 0–12.6) in the
Relapse

Nine out of the 24 patients receiving TCD-PBSC relapsed with a cumulative probability of 48.7% (95% CI 24.4–73.2), whereas 3/23 patients relapsed in the UM-PBSC group (cumulative probability, 15.4% at 2 years, 95% CI 0–35.2) (P = 0.06, Fig 3). However, only 2/10 patients receiving grafts treated with Campath-1H 10 mg relapsed compared with 7/14 patients receiving grafts treated with Campath-1H 20 mg (P = 0.14). None of the six CML patients relapsed in the UM group, whereas 5/6 relapsed in the TCD group. However, 4/5 relapsed patients suffered only either molecular or cytogenetic relapse, and one patient transplanted for accelerated-phase CML had haematological relapse.

There was no difference in the relapse rate of non-CML patients, with three and four patients with acute leukaemia relapsing in UM and TCD group respectively. Complete donor chimaerism was observed in the majority of the patients with acute leukaemia, and in all of the six CML patients in the UM group, whereas all the CML patients in the TCD group had persistent mixed chimaerism prior to relapse (45–90% donor cells). Following DLI conversion to full donor chimaerism was observed in all the responders.

On multivariate analysis, graft manipulation was the only factor that positively influenced acute GVHD (P = 0.04, relative risk 0.98, 95% CI 0.92–0.94) or chronic GVHD (P = 0.001, relative risk 0.07, 95% CI 0.008–0.6).

**Disease-free survival (DFS) and GVHD following DLI**

At the time of writing, all of the four patients with CML who were documented to have cytogenetic and/or molecular relapse following TCD-PBSC were in remission following escalation of the DLI dose. The only patient who had a haematological relapse was transplanted in the accelerated phase of CML. He succumbed to post-DLI aplasia. Only one of the four patients with acute leukaemia who relapsed was a disease-free survivor at 12 months follow-up. Two patients succumbed to relapsed disease and another was still on treatment at the time of writing.

Disease control with DLI was at the cost of only a slight rise in the overall incidence of GVHD. Four patients developed grade 2–3 GVHD following DLI in the TCD group. In three of them, it followed bulk dose DLI (1 × 10^7/kg) for relapsed AML or ALL, and one patient was a long-term
survivor. Only one of the four patients receiving an escalating dose DLI for CML developed grade 2 GVHD which responded to steroids.

The overall probability of GVHD in the DLI in the TCD group was 25% (95% CI 9–41, P = 0.05) and in disease-free survivors was 16.7% (95% CI 2.7–30.7, P = 0.02) which was still significantly lower than the UM group.

**Immune reconstitution**

The recovery of the ALC was slower in the TCD group at 30 d (mean ± standard deviation [SD]/mm³, 410 ± 160 vs 910 ± 441 in the UM group, P = 0.002). However, this was comparable at 100 d (mean ± SD/mm³, 1029 ± 654 vs 1082 ± 612 in the UM group, P = 0.8).

In the TCD group, the ALC recovery was faster at both 30 d (mean ± SD, 0.475 ± 0.152 × 10⁹/l vs 0.364 ± 0.160 × 10⁹/l, P = 0.09) and 100 d (1.350 ± 0.707 × 10⁹/l vs 0.807 ± 0.438 × 10⁹/l, P = 0.03) in patients receiving grafts treated with 10 mg Campath-1H, compared with those receiving grafts treated with 20 mg of the antibody.

The recovery of CD4⁺ T cells was studied in the TCD group only. The CD4⁺ count at 100 d for the patients receiving 10 mg Campath was significantly higher than those receiving 20 mg Campath (mean ± SD, 0.281 ± 0.089 × 10⁹/l vs 0.161 ± 0.086 × 10⁹/l, P = 0.01). Among patients who received 20 mg Campath in vitro, the median time to achieve a CD4⁺ count of 0.2 × 10⁹/l was 7 months, compared with 3 months for those receiving 10 mg Campath-1H.

**Infections**

Three out of the 10 UM patients at risk of CMV disease and four out of the 11 TCD patients at risk of CMV disease showed reactivation of the CMV respectively (Table I). None in the UM-PBSC group had CMV disease. One patient in the TCD-PBSC group developed CMV colitis at 60 d post transplant, following a failure to comply with weekly CMV monitoring. This, however, resolved following antiviral therapy. Other serious infections were documented in seven UM-PBSC recipients (bacterial sepsis, three; resistant herpes simplex virus, two; aspergillus, one; Clostridium difficile, one) and in four TCD-PBSC recipients (community respiratory virus, two; suspected fungus, one; suspected pneumocystis pneumonia, one).

**Non-relapse mortality**

Only four patients died from transplant-related causes in the TCD group at a median follow-up of 24 months (range 6–45 months), compared with 10 deaths in the UM group. The probability of NRM was 19.1% (95% CI 1.9–36.3) compared with 66.3% (95% CI 40.7–91.9) in the UM group (P = 0.05, Fig 4). Half of the mortality in the UM group was attributable to GVHD, whereas there was no GVHD-related mortality in the TCD group (Table II). It should be noted that the NRM in the UM-PBSC recipients at 24 months was only 24.1% (Fig 4). However, the five deaths that occurred in the UM group beyond 2 years were all attributable to chronic GVHD or complications related to its therapy.

TTP, thrombotic thrombocytopenic purpura.

On multivariate analysis, graft manipulation (P = 0.06, relative risk 0.3, 95% CI 0.1–1.06) and a higher CD34⁺ cell dose (P = 0.06, relative risk 0.7, 95% CI 0.5–1.08) had a trend towards a positive influence on NRM.

**Overall survival**

The OS at 2 years was 63.4% (95% CI 41.7–85.1) for the UM group and 73.1% (95% CI 54.5–91.7) for the TCD group (Fig 5). As mentioned in the previous section, five deaths occurred in the UM group after 24 months and none occurred in the TCD group beyond this period. This conferred a significant survival advantage to the TCD group with an actuarial survival at 3 years of 73.1% (95% CI 41.7–85.1), compared with 19% (95% CI 2.3–36) for the UM group (P = 0.05). When stratified by age, there was no difference in the survival or NRM between patients aged above or below 35 years.
Fig 5. The overall survival of UM and TCD patients following transplantation.

DISCUSSION

T-cell depletion is the most effective method for prevention of GVHD, but this is often at the cost of an increase in graft rejection, relapse and poor immune reconstitution with consequent infections. In this study, we have attempted to strike a balance between these factors by optimizing the dose of Campath-1H 'in the bag'. After analysing the first 14 patients receiving Campath-1H 20 mg 'in the bag', we reduced the dose of Campath added to the graft to 10 mg because of an extremely low incidence of GVHD, and in order to explore the possibility of improving immune reconstitution and reducing relapse risk. The most notable difference was noted in the prompt immune reconstitution, which occurred without an increase in GVHD, and a trend towards a reduction in the relapse risk was also observed.

Graft failure and rejection are major concerns following T-cell depletion. All the previous studies reporting successful engraftment have incorporated additional agents such as antibodies, lymphoid irradiation or thiopeta in the conditioning regimen (Bunjes et al. 1995; Hale et al. 1998; Papadopoulos et al. 1998; Barge et al. 2001). We have demonstrated sustained engraftment in all but one patient without the use of additional agents. It is possible that additional immunosuppression is not necessary if either the dose of TBI is 1 4 Gy or if there could have been an extended effect of the Campath that was infused with the graft on host lymphocytes. In addition, the high CD34+ cell dose in the TCD grafts may also have facilitated engraftment. The neutrophil engraftment was similar in the two groups, while the platelet engraftment was faster in the TCD group. Although there was a trend towards a correlation with higher CD34+ cell count (data not shown), the only other explanation for this could be the absence of methotrexate treatment as a GVHD prophylaxis in the TCD group.

The incidence of acute and chronic GVHD following PBSC transplantation in most previous studies has varied between 27% and 52% and 35–67%, respectively, and the survival at 2 years has varied between 42% and 65% (Blaise et al. 2000; Champlin et al. 2000; Bensinger et al. 2001; Korbling & Anderlini, 2001; Schmitz et al. 2002). Our experience with the use of PBSC grafts was very similar, with the cumulative incidence of acute and chronic GVHD being 47.7% and 56% and the disease-free survival at 2 years being 63%. There was an extremely low incidence of relapse when taking account of the fact that 40% of the patients in the UM-PBSC group had more advanced disease. This favourable outcome at 2 years was offset by late mortality due to severe chronic GVHD and its therapy. The survival of our UM-PBSC cohort beyond 2 years was much lower than those reported in randomized studies and this may have exaggerated the survival advantage of the TCD group. While, this could be due to the more high-risk patients in this group, the small sample size, the improvement in supportive care since 1998 and the fact that this is not a randomized comparison, there are a few points worth noting. Recent publications suggest that on longer follow-up, GVHD following PBSC transplants is both more protracted and difficult to treat (Flowers et al. 2002). Another study reported only a 15% survival in PBSC graft recipients with chronic extensive GVHD (Pezzi et al. 2001). All the randomized studies to date have reported only on the 2-year survival of patients, and the long-term follow-up of these cohorts is required to evaluate the impact of chronic GVHD.

The use of T-cell-depleted BM grafts has been associated with a low incidence of both acute and chronic GVHD (Bunjes et al. 1995; Hale et al. 1998; Papadopoulos et al. 1998). Studies exploring the outcome of T-cell depletion of PBSC grafts are low in number. In one study, the use of Campath-1G-treated PBSC grafts was associated with 18% and 23% acute and chronic GVHD respectively (Barge et al. 2001). Another multicentre survey reported the incidence of acute and chronic GVHD to be 4% and 24% respectively (Hale et al. 2000). The incidence of acute (8.7%) and chronic (4.4%) GVHD in our cohort was much lower than in previous reports. This reduction in chronic GVHD translated into an improved survival, in the absence of an increase in infection or relapse-related deaths.

While the incidence of relapse was markedly increased in CML following T-cell depletion, the earlier detection of either a molecular or cytogenetic relapse and the use of an escalating dose of DLI enabled the induction of a second remission in all but one patient. The only exception was a patient with accelerated-phase CML in haematological relapse. Thus, the DFS for patients with CML at the time of writing was not different between the two groups maintaining the lower incidence of GVHD. Similar findings have been reported in other studies on TCD transplants in CML (Drobyski et al. 1999; Schn et al. 1999). Thus, this approach could be suitable for patients with CML at a higher risk of GVHD, if effective molecular or cytogenetic monitoring could be ensured to detect early relapse. There was no increase in the relapse rate of acute leukaemias in the TCD group. It is worth noting that the majority of the patients in the TCD group were in first remission and that previous studies have suggested that T-cell depletion does not increase the
risk of relapse in AML in first remission in the absence of other poor prognostic features (Bunjes et al., 1995; Hale et al., 1998; Papadopoulos et al., 1998).

Two previous studies have investigated immune reconstitution following the use of Campath in vitro with BM grafts. The use of both Campath-1M and -1G was associated with a slower recovery of CD4+ cells (Lowdell et al., 1998) and a high incidence of life-threatening viral and non-viral infections (Davison et al., 2000). PBSC grafts have been associated with a more rapid immune reconstitution (Bensinger et al., 2001; Storok et al., 2001). There are limited data on the immune reconstitution following T-cell-depleted PBSCT. One study on CD34+ selected PBSCT transplants demonstrated a delayed reconstitution of T-cell subsets in the first 8 months after transplant (Martinez et al., 1999). An important finding in our study was the significantly different kinetics of immune recovery noted between the two doses of Campath-1H. While the use of 20 mg Campath-1H was associated with the recovery of CD4+ T cells and ALC at a slow but reasonable pace, especially when considering that the grafts were T-cell depleted, the reduction of the dose to 10 mg resulted in prompter recovery of both these parameters. Although the follow-up was shorter for this group of patients, it is possible that the improved immune reconstitution may also have had a favourable impact on the relapse risk (Powles et al., 1998; Kumar et al., 2001).

The lower NRM in our cohort was contributed to not only by reduction in GVHD, but also by the effective control of viral infections by the pre-emptive interventions for CMV, respiratory viruses and adenoviruses (Chakrabarti et al., 2001b, 2002a, b), and a rapid recovery of the ALC and CD4+ subset. The importance of lymphocyte recovery in the outcome of viral infections and survival has been highlighted in previous studies (Bensinger et al., 1993; Pavletic et al., 1998; Chakrabarti et al., 2002b). In addition, a higher CD34+ cell dose has been reported to be associated with a lower NRM (Bittencourt et al., 2002), with a similar trend noted in our study.

The majority of Campath antibody activity used by the methods described would have to take place in vivo by antibody-dependent cell-mediated cytoxicity (ADCC) and thus the in vitro T-cell depletion is not reflective of the true extent of depletion. Approximately, 5 mg Campath should be required for T-cell depletion when added to an average PBSC collection containing 3 x 10^6 CD34+ cells, but a much larger dose is used in clinical practice because the antibody binds the CD52 antigens with low affinity and, thus, the amount of free or circulating antibody would be widely variable and difficult to predict. It is, therefore, difficult to ascertain the minimum dose of Campath necessary for optimum T-cell depletion by in vitro experiments. This can be best answered through clinical trials. The reduction of the dose of Campath-1H to 10 mg was associated with an improved immune recovery without an increase in GVHD. This could be due to a less extensive T-cell depletion. The activity of Campath antibodies extends beyond T cells to dendritic cells. It is possible that their effect on dendritic cells is responsible for the prevention of GVHD when only a partial T-cell depletion was observed (Klangsinirikul et al., 2002). The other possibility is that the free antibody remaining in the circulation is likely to be higher if a higher dose is used. Campath-1H has been shown to have a prolonged half-life, which might interfere with immune recovery (Rebello et al., 2002).

While unmanipulated PBSC is the preferred option for advanced stage leukemias, measures to reduce chronic GVHD need to be optimized. For advanced diseases, the risk of GVHD can be significantly reduced without an increase in leukaemic relapse or compromise of the immune recovery, by the judicious use of T-cell depletion. In our study, Campath-1H 'in the bag' was effective in achieving this goal following matched related transplants. The use of 10 mg Campath-1H seemed to be the more pragmatic approach for matched related grafts, with a better reconstitution of cellular immunity observed, which might translate to a lower relapse risk even in patients with more advanced disease. This theory needs to be explored in larger studies. In fact, a multicentre randomized study is being initiated in the UK to compare unmanipulated and Campath-1H-treated grafts in patients with AML in first remission.

ACKNOWLEDGMENTS

We thank the staff of the Therapeutic Antibody Centre, University of Oxford for their contributions to the production of CAMPATH-1H antibody. Their work was supported by the United Kingdom Medical Research Council, Leukosite Inc., and the EP Abraham’s Trust.

ALEMTUZUMAB IN VIVO

Alemtuzumab is now commercially available and over the last 6 years has replaced Campath-1G for stem cell transplantaion. It is generally used in the same manner as the previous rat antibody. In addition, a novel protocol was developed for a nonmyeloablative conditioning regimen: alemtuzumab was combined with fludarabine and melphalan to facilitate engraftment along with standard GVHD prophylaxis. This protocol was associated with a reduced incidence of GVHD, which is an important cause of mortality following other nonmyeloablative protocols. Amidst this excitement, we noted with dismay that the patients undergoing nonmyeloablative transplantation with this regimen were experiencing a far greater incidence of cytomegalovirus (CMV) reactivation and other virus infections.14.6

We initially compared the outcomes of transplant recipients after the nonmyeloablative regimen with those undergoing

full-intensity conditioning before receiving grafts that had been T-cell-depleted with alemtuzumab in vitro. There was a significant difference in the onset and the overall incidence of viral infections between the groups: the former group experienced an earlier onset and much higher incidence of infection.\textsuperscript{2} We also noted slower immune recovery among the nonmyeloablative group.

We subsequently analyzed the viral surveillance of all patients including those receiving alemtuzumab either in vivo or in vitro, irrespective of the intensity of the conditioning regimen. CMV respiratory and adenovirus infections were significantly increased following the use of alemtuzumab in vivo, irrespective of the conditioning regimen.\textsuperscript{2-6} Additional patients from two other UK centers were also evaluated for these viral infections. A similar trend was noted in the multicenter evaluation of nonmyeloablative transplant recipients confirming that our initial findings were not due to a center-effect or a chance finding.\textsuperscript{7} These observations led to pharmacokinetic studies on alemtuzumab. Campath-1G has an estimated half-life of about 13 hours but alemtuzumab, of 15 to 21 days, suggesting that biologically active antibody may persist for several months.\textsuperscript{8} Thus the concentration of the humanized antibody when used in vivo in the dose of 100 mg over 5 days was higher than was necessary for in vivo T-cell depletion at the time of stem cell infusion, persisting at potentially lympholytic levels for months posttransplant. This persistence probably delayed lymphocyte recovery and increased the risk of viral infections, lending credence to the hypothesis that alemtuzumab (rather than other elements of the conditioning regimens) was responsible for the increased viral infections. Subsequently, the nonmyeloablative protocol was modified to explore reduction of the alemtuzumab dose to reduce this complication.

**ALEMTUZUMAB IN VITRO**

For full-intensity conditioning, we have used a protocol of T-cell depletion with alemtuzumab in vitro, similar to that reported by Cape Town.\textsuperscript{9} We started with a dose of 20 mg alemtuzumab. Although the problems of immune reconstitution and viral infections were reduced with this protocol, we further reduced the alemtuzumab dose, because there was virtually no GVHD with this in-vitro dose of alemtuzumab. The dose reduction was aimed at further improving immune reconstitution and reducing the relapse risk. Indeed, the immune reconstitution was significantly improved and early data suggest that the relapse risk might be lower. This was achieved without any increase in the incidence of GVHD. Viral infections were also less common. Because of the lower total dose of antibody, the blood concentration was expected to fall below lympholytic levels much more quickly.\textsuperscript{9}

Our studies have demonstrated that alemtuzumab, as currently used in vivo, decreases the incidence of GVHD at the cost of poor immune reconstitution and increased infectious complications. Subsequent pharmacokinetic studies have substantiated the hypothesis that longer persistence of high levels of alemtuzumab is responsible for the untoward effects. The aim to reduce GVHD is successfully achieved with alemtuzumab in vitro with less impairment of immune recovery and fewer resultant complications. Although this might be achievable in the conventional allograft setting, the few patients, who have been treated by reduced intensity conditioning together with in vitro T-cell depletion, have had difficulty achieving durable engraftment.\textsuperscript{10}

**FUTURE DIRECTIONS**

The longer half-life of human compared with rodent monoclonal antibodies is usually perceived to be an advantage. However, alemtuzumab treatment, as we have prescribed it, prevents rejection and GVHD in stem cell transplantation has resulted in antibody persistence beyond an optimal window leading to delayed immune reconstitution. The original rat antibody Campath-1G appears to have the perfect characteristics for this purpose, but regrettably is not available commercially. Alternative, modified dosing schedules may overcome this problem.

Alemtuzumab therapy, as currently practiced, may still have a role for nonmalignant disorders, where durable mixed chimerism without GVHD is the ideal outcome. Higher doses of alemtuzumab in vivo might still be necessary for mismatched grafts. T-cell depletion in the setting of conventional sibling allografts can be achieved successfully using low doses of alemtuzumab in vitro (10 mg) without compromising immune reconstitution. A higher dose in vitro (20 mg) might suffice for matched unrelated grafts. For mismatched unrelated grafts, further host immunosuppression might be achieved with fludarabine without resorting to in vivo alemtuzumab. Thus our cumulative experience with alemtuzumab suggests that better results might be achieved by tailoring the dose and mode of the use of this reagent to match the clinical situation. Further studies are needed to optimize the dose of alemtuzumab in vivo and in vitro, relevant to the type of conditioning and the graft.

Prevention of Graft-Versus-Host Disease in Allogeneic Bone Marrow Transplantation for Leukemia by T Cell Depletion In Vitro Prior to Transplantation

THE ACUTE, and to a lesser degree, the chronic, forms of graft-v-host disease (GVHD) represent one of the major obstacles to successful bone marrow transplantation (BMT), since neither adequate preventive measures nor effective therapeutic modalities are known to date. Since GVHD results from interaction between mature donor T lymphocytes and recipient cells capable of stimulating the donor's immunocompetent cells, we have attempted to prevent GVHD by in vitro removal of mature T lymphocytes prior to transplantation. The present report represents a summary of our initial experience using three approaches for the depletion of T lymphocytes. Our data suggest that GVHD may be completely prevented by adequate removal of T lymphocytes from pretransplant marrow in patients undergoing BMT from HLA-matched sibling donors.

PATIENTS AND METHODS

A total of 21 consecutive leukemia patients, including 11 poor-risk patients with resistant disease in relapse or partial remission, underwent BMTs with T cell-depleted marrow obtained from HLA-A, B, DR-compatible matched sibling donors, starting in early 1983. Pertinent details are described in Table 1. Most patients were treated with cyclosporin 60 mg/kg on two consecutive days and two intrathoracic methotrexate injections for GCS prophylaxis followed by 2,200 rad whole body irradiation given in six fractions over three to six days from a linear accelerator at approximately 25 rad/min. T cell depletion was carried out using one of the following methods. In all cases, mononuclear-rich plasma was obtained after mixing heparinized marrow with Volds (betastrach) at a final concentration of 0.66% for one hour at room temperature by removal of the RBC sediment. Protocol 1: Ficol-Hypaque (FH) enrichment of stem cells, followed by separation of T cells rosetting with neuraminidase-treated sheep RBCs (E-RFC) over a second FH gradient. Protocol 2: Enrichment of stem cells by mixing marrow cells with soybean agglutinin (2 mg/mL) and separation of agglutinating cells over a 5% bovine serum albumin gradient. This procedure was previously described. Protocol 3: Treatment of marrow mononuclear cells (50 to 100 x 10^6/mL) reconstituted in buffered saline supplemented with Ca^++ and Mg^++ with a mononuclear rat-anti-human lymphocyte antibody (CAMPATH-1), originally described by Hale et al., at 100 µg/mL for 30 minutes, followed by addition of autologous donors' fresh serum as a source of complement for an additional 30 to 45 minutes in a 37°C bath. In all protocols, T cell removal was confirmed by studying E-RFC and colony formation (CFU-GM) before and after the procedure. None of the patients, received posttransplant immunosuppressive therapy.

RESULTS AND CONCLUSIONS

These data are based on a small and nonhomogenous group of patients (six in protocol I, five in protocol II, and ten in protocol III) including poor-risk patients with relapse or resistant disease, and therefore no firm conclusions can be reached on the role of T cell depletion in the overall survival and success rate following BMT. Nevertheless, several conclusions are noted: (1) All three protocols used are efficient for depletion of immunocompetent cells.

*Percentage of remissions with SBRTs before and after T cell depletion.
†Only 1,000 rad was administered, plus arabinoside ($k + [ARA]= k$ mg/kg).
‡[ARA]= $k +[ARA]= k$ mg/kg.
§Chemotherapy consisted of 22 g rad six times.
||Total lymphoid irradiation, 160 rad four times, was added.

Competent T lymphocytes from the marrow in vitro; (2) in vitro CFU-GM is not seriously affected by the procedures used; (3) rapid engraftment of all hematopoietic elements occurred in all patients; (4) None of the patients developed any clinical signs of acute or chronic GVHD with an observation period >16 months in the first patients; (5) the posttransplant course was generally smooth, with a short hospitalization period.

Of the protocol I patients, two are alive and well (six to 12 months), one died of rejection (on day 103), and two poor-risk patients relapsed (on days 48 and 111). Of the protocol II patients, two are alive and well >1 year (one with testicular relapse), two (one with chronic myelogenous leukemia [CML]) died of rejection (on days 52 and 76), and one poor-risk patient died of relapse (on day 76). Of the protocol III patients, six are alive and well (30 days to >1 year), two of three poor-risk patients received transplants during relapse died of relapse (on days 48 and 172), and the two CML patients died of rejection.

The single major problem that appears to be related to the T cell depletion procedure seems to be graft rejection occurring in five patients (1/6, protocol I; 2/5, protocol II; 2/10, protocol III), indicating that donor T cells play a role in abrogating residual host resistance. All attempts to retransplant rejected grafts even without cell depletion, with or without further conditioning, failed. It appears, therefore, that further conditioning pretransplant might prove useful in abrogating host resistance to T cell-depleted marrow allografts. Indeed, the last three patients who received transplants in protocol III received...
total lymphoid irradiation (150 rad four times in two days) immediately prior to the standard conditioning regimen.

The complete eradication of GVHD seems to be encouraging and may open new horizons for wider applications of BMT in clinical practice. However, further observations are necessary in controlled clinical trials in good-risk patients for careful evaluation of the overall effects of T cell depletion in long-term survival and incidence of leukemic relapses.

REFERENCES
hydroxyethyl starch. Alternatively, a mononuclear cell fraction was isolated by centrifugation over Ficoll-Hypaque.45 The cells were suspended in approximately 250 mL of balanced salt solution (containing Ca²⁺ or culture medium to give a cell concentration of no more than 10⁶/mL. Campath-1M was added to give a final concentration of 0.1 mg/mL and the suspension was mixed and left at room temperature for 10–15 min. Donor serum (or AB serum was added to a final concentration of 20–25% (v/v) and the suspension was incubated at 37 °C for 30–45 min. Usually the cells were then washed with fresh frozen plasma or saline containing human albumin with the intention of removing excess antibody and anaphylotoxins. Occasionally the whole mixture was used. T cell depletion was estimated either by E-rosetting or by immunophenotyping using suitable fluorescent-labelled mAb. In almost every case, the fraction of residual T cells was <1% of the final inoculum and in many cases residual T cells were undetectable. Experiments have shown that complement, although added at an optimal concentration, is likely to be the limiting factor46,47 and so it is likely that any residual antibody-coated cells which had not been lysed in vitro, would still be eliminated in vivo.

Adback of T cells

Because of concern about the risk of relapse and the belief that donor T cells contribute a beneficial anti-leukaemic effect, various methods have been used to add back small, controlled numbers of lymphocytes.12,15,46 In some cases, a fixed number has been added to the BM inoculum after treatment with Campath-1M and complement. In another scheme, used by the team at Jerusalem, the donor lymphocytes were given in graded doses to the recipient after the transplant.15 The rationale was to start with a very small, probably ineffective, dose and to give ten times more each fortnight until a maximum (of about 10⁷ per kg) was reached. Some patients with poor-risk leukaemia finally received donor T cells which had been activated with IL-2. If there were signs of GVHD at any stage, then no more donor lymphocytes were given. Most recently the timing of the first T cell adback has been delayed until about 2 months post-transplant and it has not been given at all if there were any sign of GVHD from the donor marrow. For the purposes of this analysis we have pooled all of the patients who actually received any form of T cell adback, irrespective of the precise dose or timing.

### Treatment of bone marrow with Campath-1G

Auffy coat or mononuclear cell fraction was prepared as before and Campath-1G was added to give a final concentration of 0.05–0.1 mg/mL. The mixture was incubated at room temperature for 30–45 min before infusion into the recipient without washing. In this case, it was anticipated that the excess antibody could also contribute to the immunosuppression of the host. It was not expected that T cells would be efficiently lysed in vitro under these circumstances as the IgG2b antibody is less lytic with complement than the IgM and no extra source of complement was added. The aim was to opsonize the donor T cells for clearance in the recipient. However, analysis by immunofluorescence in several patients has shown about 90% depletion of T cells during the in vitro incubation. This may be due to residual donor plasma in theuffy coat fraction as no T cell lysis was seen when mononuclear cells prepared on Ficoll-Hypaque were used (W. Fibbe & R. Willemze, University of Leiden, unpublished data); however, some cell-mediated killing in vitro may be possible.

### Statistical analysis

Acute GVHD was diagnosed and staged according to the Seattle criteria.48 Chronic GVHD was staged according to the clinical criteria prevailing at each centre; 'mild' and 'moderate' were both scored 'M' and 'extensive; or 'severe' were scored 'S'. Percentages of patients suffering graft failure or GVHD were calculated as a fraction of patients at risk from those complications. Patients were considered not evaluable for graft failure if they died before day 100 without evidence of engraftment, not evaluable for acute GVHD if they died before day 100 without acute GVHD and not evaluable for chronic GVHD if they died (or were last reported) before day 120 without
Control of graft-versus-host disease and graft rejection by T cell depletion of donor and recipient with Campath-1 antibodies. Results of matched sibling transplants for malignant diseases

G. Hale & H. Waldmann for Campath users

Department of Pathology, University of Cambridge, Cambridge, UK

Summary:

Campath-1 (CDw52) antibodies (IgM and IgG2b) have been used in vitro and in vivo for control of GVHD and prevention of rejection following bone marrow transplantation. Results of 951 patients with malignant disease transplanted from HLA-matched siblings are reported. Both Campath-1M and Campath-1G are shown to be effective when used in vitro for prevention of graft-versus-host disease (GVHD). Graft failure was reduced by addition of cyclosporin A (CsA) post-transplant and possibly also by total lymphoid irradiation (TLI) pre-transplant. However, treatment of the recipient with Campath-1G to deplete residual lymphocytes was more effective, reducing the incidence of graft failure from 21% to 9% (in the absence of CsA). GVHD was virtually eliminated and leukaemia-free survival was improved. However, the risk of relapse was increased by T cell depletion, certainly in CML and to a lesser extent in AML. Addition of donor T cells to the depleted bone marrow or early post-transplant restored the risks of GVHD, graft failure and relapse to much the same as without T cell depletion. One problem associated with the use of Campath-1G in vivo was a significant delay (by up to 7 days) in neutrophil engraftment. This was unlikely to be caused by toxicity to progenitor cells and we argue that small numbers of lymphocytes may be required to assist early engraftment, possibly by cytokine production. If this problem can be overcome, T cell depletion of donor and recipient may be a good alternative to conventional GVHD prophylaxis for matched sibling transplants, resulting in a superior quality of life for the survivors. It is also likely to be particularly beneficial in transplants for non-malignant diseases and transplants from unrelated donors.

Despite the undoubted advances in drug-based immunosuppression in recent years, GVHD is still a significant complication of BMT, particularly when the donor and the recipient are not HLA-matched siblings.

It is generally accepted that the most effective way of preventing both acute and chronic GVHD is by depletion of T lymphocytes from the donor BM. One of the simplest ways of achieving this was with the moAb Campath-1M which activates human complement and has been widely used by many transplant centres²-³ (Appendix, Protocol 01). However, the benefits of T cell depletion are largely negated by an increase in the risk of graft rejection and leukaemia relapse. These potential problems were noted in some of the early clinical studies²,4,6 and had been predicted from animal experiments.⁵-⁷ Subsequent analysis has shown a risk of graft failure of 10-20% in patients receiving T cell-depleted marrow from matched siblings although there has been some variation between different studies, reflecting differences in the degree of depletion and possibly also in the conditioning regimens.⁵,⁶,8-12 An increased risk of leukaemia relapse is most noticeable in patients with CML.¹³ The effect in acute leukaemias seems to be much smaller.¹⁴

Some groups have tried to overcome these problems of Protocol 01 by adding back small numbers of T cells to the BM inoculum. Although this did diminish graft rejection, GVHD was also restored to the about previous frequency and intensity.¹³,¹⁵,¹⁶ The effect of these efforts on relapse has been hard to assess because of the small numbers reported so far but in general it seems as though the status quo was restored. In other studies the problem of graft rejection has been tackled by the addition of other immunosuppressive agents such as CsA or total lymphoid irradiation (TLI)¹⁷ and they have met with some success, as will be shown here.

We have also investigated a new approach, based on experiments in animals which showed that treatment of the recipient with depleting anti-T cell antibodies could abolish rejection of T cell-depleted BM, even with reduced irradiation or when the donor and recipient differed across major histocompatibility barriers.⁹,¹⁸ Evidence from clinical studies suggests that graft failure is mainly due to rejection by host lymphocytes as donor-specific cytotoxic T cells have been isolated from several patients with graft rejection.¹⁹-²² Furthermore, in both monkeys and humans we observed that autologous BM depleted of T cells with Campath-1M engrafted normally whereas there was a high incidence of rejection of T cell-depleted BM from unrelated or HLA-mismatched donors.²³
Our aim was to obtain an antibody which could give lymphocyte depletion in the human comparable to that obtained in those experimental animals. Not all cell surface antigens are equally good targets for antibody attack but the Campath-1 (CDw52) antigen seemed to be a particularly good one.1.26,27 This abundant antigen is a small, lipid-anchored glycoprotein which is present on virtually all human lymphocytes. Its expression on B cells was not considered a problem in the context of BMT, rather it might be an advantage as depletion of B cells could reduce the potential target for EBV infection and lymphoproliferation during the period when there is little control by T cells. This has been a problem with some other methods of T cell depletion.26-29 Furthermore, if Campath-1 antibodies could be used to deplete lymphocytes in vivo, they might also contribute to the elimination of residual disease in patients with lymphoid malignancies.

The original IgM antibody Campath-1M, although extremely lytic with complement, gave only transient depletion of lymphocytes in patients with CLL or lymphoma.30 We therefore developed the rat IgG2b antibody Campath-1G, which has an almost identical specificity.31 The IgG2b subclass, besides being the best rat IgG for activating complement32 is also optimal for binding to human Fc receptors and activating cell-mediated killing.33 Campath-1G proved to be very efficient at depleting lymphocytes in vivo as was shown in several patients with lymphoid malignancies and in patients suffering steroid-resistant kidney graft rejection.34,35 In both studies, the treatment with Campath-1G gave a beneficial clinical response in many of the patients. Subsequently the humanized antibody, Campath-1H (IgG1), was constructed by genetic engineering using the complementarity-determining regions of Campath-1G.36 It is equally potent in vivo but is less immunogenic on repeated administration.37,38 However, studies in BMT using Campath-1G had already started before Campath-1H became available. We did not consider there was any advantage in using the humanized antibody in this context because the treatment was only short-term at a time when the level of immunosuppression is such that an antiglobulin response is unlikely.

The first objective was to see whether treatment with Campath-1G would decrease the risk of graft rejection in the context of 'standard' T cell depletion. This was not so easy to test because the actual incidence was comparatively low and so quite a large number of patients is needed to demonstrate an effect. For example, for a study to have a 90% chance of showing a significant reduction from 15% graft failure to 5%, then about 55 patients would be required. Initially we did not know whether the recipient's effector mechanisms would be compromised by the conditioning regimen, so it was possible that administration of antibody at the time of the transplant might not be effective. Therefore a study was designed where Campath-1G was given at 5-10 mg/day for 5 days before the start of chemoradiotherapy (Protocol 02).

Although this had the slight disadvantage that extra inpatient time was required, this protocol had several other advantages: (1) the degree of lymphopenia produced by Campath-1G could be measured, uncomplicated by other treatments, (2) adverse effects of the antibody could likewise be assessed, and (3) most of the antibody would be cleared by the time of the transplant and so be unlikely to contribute to extra depletion of the donor T cells. For this study, the T cell depletion with Campath-1M and other elements of the conditioning regimen were kept the same as in historical control groups. No other agents to prevent graft rejection (e.g. CsA, TLI) were given. The plan is to enrol 100 patients with acute leukaemia in first remission which will provide a homogenous group where the effect of the antibody protocol on relapse can also be observed. To date about 75 such patients have been enrolled by three transplant teams (Royal Free, London; University Hospital, Ulm; King Faisal Hospital, Riyadh). The interim results are very satisfactory but a detailed report will be published when the study is complete. Here we have included these study patients with a larger group of patients, including CML and advanced disease, who all received the same antibody protocol.

Meanwhile, other centres have explored the use of Campath-1G for prevention of GVHD, either adding it in vitro to the donor BM (Protocol 03),31,39,40 or by giving it in vivo at or around the time of transplant (Protocols 04 and 06).41 In both cases, it was intended that the antibody would also contribute to prevention of rejection. The logical development was to combine these treatments and give the antibody both in vivo and in vitro (Protocol 07). Although the numbers of patients treated with these newer protocols is still relatively small, it is clear that Campath-1G used in either way can reduce the incidence of GVHD.

In this report we focus on transplants from HLA-matched siblings for leukaemia and other malignant diseases. Similar protocols have been used in both unrelated donor transplant and in HLA-matched or mismatched transplants for non-malignant diseases. There have already been some reports of those studies.40,42 The results are broadly in agreement with those described here.

All the results described here are from open studies. There were several reasons why we did not consider it appropriate to carry out a prospective randomised trial. Few centres would be prepared to continue with the original T cell depletion protocol for a 'control' group, given the past experience of graft failure and the perception that the proposed new treatments would probably be of benefit. If the comparison were to be with 'standard' therapy (e.g. MTX/CsA), then we did not know what differences to expect in transplant-related mortality or leukaemia-free survival. There were too many possible variables in the antibody treatment to choose between (dose, timing etc) before a good trial could be designed. Therefore we have first explored these variables by testing alternative protocols and comparing the results with the most similar historical group.
Patients and methods

Transplants and conditioning regimens

A total of 986 transplants were reported from HLA-matched siblings for patients with leukaemia and other malignant diseases. Of these, 35 were excluded from analysis here either because antibodies other than Campath-1M or Campath-1G were used (2 cases) or because the available follow-up was < 100 days. The 951 transplants analysed were carried out at 30 centres between July 1983 and March 1993 (Appendix). During this time different protocols of antibody treatment were tested in roughly chronological order (Figure 1); however, several of them have been in use concurrently at different centres. Patients were transplanted for a typical range of diseases, 554 with acute leukaemia in CR1 or CML in CP1 and 397 with more advanced disease (Table I). The distribution among different antibody protocols was not uniform; for example, patients with CML were mostly treated according to the original protocol (01) (172 patients, median age 35 years) and only a small number (41 patients, median age 41 years) have been enrolled in subsequent protocols because of the feared increase in relapse after T cell depletion. These recent CML patients received additional anti-leukaemia conditioning with thiopeta, but it is too early to tell what impact that will have on relapse.

Conditioning regimens varied considerably. Seventytwo patients (8%) were conditioned with busulphan plus CY; the rest received CY/TBI with or without other anti-leukaemia drugs. The schedule for TBI varied according to the usual practice and facilities available at each centre. Some patients also received TLI in order to reduce the risk of graft rejection. No post-transplant immunosuppression was given in the majority of cases (60%, 64%). Two patients received MTX and 6 received MTX/CsA. They are included with the 334 who received CsA post-transplant. A summary of the patient characteristics and conditioning according to the different antibody protocols is given in Table II.

Monoclonal antibodies

Campath-1M (IgM) and Campath-1G (IgG2b) are rat mAb which recognise the CDw52 antigen. Initially they were prepared in the Department of Pathology from ascitic fluid of rats inoculated with hybrid myeloma cells. The antibodies were purified by precipitation with ammonium sulphate, dialysed against phosphate-buffered saline and sterilised by membrane filtration. Subsequently, they were prepared from the culture supernatant of cells grown in hollow-fibre fermentors (Acusyst Jr, Endotronics). Since 1990, this has been carried out in the Therapeutic Antibody Centre, Regional Transfusion Centre, Cambridge. Campath-1M was purified by precipitation with ammonium sulphate as before. Campath-1G was purified by affinity chromatography on Protein A, followed by ion exchange on S-Sepharose under the control of a Biopilot chromatography system (Pharmacia). The cell lines were tested for microorganisms and viruses according to EC guidelines and the purified antibodies were submitted to a panel of tests to ensure their biological activity and freedom from contaminants.

Treatment of BM with Campath-1M and human complement

Marrow was aspirated and a buffy coat fraction was prepared by centrifugation or by sedimentation with

hydroxyethyl starch. Alternatively, a mononuclear cell fraction was isolated by centrifugation over Ficoll-Hypaque. The cells were suspended in approximately 250 ml of balanced salt solution (containing Ca²⁺ or culture medium to give a cell concentration of no more than 10⁹/ml. Campath-1M was added to give a final concentration of 0.1 mg/ml and the suspension was mixed and left at room temperature for 10-15 min. Donor serum (or AB serum was added to a final concentration of 20-25% (v/v) and the suspension was incubated at 37°C for 30-45 min. Usually the cells were then washed with fresh frozen plasma or saline containing human albumin with the intention of removing excess antibody and anaphylatoxins. Occasionally the whole mixture was infused. T cell depletion was estimated either by E-rosetting or by immunophenotyping using suitable fluorescent-labelled mAb. In almost every case, the fraction of residual T cells was <1% of the final inoculum and in many cases residual T cells were undetectable. Experiments have shown that complement, although added at an optimal concentration, is likely to be the limiting factor⁴⁸,⁴⁹ and so it is likely that any residual antibody-coated cells which had not been lysed \textit{in vitro}, would still be eliminated \textit{in vivo}.

\textbf{Treatment of bone marrow with Campath-1G}

A buffy coat or mononuclear cell fraction was prepared as before and Campath-1G was added to give a final concentration of 0.05-0.1 mg/ml. The mixture was incubated at room temperature for 30-45 min before infusion into the recipient without washing. In this case, it was anticipated that the excess antibody could also contribute to the immunosuppression of the host. It was not expected that T cells would be efficiently lysed \textit{in vitro} under these circumstances as the IgG2b antibody is less lytic with complement than the IgM and no extra source of complement was added. The aim was to opsonize the donor T cells for clearance in the recipient. However, analysis by immunofluorescence in several patients has shown about 90% depletion of T cells during the \textit{in vitro} incubation. This may be due to residual donor plasma in the buffy coat fraction as no T cell lysis was seen when mononuclear cells prepared on Ficoll-Hypaque were used (W. Fibbe & R. Willemze, University of Leiden, unpublished data); however, some cell-mediated killing \textit{in vitro} may be possible.

\textbf{Addback of T cells}

Because of concern about the risk of relapse and the belief that donor T cells contribute a beneficial anti-leukaemic effect, various methods have been used to add back small, controlled numbers of lymphocytes. In some cases, a fixed number has been added to the BM inoculum after treatment with Campath-1M and complement. In another scheme, used by the team at Jerusalem, the donor lymphocytes were given in graded doses to the recipient after the transplant. The rationale was to start with a very small, probably ineffective, dose and to give ten times more each fortnight until a maximum (of about 10⁹ per kg) was reached. Some patients with poor-risk leukaemia finally received donor T cells which had been activated with IL-2. If there were signs of GVHD at any stage, then no more donor lymphocytes were given. Most recently the timing of the first T cell addback has been delayed until about 2 months post-transplant and it has not been given at all if there were any sign of GVHD from the donor marrow. For the purposes of this analysis we have pooled all of the patients who actually received any form of T cell addback, irrespective of the precise dose or timing.

\textbf{Statistical analysis}

Acute GVHD was diagnosed and staged according to the Seattle criteria.⁵⁰ Chronic GVHD was staged according to the clinical criteria prevailing at each centre; 'mild' and 'moderate' were both scored 'M' and 'extensive, or 'severe' were scored 'S'. Percentages of patients suffering graft failure or GVHD were calculated as a fraction of patients at risk from those complications. Patients were considered not evaluable for graft failure if they died before day 20 without evidence of engraftment, not evaluable for acute GVHD if they died before day 100 without acute GVHD and not evaluable for chronic GVHD if they died (or were last reported) before day 120 without
chronic GVHD. Patients who suffered graft failure were subsequently not considered to be evaluable for GVHD (even if they did suffer GVHD from an unpurged 'top-up' or second transplant). This method of calculation is likely to slightly over-estimate the incidence of these complications compared with the true actuarial incidences but information about the date of onset of graft failure or GVHD was not always available. Because the aim of these studies was to simultaneously reduce the risk of either complication, a composite result was also calculated. A 'bad' outcome was defined as graft failure (complete or partial) or severe (grade III or IV) acute GVHD or severe chronic GVHD. Relapse in CML was defined by haematological criteria and in this analysis we did not consider cases of relapse which were detected only cytogenetically or by PCR.

Actuarial survival data reported in the text are at 2 years unless otherwise stated, with standard errors calculated as described by Peto et al. Transplant-related mortality was defined as death from any cause except following haematological relapse. If a patient suffered relapse, their contribution to the actuarial plot was censored from that date. For univariate analyses the chi-square test (GVHD and graft failure), the Mann–Whitney U-test (time to engraft) or the log rank test (survival and relapse) were used as appropriate. Comparisons using the log-rank test were evaluated from 0–2000 days. Probability (p) values were one-sided as we could predict the sign of the differences in advance.

The database contained information on centre, sex, age, disease, status at transplantation, TBI dose rate, total dose, number of fractions and timing, TLI dose, chemotherapy, antibodies in vivo, donor sex, date of transplant, cell dose, T cell dose, method of T cell depletion in vitro. T cell addback, post-transplant immunosuppression, time to reach neutrophils 0.5 × 10⁹/l, graft failure, acute and chronic GVHD, time to relapse, survival and cause of death. Follow-up was requested for all patients between April and June 1993. The response was good and in fewer than 5% of the patients was no reply obtained from a centre or the patient was reported as 'lost to follow-up' (usually because of returning to a foreign country).

### Results

**T cell depletion in vitro with Campath-1M and complement (Protocol 01)**

The impact of T cell depletion with Campath-1M on GVHD and graft failure has been reported before. With more patients and longer follow-up (median 7.3 years) we are now in a position to assess the effects of CsA and TLI and to evaluate the risk of leukaemia relapse (Table III). The overall incidence of graft failure (early or late, partial or complete) was 18%. Patients who received post-transplant immunosuppression with CsA had less graft failure (13%) than those who did not (21%) (p < 0.04). Likewise, the rate of graft failure was lower in patients who received TLI (12%) than in those who did not (19%) but this did not reach statistical significance. However, when we looked at the overall rate of severe complications (graft failure or severe GVHD), TLI showed a significant advantage (p < 0.02). A small proportion of patients received both CsA and TLI which confounded the individual effects. We therefore looked separately at the effects of CsA in patients who did or did not receive TLI (Table III). Both TLI and CsA seemed to give a similar reduction in graft failure. There was also slightly less GVHD in the patients who received TLI. Overall, both treatments independently reduced the combined incidence of these complications.

It was only in the groups receiving additional CsA that we could see a significant reduction in transplant-related mortality (45% without CsA, 28% with CsA, p < 0.0001). This was reflected in superior survival of the CsA group (39% without CsA, 54% with CsA, p < 0.006) but because of a slightly higher risk of relapse, the difference in leukaemia-free survival was only marginal (35% without CsA, 42% with CsA). It is not clear why the short-term advantage seen with TLI was not reflected in a reduced transplant-related mortality because the two groups of patients were comparable for all the other prognostic factors which had been reported (Table II).

Although many of the improvements seen with these immunosuppressive treatments were modest, it gave some encouragement to the idea that graft failure could

be overcome and we hoped that treatment with the moAb would have a more decisive impact.

The risk of relapse for patients with early leukaemia transplanted according to Protocol 01 is shown in Figure 2. With up to 10 years follow-up, the risk of relapse in ALL and AML shows a plateau at approximately 30%, with most cases occurring in the first year. In CML, the risk of haematological relapse continues to rise for at least 5 years, reaching an apparent plateau of about 65% by 7 years.

**Campath-1G for control of rejection and GVHD (Protocols 02–07)**

The results to date using Campath-1G in vivo and/or in vitro in order to reduce both graft rejection and GVHD are shown in Table IV and Figure 3. They are compared with the results obtained using the original protocol. In all of the categories there were some patients who received post-transplant immunosuppression with CsA, although this was less frequent with the more recent protocols than originally. As we have shown above, CsA seems to reduce the risk of graft failure with T cell depletion. So that the data are more comparable, we have only shown the results in the patients who received no post-transplant immunosuppression. The results and conclusions were the same when the CsA-treated patients were included but in the absence of CsA we can much more confidently infer an anti-GVHD effect of the antibody treatments.

Protocol 02 shows a significantly lower incidence of both graft failure and acute GVHD. This resulted in a substantially lower transplant-related mortality compared with protocol 01 (21% vs 45%, p < 0.0001) with significantly improved survival and leukaemia-free survival (48% vs 35%, p < 0.004). The results on this protocol were slightly superior to the use of CsA with T cell depletion but not significantly so. The overall risk of relapse is almost identical between Protocols 01 and 02 but it would be premature to draw any firm conclusions because of the comparatively short follow-up of Protocol 02 and the difference in the mix of patients (e.g. fewer patients with CML in protocol 02).

In Protocol 03 (Campath-1G in vitro) the incidence of either GVHD or graft failure is very low. It provides very clear evidence that GVHD can be abrogated using Campath-1G without the need for exogenous complement. The number of patients is too small for the reduced incidence of graft failure to be statistically significant. However, the transplant-related mortality is lower than for the comparable original group (20% vs 45% p < 0.04) and the leukaemia-free survival is better (68% vs 35%, p < 0.01). It should be noted that all the patients in this group received TLI which may have helped to reduce the rate of graft failure. Nevertheless, the improvement in transplant-related mortality and leukaemia-free survival is still maintained when the group is compared with only those patients from the original protocol who also received TLI.

The combined results from Protocols 04 and 06 (Campath-1G in vivo only) show a low incidence of graft failure and acute GVHD but a substantially increased incidence of chronic GVHD. Most of the cases of severe chronic GVHD occurred on Protocol 04 where the Campath-1G was stopped on the day of transplant. These results provide clear evidence that Campath-1G in vivo can deplete the donor T cells sufficiently to prevent much of the acute GVHD that would otherwise have been expected but presumably a few T cells survive and give rise to chronic GVHD in many patients.

On the basis of the results so far, the combination of Campath-1G in vivo and in vitro (Protocol 07) was expected to give optimal control of both GVHD and graft failure. Control of GVHD was indeed impressive with no cases of acute GVHD > grade I or chronic

Results are compared with the first group (Protocol 01). Those which are significantly better are highlighted in bold script, those which are worse are in italic. In each case the p value is also given.

Although the data presented in this table are of only patients who received no post-transplant immunosuppression, essentially identical results were obtained when all patients were analysed irrespective of post-transplant immunosuppression.

GVHD of any grade being reported to date. However, there have been a total of seven cases of graft failure in 28 patients (including two who received CsA). Perhaps the explanation for this can be found in the rates of engraftment which are described below.

**T cell addback**

Several protocols for adding back T cells were used. In 118 cases the donor BM was first depleted with Campath-1M and complement and in 70 cases Campath-1G was used. None of the patients received additional Campath-1G in vivo. The results from the different methods were essentially indistinguishable and so they have been pooled (Table V). About half of the patients received post-transplant CsA and these have been analysed separately because of the effect which CsA had in the original protocol. Whether or not CsA was given, T cell addback gave a significant reduction in graft failure and a significant increase in GVHD, both acute and chronic. Essentially the status quo was restored, although in the case of patients who did not receive CsA, the amount of GVHD was probably not as great as would have been seen with no manipulation of the donor T cells. With CsA, the transplant-related mortality was significantly worse with T cell addback compared with the original protocol (42% vs 28%, p < 0.005) but there was no difference without CsA because of the poorer results in the original protocol (44% vs 45%).

Overall (with or without CsA), the risk of relapse after T cell addback was significantly less than with the original protocol (26% vs 38%, p < 0.007). Because of the increase in transplant-related mortality, the leukaemia-free survival was little different (42% vs 38%). However, the patients who received T cell addback included significantly more with advanced disease (55% vs 39%, p < 0.0001) so the strategy may have been more successful than is immediately apparent. When we analysed all patients with early disease (CR1 or CP1) then T cell addback still reduced the risk of relapse compared with T cell depletion by any method (16% vs 27%, p < 0.02). Leukaemia-free survival was still the same (49% vs 50%). When we analysed relapse and leukaemia-free survival separately according to the disease and status at the time of transplant, there were no significant differences but this is probably because the numbers of patients in each category are too small.

**Rate of engraftment**

Despite the problem of graft rejection in a minority of patients, prompt neutrophil engraftment is the norm following T cell depletion of the donor bone marrow. We analysed the effect of T cell depletion in vitro and in vivo on engraftment rate in this group of patients and compared them with patients who received similar protocols of antibody treatment for transplants from unrelated or mismatched donors (Table VI).

Using the original protocol (01) the median time to reach neutrophils 500 × 10⁹/l (for those patients who did engraft) was 19–20 days. Treatment with CsA or TLI made no difference. Likewise, using Campath-1G in vitro (Protocol 03), rapid engraftment was seen (median 16–17 days). When T cells were added back, using either protocol, engraftment was still rapid (17–18 days) although in many cases the T cells were not given until after engraftment was documented. However, in every protocol where Campath-1G was given in vivo, there was a significant delay in neutrophil engraftment ranging from 23 to 27 days. The overall median for all evaluable patients who received antibody in vivo was 24 days whereas the median for patients who only received antibody in vitro was 19 days (p < 0.001).

It is apparent that the same delay in engraftment is not seen in all of the corresponding groups of unrelated/mismatched transplants. This is particularly so for Protocol 02 where the mismatched/unrelated transplants engraft as promptly as the original T-depleted group (note that patients who failed to engraft were not included).

The timing of the in vivo antibody seems to be important and the more that was given close to the transplant, the greater is the delay in engraftment. The original intention in Protocol 02 had been to give the Campath-1G well before the transplant and this was
always done with the unrelated/mismatched transplants. However, it happened that one centre often gave the 5-day course of Campath-1G much closer to the transplant for matched siblings, the final day usually being day -1. Forty-one evaluable transplants performed at this one centre showed an extra delay in engraftment (median day 28) compared with the 87 transplants performed at all other centres (median day

The results are pooled from all patients receiving in vitro depletion alone (Protocols 01 and 03) or in vivo depletion (Protocols 02, 04, 06, 07). Patients who failed to engraft or who received T cell addback are excluded.

24. \( p < 0.001 \). Nevertheless, the 87 transplants were still delayed compared with the original protocol \( (p < 0.005) \).

Immune reconstitution and infections post-transplant

We did not centrally collect data on the recovery of lymphocyte subsets or the incidence of non-fatal infections because of the huge amount of complex reporting and analysis this would have entailed. We can say that lymphoproliferative disease was rare. Only five cases were reported which is equivalent to an actuarial risk of approximately 1% at 5 years. The number of fatal infections late after transplant certainly did not seem to be significantly more than that seen with conventional GVHD prophylaxis, because transplant-related mortality did not increase much after the first 9 months (Figure 3). However, individual centres have observed relatively slow lymphocyte regeneration following T cell depletion with Campath-IM²¹,²² and some have found a high incidence of CMV viremia (A. Bacigalupo (Genoa) & D. Bunjes (ULm), unpublished data).

Comparison of transplant outcome with published results using MTX/CsA

The generally accepted 'standard' prophylaxis for GVHD is currently the combination of a short course of MTX with CsA.³³,³⁴ Results for 580 patients with early disease have been published by the International Bone Marrow Transplant Registry (IBMTR).³⁵ We compared the pooled results for 466 patients with early disease who received T cell depletion (by any protocol) and no T cell addback (Table VII). As expected, the incidence of both acute and chronic GVHD was

Results for all patients with early disease were pooled, irrespective of antibody protocol. Patients who received T cell ablation were excluded. They are compared with published data for a similar cohort of patients who received conventional GVHD prophylaxis. In this table (and in Table VIII), unlike the others, the results are presented ± 95% confidence interval, which for the Campath group was taken to be approx × the SE (which is quoted elsewhere).

substantially lower with T cell depletion. The transplant-related mortality was not improved, presumably because of the complications associated with graft failure. An increase in the risk of relapse with T cell depletion is striking in the case of CML and modest in the case of AML. For ALL, there does not seem to be a significant increase in relapse risk. Overall the leukaemia-free survival is lower for the T cell-depleted patients, most notably those with CML.

It is very difficult to measure the effect of chronic GVHD on the quality of life of the long-term survivors who received conventional GVHD prophylaxis, although it is accepted that this is still a significant problem for many patients. We made an approximate calculation of ‘disease-free’ survival (meaning free from leukaemia or GVHD) by multiplying the leukaemia-free survival by the fraction of patients who were free from chronic GVHD. This is not strictly correct because some of the patients with severe chronic GVHD will have died as a result and those with milder forms are likely to be at lesser risk of relapse and so more likely to survive. However, the two errors are opposite and will tend to cancel out. By this criterion, the patients who received T cell-depleted transplants tend to do slightly better.

The results are also aligned with an IBMTR report for patients who received T cell-depleted BM in order to compare the risks of relapse (Table VIII). The IBMTR data were calculated at 3 years and patients who failed to engraft were excluded, so we did the same. In practice it made very little difference to the result. The IBMTR data will include many different methods of T cell depletion and there is likely to be some overlap of patients with our database. The results show a smaller risk of relapse in each category for patients in the Campath-1 users database but the differences are unlikely to be statistically significant.

Discussion

We have described here one of the largest collections of data about T cell depletion in allogeneic BMT and from it we can draw some important conclusions.

Both Campath-1G and Campath-1M are equally effective in vitro for prevention of both acute and chronic GVHD. Technically, they are simple to use and have been employed with equal success by large and small transplant centres. Previous studies with other opsonizing antibodies were quite unsuccessful, which emphasizes the point that the antibody isotype and/or target antigen are critically important for cell depletion.

We have also shown that administration of Campath-1G in vivo is an alternative way of preventing acute GVHD, although the incidence of chronic GVHD is then greater, presumably because the effective antibody dose contacting the donor T cells is very much smaller, pabody < 5% of the concentration achieved in vitro. The original IgM antibody relied on complement for T cell depletion. We cannot assess the extent to which complement-dependent lysis or ADCC is important for the action of Campath-1G; however, our previous studies using a non-Fc binding lgG in vivo led us to believe that cell-mediated killing is important for its action. If so, the present results imply that the requisite effectors are still sufficiently active after intensive chemoradiotherapy.

The use of Campath-1G in vivo before conditioning with CY/TBI (Protocol 02) allowed us to extend the observations on the extent of lymphopenia and the side-effects it causes. These studies (D. Bunjes, G. Prentice & D. Spence, unpublished data) confirm the original findings already reported for Campath-1G and Campath-1H in BMTs, kidney transplants and rheumatoid arthritis. In brief, the first dose of antibody causes a substantial lymphopenia which is accompanied by the cytokine release effect typical of many lymphocyte-directed antibodies. Subsequent doses have lesser side-effects but tend to increase the degree of lymphopenia.

Our principal objective in using Campath-1G was to reduce the risk of transplant rejection by eliminating the residual host T cells. Sensitive limiting dilution assays showed that the extent of in vivo depletion by Campath-1G is comparable or greater than that achieved with busulphan/CY or TBI. Some centres also studied the use of conventional immunosuppressive agents, CsA or TLI, to achieve the same end. The
results suggest that CsA or TLI reduce the risk of graft failure by about one-third (from 23% to about 15%) whereas Campath-1G in vivo reduces it slightly more (to 9%) (Tables III and IV). The lowest rate of combined complications (graft failure and/or GVHD) was obtained with the combination of Campath-1G plus Campath-1M (Table IV). Only small numbers of patients have been given combined treatment (e.g. TLI plus CsA (Table III) or Campath-1G plus CsA, data not shown) but on the whole they have done very well. However, it is extremely difficult to assess the activity of each agent in a study where they were combined, even if ultimately this might be the best treatment. This is exemplified in Protocol 03 where patients were given TLI with Campath-1G in vitro. The incidence of graft failure (and GVHD) was very low but we cannot tell whether this is mainly due to the effect of the TLI or whether the excess Campath-1G infused with the BM also helped to deplete host T cells.

Particular teams have used moAb to prevent graft rejection, particularly the collaborative European Immunodeficiency Group who have used a combination of non-depleting CD2 and CD11a (LFA-1) antibodies, which can block the activity of T cells and are tolerogenic in some animal models. It is difficult to compare our results because the circumstances are very different. On the basis of animal experiments, we expect that a combination of cell-depleting and function-blocking antibodies would be likely to create the best situation for donor-specific tolerance but it is clear that the individual roles of the components of such a mixture needs to be clinically evaluated first.

One of the unexpected effects of in vivo therapy with Campath-1G was a significant delay of about a week in neutrophil engraftment. This was not seen in protocols which involved only in vitro treatment with Campath-1M or Campath-1G. We therefore think that it is very unlikely that the antibody is exerting an effect directly on the BM progenitors, e.g. direct toxicity or inhibition of homing or proliferation, as the patients who received marrow treated in vitro would presumably suffer the worst. Furthermore, recent experiments with Campath-1H show no evidence for Campath-1 expression on long-term colony-forming cells. It is conceivable that Campath-1G has a damaging effect on the stem cell supporting microenvironment, i.e. the stromal cells, but if that were the case we would expect an effect of at least equal magnitude in the patients who received mismatched or unrelated BM. In fact, paradoxically, they tend to engraft more rapidly (Table VI). A hypothesis which might explain all the observations is that lymphocytes (we cannot say whether T cells or B cells or both) are able to secrete cytokines which directly or indirectly stimulate the growth and differentiation of the progenitors during the critical few weeks after the transplant. We would propose that only very small numbers of lymphocytes are needed. Donor or host cells would suffice. It would be only when both are depleted below a small critical threshold that delayed engraftment would be observed. In transplants from less well matched donors there would be a greater scope for immediate lymphocyte proliferation due to alloreactivity. This in itself might generate the required cytokines, or at least expand the very small pool which remain after T cell depletion of donor and recipient.

It is well documented that T cell depletion results in a significant increase in the risk of relapse following BMT from HLA-matched siblings for CML. The effect is much greater than would be expected merely from the abrogation of GVHD and this is taken as evidence that the GVL and GVH effects of donor T cells are not identical. Surprisingly, there seems to be much less relapse in patients receiving T cell-depleted transplants from unrelated donors. We still wonder whether the absence of T cells allows a preferential expansion of the malignant clone during the early post-transplant recovery, although early evidence that relapse was associated with delayed engraftment has not been substantiated in the present analysis. In due course this hypothesis might be tested by analysis of the T cell addback data according to the time of re-infusion: currently the follow-up on those patients is too short.

In the case of acute leukaemia, it is less clear whether T cell depletion has a detrimental effect on relapse. The few prospective randomised trials carried out so far were too small to detect an effect. Analysis of pooled data by the IBMTR suggests that the effect is significant in AML but only marginal in ALL. Here we have a rather larger group of patients (probably including some overlap with the IBMTR) and obtain very similar results although the risk of relapse is slightly lower in each category (Table VIII). Comparison with the registry results for transplants using MTX/CsA shows a very similar risk of relapse in ALL-CRI, slightly higher in AML-CRI and substantially higher in CML-CP1 (Table VII). In this comparison, T cell depletion is unfavourable unless the morbidity associated with chronic GVHD is taken into account. However, the T cell depletion results were pooled from all the protocols described here, including those which had relatively poor transplant-related mortality due to graft failure (Protocols 01 and 07) or GVHD (Protocols 04 and 06). Currently the transplant-related mortality in Protocols 02 and 03 is lower than reported for MTX/CsA; we do not yet have sufficient numbers or follow-up to comment on relapse, but leukaemia-free survival so far is satisfactory (Table IV, Figure 3).

There have been several attempts to separate the beneficial and harmful effects of donor T cells. Based on data which suggest that GVL and GVH effects may be distinct. In some cases depletion of just one T cell subset has been tried. However, the results have not been better than with complete T cell depletion. Another approach, which has been tried here, was to deplete the marrow as effectively as possible then add back a small defined number of donor T cells. The problem is that it is impossible to define in advance the ideal number which will not cause GVHD as this will be a threshold phenomenon where the level depends on the particular genetic make up of donor and recipient, among other factors. One way to

Results are calculated as in Table VI and compared with published data for T-depleted transplants. In both cases, patients with graft failure were excluded (most of them would have died before being at risk of relapse but a few who received autologous BM may have relapsed). Inclusion of these patients in the Campath group made essentially no difference to the results.

minimise this problem is to give the T cells in graded doses over several weeks, stopping if GVHD occurs. However, it is still hard to control the extent of GVHD and the overall incidence is similar to that seen without T cell depletion. We have been able to show that addback of donor T cells results in a decrease in the risk of relapse, although the numbers treated so far are relatively small, so the effect was only significant when results from patients with different diseases are pooled. Nevertheless, separation of GVH from GVL is not yet demonstrable.

At present the tetrad of immunological problems associated with BMT – GVHD, rejection, relapse, infection – still remain interconnected. Measures which decrease one are likely to increase the others. We believe the long-term aim should be to isolate these problems and deal with them individually. A possible way forward is suggested by the recent advances in semi-quantitative analysis of minimal residual disease and the demonstrations that donor T cell infusions can be used to effectively treat outright relapse in some cases. We wonder whether T cell depletion of donor and recipient might be used to ensure a good recovery from the transplant procedure without GVHD or rejection and then donor T cells only be added later if there is evidence that a definite tumour burden still remains. Advances in the understanding of cytokines and their clinical application might lead to further improvements in the management of the post-transplant haemopoietic and immune reconstitution.

Of course, the problem of increased relapse is not relevant in transplants for non-malignant conditions such as aplastic anaemia and inherited disorders of the blood system. That would be an ideal situation to use donor and recipient T cell depletion for control of GVHD and rejection. So far relatively few patients have been treated but the results are very encouraging. We also expect that T cell depletion will have an important role in unrelated donor transplants where the immunological complications are relatively more severe.

Received 29 August 1999; accepted for publication 21 October 1999

Summary. Autologous transplantation has an established role in the treatment of lymphoproliferative disorders, but allogeneic transplantation remains controversial. In an attempt to reduce the high procedure-related mortality reported with allografting in lymphoma, we have used BEAM (BCNU, etoposide, cytarabine and melphalan), a standard conditioning regimen for autologous transplantation. As BEAM may be insufficiently immunosuppressive to permit durable engraftment in the allogeneic setting, patients received additional pretransplant immunosuppression with the anti-CD52 antibody CAMPATH-IG from day -5 to day -1.

Twelve patients (median age 46 years) underwent allogeneic transplantation for lymphoma (n = 11) or chronic lymphocytic leukaemia (n = 1) from HLA-identical (n = 9) or mismatched (n = 3) sibling donors. Cyclosporin A and methotrexate were used as graft-versus-host disease (GVHD) prophylaxis. One patient died of progressive lymphoma at day +12, the remaining 11 patients engrafted rapidly, with eight demonstrating full donor chimerism. One patient had an episode of rejection and received a further stem cell infusion with sustained recovery. Only one patient developed GVHD (grade I). The low incidence of acute GVHD may be in part related to persisting levels of in vivo CAMPATH-IG at the time of transplantation. Of 11 evaluable patients, nine achieved complete remission (CR), and a further patient achieved CR after donor lymphocyte infusion at 5 months.

Our preliminary experience is that this regimen was well tolerated with a low risk of GVHD and appears no more toxic than a BEAM autograft. Further follow-up is required to see whether the low incidence of GVHD impacts upon relapse risk.

Keywords: lymphoma, allogeneic transplantation, BEAM, CAMPATH.

The use of high-dose therapy and autologous haemopoietic stem cell transplantation has a clearly established role in the treatment of Hodgkin's disease and non-Hodgkin's lymphoma (NHL) (Reece et al. 1994; Philip et al. 1995; Freedman et al. 1996). In contrast, the place of allogeneic transplantation in lymphoma is controversial as reported studies both from single centres and from registries have shown a high transplant-related mortality (TRM). Thus, a TRM of 34\% was reported in a series of patients with Hodgkin's disease undergoing allogeneic BMT using conditioning with busulphan/cyclophosphamide or cyclophosphamide/totai body irradiation (TBI) (Jones et al. 1990). In a report from Seattle of 53 patients with Hodgkin's disease undergoing allogeneic BMT, 28 (53\%) suffered non-relapse deaths (Anderson et al. 1993). Reports from the International Bone Marrow Transplantation Registry (IBMTR) and the European Bone Marrow Transplant Group (EBMT) on allogeneic transplantation for Hodgkin's disease have shown a 3-year TRM in excess of 60\%, leading to the conclusion that in most circumstances this procedure could not be recommended (Gajewski et al. 1996; Milpied et al. 1996). A high TRM has also been reported in NHL. In an EBMT series in which the majority of patients received TBI-based conditioning regimes, the TRM for the allograft group was...
25% compared with 11% for the autologous group (Chopra et al., 1992). Recently, a multicentre study of allogeneic BMT in 111 patients with advanced low-grade lymphoma reported a TRM of 40% (Van Besien et al., 1998). A similar high TRM has been seen using the non-TBI-based conditioning (Demirer et al., 1995) CBV regimen (cyclophosphamide, carbamustine and etoposide).

Some studies have suggested that the risk of relapse may be reduced compared with patients undergoing autologous transplantation, possibly as a result of a graft-versus-lymphoma effect (Jones et al., 1990). In NHL, a prospective study of allogeneic compared with autologous transplantation reported a relapse rate of 13% in the autologous arm compared with 51% in the autologous arm (Rakanatharathorn et al., 1994). In low-grade lymphoma, a low rate of recurrence (16%) was reported by Van Besien et al. (1998), although the overall survival was only 49% for a high TRM. A similar low probability of relapse compared with autologous transplantation was reported by Verdonck et al. (1997) in low-grade lymphoma.

The use of potentially less toxic conditioning regimes has been explored by several groups, although the number of reports in the literature remains relatively small. Single agent, melphalan (200 mg/m²) has been shown to permit engraftment in patients with leukemia undergoing allogeneic transplantation from HLA-identical siblings (Singhal et al., 1996). Although the BEAM regimen (BuCVe, etoposide, cytarabine and melphalan) has been widely used as a conditioning protocol for autologous transplantation for lymphoma, there is little experience in its use for allogeneic transplantation. Van Besien et al. (1995) reported on a series of three patients who received BEAM before allogeneic transplantation and demonstrated engraftment in all cases. More recently, a report of a phase II study of BEAM conditioning before autologous transplantation in 30 patients with lymphoid malignancies revealed it was well tolerated, although the incidence of grade II–IV acute graft-versus-host disease (GVHD) was 31% (Frezia et al., 1998). Here, we report our experience of allogeneic transplantation using BEAM conditioning combined with pretransplant CAMPATH-Ig, which was used as additional immunosuppression to facilitate engraftment in recipients of both HLA-matched or one antigen disparate sibling transplants and to provide additional anti-lymphoma activity.

**Patients and Methods**

**Patients.** Between January 1997 and April 1999, 12 patients with NHL (n = 9), Hodgkin’s disease (n = 2) or chronic lymphocytic leukemia (CLL; n = 1) underwent allogeneic transplantation using peripheral blood stem cells (PBSCs: n = 10) or bone marrow (n = 2) from HLA-identical (n = 9) or one antigen mismatched (n = 3) sibling donors. Patients (see Table I) were selected to undergo allogeneic transplantation because of extensive bone marrow involvement (n = 10), peripheral blood pancytopenia (n = 1) or poor prognostic features (n = 1).

**Transplant regimen.** The BEAM treatment was as follows: BCNU (300 mg/m²) on day −6; cytosine arabinoside (200 mg/m²) on days −5 to −2 inclusive; etoposide (200 mg/m²) on days −5 to −2 inclusive; melphalan (140 mg/m²) on day −1. CAMPATH-1G (10 mg) was given intravenously on 5 consecutive days before transplant (days −5 to −1 inclusive). PBSCs mobilised with granulocyte colony-stimulating factor (G-CSF) (filgrastim; 10 µg/kg/d) were used in 10 cases and bone marrow (BM) in two patients, one of whom was one of the recipients of a mismatched graft. GVHD prophylaxis was with cyclosporine (CSA) and methotrexate (MTX) (Byrne et al., 1998) with the exception that methotrexate (10 mg/m²) was given only on days +1, +3 and +6. Donor lymphocyte infusions (DLIs). Donor leukocytes were harvested by leukapheresis on a Fenwal CS3000 cell separator and the CD3+ count was assessed by flow cytometry using a FACScan/Libur (Becton Dickinson) and the CellQuest software. The cells were reinfused fresh or cryopreserved at −80°C in 10% DMSO for subsequent reinfusion.

**Chimerism studies.** Chimerism was studied using four VNTR regions (TNFα, p53[CA], D6S264 and Rb1). Donor/recipient pairs were screened using each microsatellite locus to find at least one informative primer set which was then used to determine the degree of chimerism after transplantation. After amplification, the PCR products were separated on an acrylamide gel using the ABI Prism 377 Automated DNA Sequencer. Gene-Scan Analysis software was used to calculate the peak area of alleles as a quantitative measure of chimerism. The sensitivity of detection using this method is 0.1% (Milin et al., 1999).

PCR was undertaken on those patients in whom a molecular marker of disease (either clonal IgH gene rearrangement or presence of the t(14:18) translocation) had been assigned at presentation. PCR for the IgH framework III or t(14:18) major breakpoint region translocation was performed after transplantation and was defined as residual disease by the presence of the same sized products as the diagnostic specimens.

Serum levels of CAMPATH-1G. Serum levels of CAMPATH-1G were measured in 12 patients; in all cases antibody was given from day -5 to day -1. Serum levels were collected before antibody treatment, 1 h after the final dose (peak level), immediately before transplant and 1 h after transplant. The samples were stored frozen at -25°C and heat inactivated at 56°C for 30 min before analysis to destroy any complement activity (tests have shown that this treatment does not damage the antibody). Antibody concentrations were measured by indirect immunofluorescence with a CD52+ T-cell line (HUT-78). The cells were incubated at 4°C for 30 min with test samples or standards serially diluted in PBS containing 0.1% bovine serum albumin (BSA). The cells were washed five times with PBS and then incubated with the detection reagent FITC-labelled anti-mat IgG (Sigma; F-6258). They were washed again and were fixed with 1% formaldehyde before analysis by flow cytometry. The mean fluorescence was measured and antibody concentrations were calculated by interpolation from a standard curve constructed using a reference batch of the therapeutic antibody. The whole experiment was carried out in duplicate and the mean results were used. The overall coefficient of variation was 17%. CAMPATH-1G is a rather low-affinity antibody and the limit of quantification (defined as the concentration that gave fluorescence 50% above background) was 0.13 μg/ml.

RESULTS

Engraftment, GVHD and toxicity

One patient with primary refractory Hodgkin's disease died of disease progression at day +12. The remaining 11 patients who engrafted achieved neutrophils of >0.5 x 10⁹/l at a median of 16 d (range 12-29) and platelets of >20 x 10⁹/l at a median of 21 d (range 14-35). One patient had graft failure at day +28 and required a further PBS infusion from the same donor which resulted in sustained engraftment. The conditioning therapy was well tolerated with minimal mucositis and no significant renal, pulmonary or hepatic toxicity. The median post-transplant in-patient stay was 16 d (range 14-25 d). Only one patient, who was the recipient of a one-antigen mismatched transplant, developed GVHD (grade I). With a median follow-up of 12 months (range 6-32), no patient has developed chronic GVHD. Cytomegalovirus (CMV) reactivation by PCR was seen in two patients, both of whom had mismatched

transplants but neither developed CMV disease. One recipient of a mismatched transplant died from para-influenza pneumonia at 6 months after the transplant while in remission.

**Disease response**

At the time of transplant, eight patients were in partial remission and four had resistant or progressive disease (Table II). At 3 months after transplantation, all patients were assessed by computerized tomography (CT) scan and bone marrow analysis. Of 11 evaluable patients, nine had achieved a complete remission at this stage. Two patients with follicular lymphoma achieved a partial remission (PR) at 3 months, with evidence of persisting bone marrow infiltration on trephine biopsy. Of these, one had an overt relapse at 6 months with rapid progression and death despite intervention with DLIs. The other patient received DLI (5 × 10⁷ CD3+ cells/kg) at 5 months, and when assessed at 6 months by CT and bone marrow was in clinical and molecular remission according to PCR for t(14;18). One patient with follicular lymphoma developed a localized nodal relapse that was treated with radiotherapy and DLI (2 × 10⁷ CD3+ cells/kg) and remains in remission with a short follow-up. Another patient with follicular lymphoma who was in clinical remission but persistently positive by PCR for t(14;18) in bone marrow aspirates received DLI (5 × 10⁶ CD3+ cells/kg) at 15 months and remains PCR positive 4 months later. Currently, 9 out of 12 patients are alive, of whom eight remain event free with a median follow-up of 12 months. The overall survival and disease-free survival of the patients is shown in Figs 1 and 2.

**Chimerism**

Of 11 evaluable patients, eight had full donor chimerism when assessed at 3 months after transplantation and two patients had evidence of mixed chimerism (see Table II). The remaining one patient, who received BM rather than PBSCs, has 100% recipient DNA at 6 months but remains in complete remission at 18 months after the transplant.

![Cumulative Survival](image)

**Fig 1.** Event-free survival.

![Overall Survival](image)

**Fig 2.** Overall survival.

**Minimal residual disease**

Of eight patients with evidence of a clonal population of B cells in the marrow immediately before transplant, the result of either an IgH or a bcl-2 rearrangement, five achieved a molecular remission (Table II). One patient with follicular lymphoma who achieved a PR with a persistent bcl-2 rearrangement entered clinical and molecular remission after receiving DLI therapy, whereas another patient who achieved CR remains PCR positive at 19 months despite DLI therapy at 15 months.

**Serum levels of CAMPATH-1G antibody**

Antibody levels were measured to establish whether there was residual CAMPATH-1G at the time of transplant that might contribute to depletion of donor T cells. The peak concentration on day −1, 1 h after the last infusion of antibody, was 1.8 ± 1.1 μg/ml (mean ± SD). The stem cell infusion started 17 ± 3 h later and, at that point, the serum antibody concentration was 0.9 ± 0.6 μg/ml in 10/12 patients but <0.13 μg/ml in two patients. At 1 h after the stem cell infusion (24 ± 4 h after the peak antibody level), the serum antibody concentration was 0.7 ± 0.6 μg/ml in 6/11 patients and <0.13 μg/ml in 5/11 patients (one sample was not collected). The antibody half-life under these conditions was ∼13 h. All antibody levels were well below the concentration required for saturation binding to cells *in vitro* (∼25 μg/ml), but the mean level observed at the time of bone marrow infusion would still be sufficient to mediate a substantial degree of cell killing by antibody-dependent cell-mediated cytotoxicity (ADCC) (Hale et al., 1987).

**DISCUSSION**

This paper describes our preliminary experience of the BEAM regimen for allogeneic transplantation in lymphoproliferative disorders. The BEAM regimen has been extensively used before autologous transplantation and it is well tolerated with low incidence of side-effects and a TRM of <10%
(Chopra et al., 1993). We reasoned that BEAM would be a suitable conditioning regimen for allogeneic transplantation. However, because of concerns that BEAM might not be sufficiently immunosuppressive to permit engraftment in the allogeneic setting, particularly when using mismatched family members, we added pretransplant CAMPATH-1G. There are other theoretical advantages relating to the use of CAMPATH before transplant in the lymphoproliferative disorders as the CD52 antigen recognized by the CAMPATH antibodies is heavily expressed on lymphoid neoplasms. Thus, CD52 is expressed on 100% of low-grade B-cell NHL, the majority of high-grade B-cell NHL and a significant proportion of T-cell lymphomas (Salsbury et al., 1994). Indeed, CAMPATH-1H, the humanized version of CAMPATH-1G, is currently being evaluated as therapy in CLL (Osterborg et al., 1997). B-prolymphocytic leukemia (Bowen et al., 1997) and low-grade NHL (Landin et al., 1998).

This protocol aimed to use PBSC where possible to obtain a high stem cell dose to facilitate engraftment when using a regimen that might not be as immunosuppressive as TBI-based conditioning regimens and that is not truly myeloablative, as exemplified by reports of haemopoietic recovery after BEAM without stem cell support (LaPorte et al., 1991). In this study, we used PBSC in 10 patients, two donors preferring to give bone marrow. All evaluable patients achieved sustained haemopoietic engraftment, although one patient required a second infusion of PBSCs at day +28. Also, one recipient of a mismatched transplant had autologous reconstitution, and it may be relevant that this patient received BM rather than PBSC. The BEAM–CAMPATH regimen was well tolerated with minimal non-haemopoietic toxicity. This low toxicity contrasts with the results obtained using CBV as conditioning for allogeneic BMT in lymphoma (Demirer et al., 1995) in which there was a high TRM due primarily to pulmonary toxicity, which was seen particularly in those patients who received doses of BCNU of 600 mg/m². The dose of BCNU conventionally used in BEAM is only 300 mg/m², and a low incidence of pulmonary toxicity has been seen after autologous transplantation using this dosage (Chopra et al., 1993).

No cases of acute GVHD higher than grade 1 were seen. A low incidence of GVHD using CAMPATH-1G as part of the conditioning protocol was reported, particularly if the antibody was continued after transplantation (Hamblin et al., 1996). In our study, CAMPATH-1G was given up to day 1 before transplant (i.e. day –11) and, to assess the presence of residual antibody at the time of transplant, serum levels were analysed 1 h after the final dose (peak), immediately before transplant and 1 h after transplant. The levels of antibody measured immediately before transplant were found to be sufficient to mediate a substantial degree of ADCC and, therefore, killing of infused T cells in the majority of patients (Hale et al., 1987). Furthermore, the serum levels observed after transplant were still sufficient to mediate ADCC in approximately half of the patients. However, the levels were less than half of those seen directly after antibody infusion, and the T cell depletion would likely be less effective than if the CAMPATH-1G was continued after the transplant. Nonetheless, it is probable that there was purging of donor T cells by residual CAMPATH-1G using this protocol, and this may have been sufficient to abrogate the development of significant GVHD. It is also possible that the use of BEAM may be associated with a lower GVHD risk because of reduced tissue damage and hence of cytokine release compared with TBI-based regimens. We used GVHD prophylaxis with CSA and MTX, although it has been our policy to discontinue CSA at 3–4 months and it is possible that further reductions in immunosuppression can be made in order to maximize any graft-versus-lymphoma effect.

Eight of the 12 patients transplanted in our study had low-grade lymphoma, and in a recent analysis of 64 patients undergoing allogeneic transplantation for lymphoma this subgroup was found to have the most favourable outcome with the lowest rate of disease recurrence (Van Besien et al., 1996). That these results could be improved by a reduction in TRM has led to the development of minitransplant regimens that have been predominantly fludarabine based (Khouri et al., 1998). Although perhaps not a true minitransplant regimen, BEAM–CAMPATH has a significantly lower toxicity profile than that seen with TBI-based regimens.

DLIs were administered to four patients, all of whom had follicular lymphoma. One patient received a DLI for residual disease after transplant and entered clinical and molecular remission. A second patient who achieved CR but remained persistently PCR positive for (14;18) for more than a year has not entered a molecular remission 6 months after DLI therapy. One patient who relapsed at 6 months progressed rapidly and died despite DLI therapy. A fourth patient who had a localized relapse at 10 months was treated with radiotherapy and DLIs and remains in remission, although the follow-up is short. Thus, DLIs have proven effective in at least one patient and our current approach is to consider DLIs for patients not in CR at 3 months or who are in clinical CR but remain PCR positive at 12 months.

In conclusion, our preliminary experience suggests that the toxicity of BEAM–CAMPATH is similar to that seen after autologous transplantation. An additional advantage of this regimen is the fact that fertility, at least in some women, is maintained (Chopra et al., 1993). There has been a striking low incidence of acute and chronic GVHD and longer follow-up will be required to determine whether this is maintained and whether this has an impact upon relapse risk. Because of the low toxicity that we have observed, we are proposing to extend its use in patients aged up to 65 years.

T cell depletion by exposure to Campath-1G in vitro prevents graft-versus-host disease

Summary:

Campath-1G is an immunosuppressive monoclonal antibody directed against human lymphocytes. Its effectiveness in preventing graft-versus-host disease (GVHD) by simple opsonisation of bone marrow T-cells has been studied in 36 consecutive allografts: in 17 for leukaemia, one for essential thrombocytosis and four for myeloma, this was the sole means of GVHD prophylaxis. A further eight patients with aplastic anaemia received 3 months post-transplantation cyclosporin A (CsA) for this purpose whereas in the ninth and tenth the preparative regimen has been modified with this immunosuppressive agent now discontinued. Nucleated cells were harvested and after quantitative recovery of the mononuclear population on the Cobe 2997 separator they were exposed to 20 mg Campath-1G for 30 min at room temperature and then infused. Following standard conditioning, which included total lymphoid irradiation, the median days to reach 0.5 and 1.0 x 10⁹/l neutrophils were respectively 18 (range 9–34) and 28 (range 10–59); to 25 and 100 x 10⁹/l platelets the corresponding times were 17 days (range 5–32 days) and 27 days (range 13–127 days). In all, the day 14 trephine biopsy showed engraftment. At median follow-up of 20 months (range 5–44 months) only one patient has developed possible grade I cutaneous GVHD that responded promptly to corticosteroids: no chronic GVHD or CMV pneumonitis has been encountered. Of those with haematological malignancy transplanted in remission only two with acute leukaemia have relapsed. In aplastic anaemia graft loss initially occurred but this has been overcome by adding Campath-1G in vivo and omitting CsA. These results, although preliminary, show that in vitro opsonisation by an antibody can virtually abolish GVHD.

Allogeneic BMT is potentially curative for patients with aplastic anaemia,1 immunodeficiency diseases2 and certain congenital enzymphathies.3 It has also been employed as a means of intensification therapy for a variety of malignant tumours arising from the haematopoetic system.4–9 The majority of these procedures are complicated by acute or chronic GVHD which have a high morbidity and substantial mortality.10,11 Attempts to reduce both its incidence and severity have included post-transplant immunosuppression with MTX, cyclosporin A (CsA), combinations of the two or even more complex regimens.12,13 None of these approaches has been uniformly successful. Furthermore, it has been suggested that the occurrence of GVHD can be justified on the basis that there is an associated reduction in leukaemic relapse.14 However, the devastation wrought by the more advanced grades of GVHD appears to offset these benefits so that survival rates are not significantly different.15 Unfortunately in such analyses inappropriately little weight is given to the discomfort inflicted on the recipients.16

In contrast to the more conventional immunosuppressive regimens came a different approach based on experimental work in a variety of animal models where it was shown that removal of mature T lymphocytes from the graft could reduce GVHD. Clinical studies, using a variety of mechanical methods or mAbs, met with variable success.16 Historically the use of an opsonising antibody with the intent that the coated cells be removed in the host was mooted more than a decade ago although this manoeuvre was of limited benefit with the antibody used.17 The development of a rat monoclonal immunoglobulin that fixes human, as opposed to rabbit, complement and could react with all lymphocytes, while sparing colony-forming cells, suggested that it would be a useful reagent in BMT.18 Experience has confirmed a significant reduction in acute and chronic GVHD.19 However, an associated problem was the increased incidence of graft failure resulting in a number of deaths. Such rejection was encountered more frequently with mismatched donors but rarely in autologous transplants employing the same purging technique20 with the conclusion that alloreactive recipient T lymphocytes can be implicated in its pathogenesis and so raising the question whether extra immunosuppression might not override this complication.21

More recently, the rat IgG2b mAb Campath-1G became available and this has the important characteristic of fixing human complement as well as binding to Fc receptors, thereby providing the capacity to clear
coated lymphocytes in vivo. This feature is potentially attractive in that it leads to depletion of those residual helper or CD4 lymphocytes which are refractory to conditioning by total body irradiation (TBI) and combination chemotherapy. In some studies Campath-1G has been given to the recipient but, alternatively, marrow cells can be exposed to its action in vitro. We have now established that this treatment can lead to the virtual prevention of acute and chronic GVHD in patients having haematological malignancy or aplastic anaemia with the additional important modification that no post-transplant immunosuppression was given in the former group, initially only 3 months therapy with CsA in the latter and this practice has now also been discontinued.

Patients and methods

Patients

Thirty-two individuals received 36 allogeneic transplants from HLA-identical and MLR non-reactive siblings in a programme approved by the Ethics and Research Committee of the University of Cape Town Groote Schuur Hospital (Table I).

a. = second transplant; AIDS = acquired immunodeficiency syndrome; APL = acute progranulocytic leukaemia; b. = third transplant; CCR = continuous complete remission; CNS = central nervous system; DC = disease controlled; FSP = first stable phase; NPTI = no post-transplant immunosuppression; PCP = Pneumocystis carinii pneumonia; PP = plateau phase; PTI = post-transplant immunosuppression with CsA; S = heavily sensitised; VOD = veno-occlusive disease
Prevention of GVHD with Campath-1G

Acute leukaemias
Patients with AML underwent one induction and two consolidation courses with a combination of Ara C, daunorubicin and etoposide. In ALL, the regimen comprised Ara C, etoposide and MTX with follicic acid rescue. Once in CR they received total body irradiation (TBI) in fractions of 2 Gy twice a day on days -10 to -8, CY (60 mg/kg with uromexan (mesna) cover on days -6 and -5 and 1.5 Gy total lymphoid irradiation (TLI) twice a day on days -3 and -2.

Chronic granulocytic leukaemia and essential thrombocythaemia
Disease control was rapidly achieved with hydroxyurea after which the same conditioning regimen was employed.

Myeloma
Plateau phase of the disease was induced with pulses of CY, vincristine, adriamycin (doxorubicin hydrochloride) and steroid after which a priming dose of 400 mg/m² of CY was given on day -12. 2 Gy of TBI twice a day on days -10 to -8 followed by 140 mg/m² of melphalan on day -6 and then 1.5 Gy of TLI twice a day on days -3 and -2.

Post-transplant immunosuppression was not employed in these three groups with haematological malignancy.

Aplastic anaemia
On admission, CY 50 mg/kg was given, under uromexan (mesna) cover, on days -12 to -9 followed by 1.5 Gy of TLI twice a day on days -7 to -2.

Three patients lost their established grafts and were reconditioned with the same CY regimen but TLI was replaced with an iv regimen comprising 30 mg/kg of antilymphocyte globulin (Swiss Serum Institute, Bern, Switzerland) on days -4 to -2 combined with 10 mg of Campath-1G on days -5 to +4 in two patients, and inadvertently omitted in the third. This individual again rejected and was successfully re-transplanted after preparation with TBI.

CSA, as a single agent titrated to a whole blood assay level of 200 ± 50 ng/ml, was used for 3 months in the first eight patients but, based on the stable haematopoiesis achieved in the regrafts with additional in vivo moAb, it has been discontinued.

Supportive management
All individuals were in laminar downflow units and prior to conditioning commenced on selective decontamination of the gastrointestinal tract with 200 mg twice daily of oral ofloxacin. They also received 200 mg of oral acyclovir for five times in 24 h and cotrimoxazole two tablets twice a day on Mondays and Thursdays. Antibiotics were given only for confirmed fever: where this was of undetermined origin ceftazidime 1 g every 6 h was combined with gentamicin 3 mg/kg with therapeutic peak and trough levels maintained using antibiotic assays.

Bone marrow collection technique
For every kilogram of recipient lean body mass, 15 ml of BM was aspirated from the sternum and iliac crests into 1 ml of Iscove's modified Dulbecco tissue culture medium containing 10 units of preservative-free heparin for each millilitre of graft collected. A mononuclear suspension was achieved by gently passing this material through a series of stainless steel screens; cell loss was <1% and retention of viability 100%, as defined by Trypan blue exclusion.

Technical details of graft manipulation
Recovery and concentration of stem cells
The marrow-rich blood and the tissue culture medium was circulated through a Cobe 2997 blood cell separator as previously described with recovery of 100 ± 10% of haematopoietic progenitors using the CFU-GM assay.

The absence of mononuclear cells in the discard cells was confirmed and these reinfused into the donor to reconstitute red cell mass. There were no complications and all patients were discharged from hospital within 24 hours of admission.

BM infusion technique
The median total number of nucleated cells harvested was 4.1 × 10⁹/kg (range 2.3–8.0). After separation the middle volume of autologous plasma was 128 ml (range 105–180) which contained a median of 1.3 × 10⁹/kg mononuclear cells (MNC range 0.32–2.8) corresponding to 3.04 × 10⁷ T lymphocytes/kg (range 1.5–5.8); 20 mg of Campath-1G was added to this suspension, giving a ratio of 2.5 µg/10⁶ MNC cells. After gentle agitation at room temperature (± 2°C) for 30 min the entire contents of the bag were given iv to the recipient under cover of premedication with 100 mg of iv hydrocortisone and 25 mg of phenegran. Full non-invasive monitoring was used during this period. Fever was the only symptom occurring with approximately 40% of infusions but no changes in oxygen saturation or cardiovascular status were documented.

Statistics
Kaplan–Meier analysis was used to determine the probability of overall and disease-free survival for the entire group and, separately, for those with haematological malignancy or aplastic anaemia.
Results

Engraftment interval

In all procedures, including the four re-transplants, haematopoiesis was evident on day 14 by trephine biopsy. The median time to 0.5 and 1.0 x 10^9/l granulocytes were, respectively, 18 (range 9-34) and 28 (range 10-59) days and the corresponding intervals to reach 25 and 100 x 10^9/l platelets were 17 (5-32) and 27 (13-127) days.

The numbers are too small for subgroup analysis but between those with malignancy and aplastic anaemia no differences are currently discernible.

GVHD

A single patient with myeloma developed a rash which was consistent with grade I GVHD. It responded promptly to corticosteroids. No chronic GVHD has occurred.

Malignant disease

Eight of the nine patients with AML transplanted in CR remain continuously disease-free: the ninth patient, in second CR with the acute progranulocytic variant, relapsed at 1 year and after re-induction with retinoic acid, is again in CR; the tenth patient, inadvertently grafted before CR was achieved, died. Of the three with high risk lymphoblastic leukaemia, one is in CR and two are dead: one in CR of AIDS and the other, with multiple cytogenetic abnormalities, from recurrence.

All four patients with stable phase CGL and one with essential thrombocythaemia are without haematological or cytogenetic evidence of disease to date. Of the four with myeloma, the one referred to above as having GVHD, with an excellent graft but scaly skin, died from fulminating *Pneumocystis carinii* pneumonia, since he believed that the minimal rash was due to cotrimoxazole which he discontinued: the other three remain in CR.

Severe aplastic anaemia

One of the first eight in this group had been multiply transfused over 6 years prior to referral, remained pancytopenic and died of a stroke. The next seven had established haematopoiesis by day 14 but three suffered graft failure within 3 months and were successfully re-transplanted from the same donor but on a revised regimen that combines Campath-1G ‘in-the-bag’ with additional *in vivo* administration but CsA is no longer used. In these two individuals engraftment has been particularly swift and complete.

Outcome

There was no direct transplant-related mortality or development of CMV pneumonitis. With median follow-up at 20 months (range 5-44 months) the actuarial probability of survival for the entire group is 81% and for the same population, censored for disease-unrelated deaths, reflecting freedom from relapse, is 91%. For those 22 with haematological malignancies the corresponding figures are 81% and 91% and for the ten with aplastic anaemia are 80% and 90% (Figure 1).

Discussion

Even in matched siblings acute and chronic GVHD remain the most significant barrier preventing BMT from realising its full therapeutic potential. Attempts to abrogate morbidity and mortality with a number of post-transplantation immunosuppressive interventions have been only modestly successful. MTX, with or without CsA, is of benefit but does not eliminate GVHD. A wide range of moAb, used either *in vivo* or *in vitro*, has been described but no regimen has gained general acceptance.

It is therefore of interest that our preliminary data with exposure of mononuclear cells to Campath-1G *in vitro* appear to have the unique characteristic of almost completely preventing this complication. A single patient had a mild flaky skin rash whereas none has this far developed any evidence of chronic GVHD. Of note has been the absence of CMV pneumonitis, which may be an additional benefit derived from abrogating GVHD. If these results can be confirmed it would make matched sibling transplants more widely acceptable. Furthermore, it will provide an encouraging base

![Figure 1](image-url)  
**Figure 1** Kaplan-Meier analysis. Probability of survival for all 32 patients (A) and the same data censored for disease-unrelated deaths reflecting freedom from relapse (B). The corresponding curves for the groups with malignancy (n = 22) or aplasia (n = 10) are not shown separately since they are the same and both superimpose on those for the total population (n = 32). Ticks identify individuals at risk.
from which to explore varying degrees of mismatch with the recipient, whether this be from alternative family members or unrelated donor programmes.

With regard to AML in CR a single relapse occurred in one patient with APL; a third remission was readily achieved with vincristine and he is alive and well. In patients with high-risk ALL one with multiple cytogenetic abnormalities developed CNS disease and died. A longer period of observation and larger numbers are essential to define the incidence of disease recurrence but so far the antibody treatment has not had any significant adverse effect. Five patients with chronic myeloproliferative diseases also remain in remission. Here, while the benefits of avoiding GVHD are obvious, no useful statement can be made about the possible future re-emergence of the neoplastic clone. Cytogenetic studies have not, thus far, demonstrated the return of the Philadelphia chromosome in the four patients with CGL. It is possible that the intensified conditioning associated with the use of total nodal irradiation to overcome the increased risk of graft rejection may, concurrently, offset any loss of an anti-leukaemic effect from GVHD and some evidence supports this concept.33

Among the four allografts for myeloma, one patient was thought to have minimal cutaneous acute GVHD. However, it could equally well have been caused by the cotrimoxazole and unfortunately when the patient chose to discontinue this agent he developed Pneumocystis carinii pneumonia resulting in his death. The other three patients have not shown recurrence of their tumour.

The situation with severe aplastic anaemia is encouraging in that no GVHD has been encountered. It is nevertheless disappointing that, despite the initial use of post-transplant immunosuppression with CsA, four biospy-proven grafts were lost, so that repeat procedures were needed. This contrasts with the low rejection rate reported in similar cases, whether T cell depleted or not44 and irrespective of previous transfusions.34,35 The benefit attributed to the use of TLI. The reason for this discrepancy is not clear but it may reflect the small numbers in each of the series.

Additionally, while regrafting was uncomplicated and hospitalisation relatively brief this is a cost-ineffective sequence of events. In contrast, the modification used in the last two patients that combines Campath-1G 'in-the-bag' with its parenteral administration but omitting CsA, resulted in the rapid reconstitution of peripheral values in the most cellular grafts seen on the day 14 biopsies and is therefore our standard approach to allogeneic transplantation in severe aplasia. It is noteworthy that the level of 25 × 10^9/L platelets was reached on day 16 which is even earlier than the enhanced marrow recovery achieved when part of the graft is pre-incubated with IL-3 and GM-CSF.36

One caveat attending the use of irradiation in young individuals is the potential for the subsequent development of malignant disease.37 This issue remains controversial with the advantages of TNI being appreciated both with transplantation35,34,45 and in those who lack a donor.41 at least in one series, no neoplasia has occurred to date.35 Furthermore, there is the observation that aplasia, managed with regimens containing no radiation, is also associated with similar problems of clonal haematopoietic abnormalities including paroxysmal nocturnal haemoglobinuria and leukaemia.37,42

Overall, we believe that these results are most encouraging. If confirmed, they have at least three potentially important implications. Firstly, they offer a significant advantage in that acute and chronic GVHD in sibling grafts can be virtually prevented by exposure to Campath-1G 'in-the-bag'. If this benefit can be transferred to incompatible family members or matched unrelated donors both options might become more widely used and expenditure in operating BM donor registries more realistic. Secondly, in allografting for malignant disease no further intervention is necessary but in aplasia additional in vivo antibody favours rapid stable engraftment. In both of these circumstances short-term morbidity and mortality as well as hospital stay and financial costs, are reduced in parallel with eliminating the inconvenience and dangers of post-transplantation immunosuppression. Thirdly, programmes free of GVHD and graft failure may allow new drug or immunological regimens to be evaluated for anti-leukaemic activity.

It is concluded that the mAb Campath-1G, added to mononuclear cells in vitro and without further CsA or MTX, is a major advance in allogeneic BMT. The rapidity of engraftment, the failure to develop acute or chronic GVHD and the low frequency of leukaemic relapse to date are encouraging: we still need to study larger numbers of patients and to extend the period of follow-up.

Adhesion molecules play an important role in the engagement and mobilization of stem cells during peripheral blood stem cell transplantation (PBSC). Colony stimulating factors are widely used for mobilization of stem cells. During mobilization stem cells may induce some changes in the adhesion molecule expression of the stem cell and stroma which will end in the release of soluble adhesion molecules. To demonstrate this we measured the levels of various adhesion molecules in the sera of healthy donors who were primed with G-CSF (Neupogen, Roche) for allologeneic PBSC transplantation. Fifteen healthy donors (7 male and 8 female) were given 10μg/kg/day s.c. granulocyte colony-stimulating factor for 5 days. Peripheral blood stem cell collection was performed on the fifth day two hours after the last dose of G-CSF. Serum ICAM-1, E-Selectin, L-Selectin and sCD44 levels were detected by using a commercial ELISA Kit (Bender Med, Austria) before, on the third day and 24 hours after the last dose of G-CSF. The results indicate a steady rise in the levels of sCD44, sE-Selectin, sL-Selectin, and sICAM-1 after G-CSF administration, reaching a maximum after the last dose of G-CSF (p<0.05 for all instances). There is no change in the levels of sICAM (p>0.05). Further analysis will be presented to see if there is any correlation with CD44 levels and leukocyte and platelet engraftment times. This results may provide a clue to the role of adhesion molecules in stem cell mobilization but the correlation between the soluble adhesion levels and rising count of neutrophils due to G-CSF administration yet remains to be determined.

A RANDOMIZED DOUBLE BLIND TRIAL OF T-CELL DEPLETION WITH CD8/30 CELLLECTOR IN ADDITION TO CYCLOSPORIN, METHOTREXATE AND STEROIDS FOR ACUTE GRAFT VERUS HOST DISEASE PREVENTION IN HLA MISMATCHED BONE MARROW TRANSPLANTATION. Acute graft versus host disease (GVHD) is a major cause of mortality in mismatched (MM) bone marrow transplantation (BMT). T-cell depletion (TCD) reduces GVHD but increases infection and rejection. 61 patients treated with MM BMT using total body irradiation, cyclophosphamide, thiopeta, antithymocyte globulin with cyclosporin, methotrexate and steroids for AGVHD prophylaxis were randomized for partial TCD. Stratification is reviewed below.

**EX VIVO T-CELL DEPLETION WITH CAMPATH 1G COMPLETELY ABROGATES GRAFT-VERSUS-HOST DISEASE (GVHD) IN PERIPHERAL BLOOD STEM CELL (PBSC) ALLOGRAFTS. J. Jacoby, L. Wood, G. Haig, H. Wiertman. Haematology Department, Wythenshawe Hospital, South Africa; and Sir William Dunn School of Pathology, Oxford, England.

Transplantation of unmanipulated CD34+ bone marrow from HLA identical sibling donors provides rapid and stable hematopoietic recovery, but also does not preclude the use of GvHD prophylaxis. To further reduce incidence of acute GVHD, immunoselected CD34+ blood cell grafts were additionally T-cell depleted with Campath-1H (C-1H) in seven patients (3 CML, 2 AML, 2 NHL, median age 36 years, range 25-47, 3 male, 4 female). The conditioning regimen included TBI (120Gy) and Cy (120mg/kg). C-1H was given i.v. prior to conditioning for prophylaxis of graft rejection (100mg, d-11 to -7). At transplantation the CD34+ cells were thawed and C-1H was added (10μg/100 μl). Median cell numbers were 4.7 x 10^9/μg CD34+ and 6.9 x 10^9/μg CD3+ cells >95% of the T-cells were labelled with C-1H. The patients received G-CSF (5μg/kg, s.c.) post-transplant. No further GvHD prophylaxis was given. Nine patients engrafted. No graft failure or rejection were observed so far (5 follow-up). Median recovery time of neutrophils to reach 500 and 1,000/μl was 13 and 14 days, respectively. Median time to reach 25,000/μl platelets was 16 days (50,000/μl, 24). None of the patients developed GVHD. While neutrophils engrafted more rapidly compared to control patients receiving CD34+ blood cell grafts without additional treatment, no patient receiving and had no GVHD. Forty patients received cryopreserved donor T cells from the CD34 negative fraction on days 0 and 100. 0.1 x 10^9 CD3+ cells/kg, because of a switch to better PRA-screening patients developed a mild GVHD and entered molecular remission. The transplantation of closely T cell allogeneic CD34+ blood cells prevented effectively aGVHD, preserving the rapid hematopoietic reconstitution seen with PBSC grafts. Since no immunosuppressive treatment is used post-transplant, this approach provides appropriate conditions for induction of GVHD with donor lymphocyte transfusions.
In vivo CAMPATH-1H prevents graft-versus-host disease following nonmyeloablative stem cell transplantation

A novel nonmyeloablative conditioning regimen was investigated in 44 patients with hematologic malignancies. The median patient age was 41 years. Many of the patients had high-risk features, including 19 women with previous failed transplant. Recipient conditioning consisted of CAMPATH-1H, 20 mg/day on days −8 to −4; fludarabine, 30 mg/m² on days −7 to −3; and melphalan, 140 mg/m² on day −2. Thirty-six recipients received unmanipulated granulocyte colony-stimulating factor–mobilized peripheral blood stem cells from HLA-identical siblings, and 8 received unmanipulated marrow from matched unrelated donors. GVHD prophylaxis was with cyclosporine A alone for 38 patients and cyclosporine A plus methotrexate for 6 sibling recipients. Forty-two of the 43 evaluable patients had sustained engraftment. Results of chimeraism analysis using microsatellite polymerase chain reaction indicate that 18 of 31 patients studied were full-donor chimeras while the other patients were mixed chimeras in one or more lineages. At a median follow-up of 9 months (range 3 to 29 months), 33 patients remain alive in complete remission or with no evidence of disease progression. Seven patients relapsed or progressed post-transplantation, and 4 of them subsequently died. Four patients died of regimen-related complications.

Introduction

High-dose chemoradiotherapy followed by allogeneic stem cell transplantation (SCT) has been extensively used to treat patients with hematologic malignancies. This procedure is often limited to patients in good medical condition because of the increased risk of regimen-related toxicity and graft-versus-host disease (GVHD) that occurs with increasing age and poor performance status. The curative potential of transplantation is not solely due to the conditioning regimen but also to the well-documented graft-versus-leukemia (GVL) effect. The most convincing evidence for this GVL effect is that donor leukocyte infusions (DLIs) can reinduce remissions in patients who have relapsed following allogeneic SCT. Patients with chronic myeloid leukemia are most likely to respond, but responses have also been documented in patients with acute leukemia. Chronic lymphocytic leukemia, myeloma, and lymphoma. In an effort to reduce the transplant-related mortality (TRM) associated with allogeneic SCT, low-intensity fludarabine-based regimens have been developed. These have been designed to be immunosuppressive rather than myeloablative to facilitate donor engraftment and thereby limit systemic toxicity. There appears to be a spectrum of hematopoietic toxicity associated with these nonmyeloablative regimens—from minimally cytopenic regimens that use low-dose total body irradiation alone to regimens that combine fludarabine with melphalan or busulfan. While these studies have demonstrated impressive allogeneic engraftment with minimal nonhematologic toxicity, there is still a significant morbidity and mortality from acute and chronic GVHD.

We have therefore developed a novel nonmyeloablative regimen for allogeneic SCT. Our regimen was designed to suppress the recipient immune system enough to allow allogeneic engraftment without excessive regimen toxicity or GVHD. The use of fludarabine as an immunosuppressant as part of the conditioning regimen was similar to previously published studies of nonmyeloablative SCT. The combination of fludarabine with 180 mg/m² of melphalan was originally described by the M. D. Anderson group. Our regimen used a different dose of melphalan, 140 mg/m²; however, the addition of an in vivo CAMPATH-1H to the conditioning regimen was new and appears to have been crucial in limiting graft-versus-host reactions.
Patients and methods

Eligibility criteria

Patients with hematologic malignancies were enrolled at 6 hospitals in England. The study design was approved by the ethics committees at each participating site. All patients gave written informed consent to participate. Patients with lymphoma, acute leukemia, myelodysplasia, multiple myeloma, chronic lymphocytic leukemia, and chronic myeloid leukemia between ages 18 and 60 years were eligible to participate. Patients required an HLA-identical sibling or unrelated donor as determined by serologic typing for HLA-A/B and molecular typing for HLA DR/DQ. Data were analyzed as of November 30, 1999.

Patient characteristics

Detailed characteristics are shown in Table 1. Forty-four patients were enrolled in the study from June 1997 to September 1999. Twenty-eight were male, and 16 were females. Age range at the time of transplantation was 18 to 56 years (median, 41 years). Fourteen patients had non-Hodgkin lymphoma (NHL). 10 Hodgkin disease, 6 acute myeloid leukemia (AML), 7 multiple myeloma, 3 hypoplastic myelodysplastic syndrome, 1 acute lymphoblastic leukemia, 1 chronic lymphocytic leukemia, 1 chronic myeloid leukemia, and 1 plasma cell leukemia. This was a cohort of patients with high-risk features, including 19 patients with a previous failed autologous (18 patients) or allogeneic (1 patient) transplant, relapse failure (2 patients), poor left ventricular function (2 patients), or refractory disorder (8 patients). The median time interval from first to second transplant was 24 months (range, 6-79 months).

MCL indicates mantle cell lymphoma; HD, Hodgkin disease; AML, acute myeloid leukemia; LG-NHL, low-grade non-Hodgkin lymphoma; T, transformed low-grade to high-grade lymphoma; MDS, myelodysplastic syndrome; HG-NHL, high-grade non-Hodgkin lymphoma; MM, multiple myeloma; ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; CMN, chronic myeloid leukemia; CR, complete remission; PR, partial remission; CP, chronic phase; PBSC, peripheral blood stem cells; MUD, matched unrelated donor; CsA, cyclosporine A; MTX, methotrexate; TBI, total body irradiation.
Monoclonal antibody

CAMPATH-1H is a humanized immunoglobulin (Ig) Gl monoclonal antibody against the CD52 antigen. It was prepared from the culture supernatant of Chinese hamster ovary cell transfectants cultured in a hollow fiber fermentor. It was purified by affinity chromatography on protein A-Sepharose (Amersham Pharmacia Biotech, Little Chalfont, England) and size exclusion chromatography on Superdex 200 (Amersham Pharmacia Biotech) and formulated in phosphate-buffered saline. The half-life of CAMPATH-1H in humans is dependent on the amount of target CD52 antigen in the patient. Based on work in progress, there is persistence on CAMPATH-1H in vivo past day 0 sufficient to cause T-cell lysis by antibody-dependent cell-mediated cytotoxicity.

Conditioning regimen

Treatment consisted of the humanized monoclonal antibody CAMPATH-1H, 20 μg/kg intravenously infusion over 8 hours on days -8 to -4; fludarabine, 30 mg/m² intravenous infusion over 30 minutes on days 7 to 3; and melphalan, 140 mg/m² intravenous infusion over 30 minutes on day -2. Thirty-six recipients received unmanipulated peripheral blood stem cells (PBSCs) from their siblings, and 8 received unmanipulated marrow from matched unrelated donors.

Stem cell and bone marrow collection

Sibling donors received granulocyte colony-stimulating factor (G-CSF) at 10 μg/kg subcutaneously once daily on days -4 to 0. Leukaphereses were performed on days 0 and +1 using conventional techniques for PBSC collection. Unrelated donors had bone marrow collected on day 0 under general anesthesia using conventional techniques. In 2 sibling donors, we failed to collect more than 2 × 10⁷/kg CD34+ cells from G-CSF-mobilized peripheral blood, and therefore bone marrow was also harvested. The total number of CD34+ cells collected from peripheral blood and the number of mononuclear cells collected from the bone marrow are shown in Table 1. Unmanipulated mobilized peripheral blood or bone marrow was infused through central venous catheters on days 0 and +1 and on day 0, respectively.

Supportive care

Patients were managed in reverse isolation in conventional or laminar airflow rooms. All patients received prophylaxis with cotrimoxazole or pentamidine against Pneumocystis carinii infection. Aseptolir and fluconazole or itraconazole prophylaxis were routinely used. Blood products were irradiated to 25 Gy. Red cell and platelet transfusions were given to maintain hemoglobin levels above 9 g/dL and platelet count above 10 to 15 × 10⁹/L. The cytomegalovirus (CMV)-seronegative patients received only CMV-negative blood products; seropositive patients received CMV-unscreened blood products. Fibrile neutropenic patients received broad-spectrum intravenous antibiotics according to each hospital's policy for the management of neutropenic sepsis. G-CSF at 5 μg/kg per day was administered subcutaneously at the discretion of the transplant physician to speed hematologic recovery in 38 patients until the patient's absolute neutrophil count was at least 1000/μL for 3 consecutive days (Table 2).

GVHD prophylaxis and grading

GVHD prophylaxis consisted of cyclosporine A (CsA), 3 mg/kg starting on day -1, and methotrexate (MTX) at a dose of 10 mg/m² on days +1, +3, and +6 for 6 sibling recipients, and it consisted of CsA alone for the other 38 patients. Intravenous CsA was switched to an oral dose as soon as the patients would tolerate medications by mouth and was continued for a median of 4 months (range, 1 to 8 months). Patients who survived 100 days or longer were evaluable for chronic GVHD. Acute and chronic GVHD were graded according to the consensus criteria.³⁶

Follow-up

Patients had regular follow-up at 3 monthly intervals post-transplantation to assess disease response and remission status. These evaluations varied depending on the underlying diagnosis but included bone marrow aspirates or biopsies, cytogenetics, computed tomography scans, paraprotein levels, and skeletal survey.

Chimerism analysis

DNA was prepared from posttransplantation recipient blood and donor blood. Following transplantation, either buffy coat or granulocyte T-cell and B-cell preparations were obtained from peripheral blood as previously described. We used 4 different primers sets each spanning highly polymorphic short tandem repeat units on different human chromosomes. With primers VWA1 (Perkin-Elmer) and TH01 (Perkin-Elmer), polymorphic chain reaction (PCR) volumes were 50 μL containing Genematch PCR buffer II (Perkin-Elmer), 1.5-mmol/L MgCl₂, 0.2 mmol/L of each dNTP, and 0.5 U of AmpliTaq DNA polymerase (Perkin-Elmer, Foster City, CA), and 5 μL of DNA. Cycling conditions were 95°C for 45 seconds, 45°C for 30 seconds, and 72°C for 1 minute for 30 cycles. With primers AC17-GCC- CTAATCGTATACCT, backwards AGTGAACGGAAGTCCACCT and HUMSTRX1 (forward CTCCTTTGAGCTCCCTTCTAAAGG, backwards CTCCTAGCAGCCAGGGAAGTCA), PCR volumes were 50 μL containing 10 mmol/L Tris⋅HCl, 11-mmol/L NaH₂PO₄, 6.7 mmol/L, 2.5 mmol/L MgCl₂, 4.5 μmol/L of each dNTP, 1 μmol/L of each primer, 0.5 U of AmpliTaq polymerase (Perkin-Elmer), and 5 μL of DNA. Cycling conditions were 95°C for 30 seconds, 58°C for 30 seconds, and 72°C for 30 seconds for 30 cycles. The forward primer of each pair was labeled with either JOE or FAM fluorescent dyes. One microliter of PCR product was denatured in 12 μL of formamide and electrophoresed through a Performance Optimized Polymer 4 (Perkin-Elmer) on an ABI 373 automated sequencer (Perkin-Elmer) in the presence of Rox 500 size standard (Perkin-Elmer). Genescan software 2.1 (Perkin-Elmer) was used to analyze the data. Primers that gave rise to recipient/donor-specific peaks were identified and used for post-transplantation determination of chimerism status in various cell populations.

Study endpoints

The primary study endpoint was the successful durable hematopoietic engraftment and TRM. There were secondary endpoints, including regimen-related toxicity, incidence and severity of GVHD, and progression-free survival.

Statistical methods

Actuarial curves were estimated according to the Kaplan-Meier method. Surviving patients were censored on the last day of follow-up. The significance of differences between the curves was estimated by the log-rank test. Cox multivariate regression analysis was performed to calculate the independent effects of various risk factors influencing nonrelapse mortality, overall survival, and disease-free survival. The proportional hazards assumption was tested using a time-dependent covariant approach.

Results

Toxicities

All patients were assessable for toxicity. The conditioning regimen was generally well tolerated in patients who only received CsA as GVHD prophylaxis. The use of MTX in addition to CsA was associated with severe mucositis and delayed engraftment (Table 2). The original intention was to give MTX to all patients, but its use was abandoned because of toxicity. There were no cases of veno-occlusive disease. Four patients died of regimen-related toxicity. One patient died on day 121 of gram-negative septicemia while still aplastic. The second patient died on day +24 of idiopathic pneumonitis after engrafting on day +14. The third

</tbody>
</table>

NE indicates nonevaluable; CR, complete remission.
*Patient received MTX as GVHD prophylaxis.
†Patient did not receive post-transplantation G-CSF.

Patient died of MRSA pneumonia on day +153. The fourth patient with myeloma, whose neutrophin clearance prior to transplantation was 23 mL/min, died of renal failure on day +148.

Engraftment

One patient was not evaluable for engraftment because of early death on day +21. Of the 43 patients eligible for assessment of engraftment, 42 had sustained engraftment as defined by neutrophil counts above 0.5×10⁹/L and an untransfused platelet count of above 20×10⁹/L for at least 3 consecutive days. Details of the neutrophil and platelet reconstitution are shown in Table 2. The median time to recover an absolute neutrophil count of 0.5×10⁹/L was 13 days (range, 8-23 days) and of 1.0×10⁹/L was 17 days (range, 8-47 days). The median time to achieve platelets above 20×10⁹/L was 13 days (range, 3-96 days) and above 50×10⁹/L was 17 days (range, 8-118 days). Patient No. 7 developed graft rejection. After initial engraftment on day +11, the patient became cytopenic on day +20 and reconstituted recipient hemopoiesis on day +31 without autologous stem cell support.

Chimerism

Thirty-one patients had chimerism studies performed using microsatellite PCR or fluorescent in situ hybridization for X and Y chromosomes on peripheral blood. Detailed results are shown in
Table 3. Patient No. 7, who rejected his graft, had only recipient myeloid and lymphoid cells present. Of the other 30 patients, 18 had only donor cells present. Of the 12 patients with mixed chimerism, 5 had detailed lineage-specific studies performed using microsatellite PCR. Three of these patients were full-donor chimeras in the myeloid and B-cell lineages but were mixed T-cell chimeras. Two patients were mixed chimeras in all lineages tested (Figure 1). Six of the 8 unrelated recipients had chimerism studies performed, and all 6 were found to have only donor cells present following transplantation (Table 3). Two patients (Nos. 1 and 11) who were mixed chimeras post-transplantation became full-donor chimeras following DLI therapy.

**Graft-versus-host disease**

No grade III-IV acute GVHD was observed post-transplantation. Three patients developed grade I skin, 1 patient grade II gastrointestinal, and 1 patient grade II skin and gastrointestinal (Table 2) acute GVHD. Only 1 patient has developed chronic GVHD, limited to skin and liver involvement. Two patients developed GVHD following DLI to treat relapse of disease. One of these patients had steroid-resistant grade IV acute GVHD, and the other had limited chronic GVHD.

**Disease response and relapses**

Current disease status is shown in detail in Table 2. The conditioning regimen induced remissions in 2 of 2 patients with refractory AML and 2 of 2 evaluable patients with myelodysplasia. Of the 6 patients with Hodgkin disease in partial remission or with refractory disease at transplantation, 2 achieved a complete remission (CR) following transplantation, and 4 are progression-free. Seven patients with NHL in partial remission or with refractory disease prior to transplantation were evaluable for disease response (Table

Discussion

TRM remains a major obstacle to successful allogeneic SCT. The introduction of nonmyeloablative purine analogue conditioning regimens has facilitated allogeneic engraftment while limiting regimen-related mortality.11,12 Despite this, GVHD remains a significant cause of mortality and morbidity following nonmyeloablative conditioning. Previously published results reporting other nonmyeloablative conditioning regimens have shown a 38% to 60% incidence of grade II-IV acute GVHD.8,11,13 This was the primary cause of death in some patients.

In our study, the incidence of GVHD was exceptionally low. No patients had grade III-IV acute GVHD, and only 2 patients (5%) developed grade II acute GVHD. The incidence of chronic GVHD was also low, with only 1 patient developing limited skin GVHD. While the incidence of chronic GVHD cannot yet be fully assessed in some of the patients because of relatively short follow-up, given the fact that only 1 patient has experienced this complication and that all but 3 of the patients are off all immunosuppression, we anticipate a very low rate of chronic GVHD. Because the use of post-transplantation CsA was similar to other nonmyeloablative regimens, the differences in the incidence and severity of GVHD may in part reflect the in vivo use of the immunosuppressive monoclonal antibody CAMPATH-1H as part of the conditioning regimen.18 This was administered to the patients on days −8 to −4 prior to transplantation. Because CAMPATH-1H has a prolonged half-life in humans, there was significant circulating antibody when the unmanipulated donor PBSCs or bone marrow was infused into the recipient, resulting in a degree of in vivo T-cell depletion. This combination of in vivo CAMPATH-1H together with CsA appears to have been very effective in preventing GVHD in both sibling and unrelated donor allograft recipients. A number of these patients have had their CsA discontinued between 1 and 3 months post-transplantation without the development of GVHD.

While our nonmyeloablative conditioning regimen facilitated engraftment in all but one of the evaluable patients, many of the patients were mixed chimeras. Some patients were mixed chimeras in all lineages tested, while others were only mixed chimeras in the T-cell lineage. It has been demonstrated that patients who are mixed chimeras may experience less GVHD than full-donor chimeras.19,20 On the other hand, mixed chimerism may diminish the potential benefit of the GVL effect seen in the allograft setting.21,22 While mixed chimeras can be converted to full-donor chimeras following DLI,2 this was not attempted as part of this pilot study. The primary end points of this study were to explore the incidence of durable engraftment and acute and chronic GVHD. DLI were only given for overt rejection of disease and were not given prophylactically or pre-emptively because we wished to assess the impact of the conditioning regimen on disease control and relapse. In the present study, we were generally not able to show the benefit of DLI in the setting of post-transplantation
